(Fig 1 and Table 3). When extrinsic evidence from RNA-seq and protein homology information is available, any program/pipeline could be useful for the de novo annotation of novel genomes. In particular, if any RNA-seq data and a genome sequence are available, starting from MAKER and BRAKER over StringTie would be a better choice for a first-time user because MAKER and BRAKER include ab initio prediction (e.g., Augustus training) unlike StringTie (evidence-based prediction only). However, MAKER could be a better choice for updating existing annotations to reflect new evidence. If various gene prediction methods and tools are used to derive the gene structure from a genome, combining these results to obtain the single consensus gene structure via Evidence Modeler, GLEAN, Evigan, or GAAP is essential (Table 3). In particular, BRAKER, StringTie, PASA, and GAAP can update any gene structure annotation by correcting exon boundaries and adding untranslated regions and alternatively spliced models based on assembled transcriptomic data. The evolutionary rapid emergence of new genes (which quickly respond to changing selection pressures) could give rise to orphan genes that might share no sequence homology to genes in closely related genomes [113]. Combining the methods and results (especially MAKER, BRAKER and StringTie) could therefore prove effective in increasing the number and accuracy of annotation predictions assigned to orphan and any other young genes.

Subsequently, functional annotation—the process of attaching biological information to gene or protein sequences—must be performed. This can be carried out through homology search and gene ontology (GO) term mapping. To investigate gene function or predict evolutionary associations, newly assembled sequences should be compared with gene sequences with known functions to find sequences with high homology using BLAST, Cufflinks, TopHat, GSNAP, Blast2GO/OmicsBox (referred to here as Blast2GO), and GAAP (Fig 1 and Table 3). To label more diverse biological information, GO term mapping should be performed, which allows information about gene-related terms and relations between genes to be stored in three categories: biological processes, molecular functions, and cellular components. Mapping is the process of retrieving GO terms associated with hits (mapping sequences) obtained via a previous homology search (mainly BLAST) that are accessible from AmiGO, Blast2GO, GO-FEAT, and eggNOG-Mapper. Starting from Blast2GO would be a practical choice for a complete novice because it has more graphic user interface mode with explanations.

While Fig 1 and Table 3 provide a summary of useful tools with key features, it is highly recommended to be familiar with the regular update of public databases and pipelines. In addition, understanding the performance and capability of various analysis from a detailed comparison and instructions of common features of annotation tools could be a very important factor for a successful genome annotation, structurally [7,111,114–117] and functionally [8,118–123].

Step 11: Build a searchable and sharable output format

Research papers and data products (researchers are usually required to submit raw sequencing data to appropriate repositories such as Sequence Read Archive [SRA]) are key outcomes of the scientific enterprise, including most successful genome projects. In addition, most genomic projects/data potentially have value beyond their initial purpose but only if shared with the scientific community, including refining assembly and annotation (see Step 12). In recent years, genomic studies have involved complex datasets such that biologists have become "big data practitioners" [124] because of improvements in high-throughput DNA sequencing and cost reductions. As a result, genomic studies have become routine procedures, and there is widespread demand for tools that can assist in the deliberative analytical review of genomic information. What happens to the data after such projects end? In general, data or data management plans have become the central currency of science because open access, open data,

and software are critical for advancing science and enabling collaboration across multiple institutions and throughout the world and increasing public awareness [125]. For example, when archiving sequencing data, repositories such as those run by the National Center for Biotechnology Information (NCBI) and European Bioinformatics Institute (EBI) both provide locations for data archiving and encourage a set of practices related to consistent data formatting and the inclusion of appropriate metadata. However, this is a difficult task for an individual research group due to the wide variety of data formats, dataset sizes, data complexity, data use cases, ethical questions, and data collection/storage/sharing practices [124,126–128]. Despite its importance, major barriers remain to sharing data, software, and research products throughout the scientific community because of the difficulties that interdisciplinary and/or translational researchers face when engaging in collaborative research [124,125,127]. To this end, recent works have provided principles that can be applied in genomic data/database projects, including data sharing and archiving via collaborations [124–128].

The following three fundamental questions on this topic should be considered: (1) Do you want to share your data? (2) Do you have enough in-house expertise and infrastructure to maintain and improve the data, including data storage space? (3) Do you want to form internal and external collaborations to increase research productivity? While each research group has different experiences and criteria in collaborations that included data sharing, engaging with multisite collaborations is highly recommended to overcome more pitfalls, including open-ended questions/concerns on genomic data. In addition, sharing open genomic data can easily facilitate reproducibility and repeatability by reusing the same genomic data.

Step 12: Reach out to the community to refine the assembly and annotation

Dropping whole-genome shotgun sequencing costs and improvements in bioinformatics pipelines and computer capabilities have resulted in the situation where a small lab can undertake genome projects (assembly and annotation), and any organism can become a model species. Ironically, the ease of sequencing and assembly presents another challenge for annotation: contamination of the assembly itself, because errors in assembly can cause errors in the annotation (structural and functional). In addition, it is important to ensure that methods are computationally repeatable and reproducible because there have been numerous reports of instability arising from a mere change of Linux platform, even when using the exact same versions of genomic analysis tools [49]. When including new data, it is also necessary to provide software infrastructure to assist in genomic data updating. Hence, assembled genomes and curated annotations should not and cannot be considered perfect, static, or "final products." Data must be maintained, refreshed, and updated to ensure their reuse and discovery.

Manual and continuous annotation is critical to achieving reliable gene models and elements; however, this process can be daunting and cost prohibitive for small research communities. While some genome consortia choose to manually review and edit sets via time- and resource-intensive meetings that often require substantial expertise, this still provides opportunities for community building, education, and training. In contrast, for small research groups, it has been proposed that involving undergraduates in community genome annotation consortiums can be mutually beneficial for both education and genomic resources [106]. Alternatively, a collaborative approach using web portals such as Apollo, JBrowse, G-OnRamp (Galaxy-based platform), and ORCAE [129–133] could be sufficiently robust and flexible to enable the members of a group to work simultaneously or at different times to improve the biological accuracy of annotation.

Despite any community-based participatory research approaches taken, the recruitment and coordination of researchers are central to any research project due to the requirement of

diverse expertise and collective learning. The ideal way would be to form a national/international collaborative research partnership with diverse organizations [19,134–136]. Alternatively, active promotion via social networks and/or web portal setup could be the most effective way (e.g., Twitter, the Ensemble website, and blogs). Finally, build collective research solidarity by attending conferences would be plausible. There have been previous successful community efforts and involvement in plant (https://nbenth.com/annotator/index, https://solgenomics.net, and https://www.helmholtz-muenchen.de/pgsb) and animal genome projects (http://www.slimsuite.unsw.edu.au/servers/apollo.php, https://bovinegenome.elsiklab.missouri.edu, http://www.gmgi.org/genomics-fish-shellfish, and https://www.sanger.ac.uk/science/data/vertebrate-genomes-sequencing) using the Apollo instance with J Browsers exhibits attractive and effective routes because it is always online, curators can log in whenever they have time, and some minor revisions only require a few seconds (to confirm the gene models). Others require up to 20 minutes to change (UTR boundaries and other structural alterations).

After the initial setup, tasks include maintaining momentum and morale, according to the recommendations described by Pedro and colleagues [137]. Participants bring their own experiences and strengths into this effort. Availability of a training webinar (e.g., https://bit.ly/3gauwn7 and https://bit.ly/36iNQds) would greatly help kick-start the process, alongside a clear set of starting tasks (e.g., a list of genes/families or regions assigned to each curator) and engagement by the community leader. The leader—an enthusiastic champion—can (1) drum up support from their collaborators; (2) fuse community expertise with resources; (3) oversee the project; and (4) act as a liaison between new members wanting to join, the infrastructure provider, and existing annotators. Considering that the collective expertise within a group may be extensive but diverse, it is necessary to standardize the curation for quality control of annotations. To minimize any conflicts that may arise during the annotation process, it is important (1) to have the initial training webinar by laying out clear rules and guidelines; (2) to select a small subset of genes and ask a group of experienced curators to evaluate whether the decisions taken in each case were uniform and sensible; (3) to record webinar training and comments regarding consensus or disagreements for reporting back to the curation team and to edit the tutorial and guidelines; (4) to address this by automated checks and controls (Apollo does not allow this for now or makes it extremely difficult); and (5) to ask multiple reviewers to check each region by reviewing the annotation history in Apollo (labor-intensive method).

Pooling the expertise, resources, and time of active communities could enable a wide range of geographically distance members to participate in a common process, to share and validate the identification of contradictions and the misrepresentation of data on the genomes [137]. After corrections, the datasets (manually verified gene sets) that emerge from these projects can be used to improve the gene sets for closely related genomes and downstream analysis. Dialog and collaboration between community members have an enormous impact. The result of an entire community agreeing on and taking ownership of a single gene set is a major stepping-stone to accelerating the field. Handling the mammoth task of manual gene annotation in the absence of dedicated funding or teams is a great challenge. However, our guidelines could provide a manageable solution for the prospect of this approach becoming commonplace and will continue to engage in community-driven curation efforts.

Advice for new genomic users to select a basic assembly and annotation pipeline

For a complete novice, our recommendation would be as below (not recommended starting from Illumina only short reads assembly).

(1) Pure long-read assembly: PacBio or ONT read sequencing (if combined, PacBio 40X and ONT 25X, or 60X for a single platform) → CANU assembler (alternatively Flye) → BUSCO assessment → Make a decision to add more sequencing data or proceed next step (See Confirm and Refine in Fig 1) → Optional BioNano with RefAligner (still expensive compared to Hi-C data) → Hi-C with 3D-DNA (alternatively HiRise or AllHiC) → Gap-closing with LR_Gapcloser → Arrow with long-read (alternatively Racon) or Pilon polisher with short-read → BUSCO assessment.

(2) Hybrid assembly: 10xGC read with Supernova → PacBio or ONT read with CANU (alternatively MaSuRCA) → The rest are same with "Pure-read assembly" from BUSCO assessment to BUSCO assessment.

(3) Annotation: NCBI or EBI (a web-based automatic pipeline) → If not, proceed a semiautomatic pipeline starting from structural annotation → RepeatMasker → Ab initio Augustus training with MAKER (alternatively BRAKER) → Evidence-based prediction (RNA-seq) with MAKER (alternatively BRAKER) → Noncoding RNA prediction with NONCODE → Functional annotation with Blast2GO (alternatively AmiGO) → Genome Browser.

Conclusions

There are no gold standards for genome assembly and annotation. However, the availability of NGS data (particularly TGS data) and their analytical tools has enabled the sequencing of several high-quality genomes of species of importance in aquaculture in recent years. Beginners and small research groups still face challenges, because genome assembly and annotation are usually complex analytical procedures (or pipelines) requiring interdisciplinary collaborations (from biology to computer science) and hefty costs for refining/maintaining the genome. The recommendations addressed here are broad guidelines that could be considered to avoid common pitfalls throughout the whole-genome assembly and annotation process. However, the comprehensive features (e.g., advantages and disadvantages) of each step and/or technology have not been extensively discussed.

Finally, newly emerging technologies and analytical tools could dramatically improve end-to-end genome assemblies and annotations in the future by replacing the years-long efforts of the past with rapid and low-cost solutions. Meanwhile, emphasis should be placed upon the following: First, define the achievable research aim. Second, avoid the trap of trying to secure a perfect/complete genome assembly and annotation, which could lead to a never-ending project. Third, perform assembly and annotation to gain firsthand experience, including in bioinformatics. Fourth, seek internal and external help and advice from experts. Lastly, be open to sharing genomic data to both increase research productivity and promote public awareness.

Acknowledgments

The authors are grateful to their colleagues, collaborators, and field/technical specialists from each company for their valuable comments.

Abstract

Genome sequencing projects were long confined to biomedical model organisms and required the concerted effort of large consortia. Rapid progress in high-throughput sequencing technology and the simultaneous development of bioinformatic tools have democratized the field. It is now within reach for individual research groups in the eco-evolutionary and conservation community to generate *de novo* draft genome sequences for any organism of choice. Because of the cost and considerable effort involved in such an endeavour, the important first step is to thoroughly consider whether a genome sequence is necessary for addressing the biological question at hand. Once this decision is taken, a genome project requires careful planning with respect to the organism involved and the intended quality of the genome draft. Here, we briefly review the state of the art within this field and provide a step-by-step introduction to the workflow involved in genome sequencing, assembly and annotation with particular reference to large and complex genomes. This tutorial is targeted at scientists with a background in conservation genetics, but more generally, provides useful practical guidance for researchers engaging in whole-genome sequencing projects.

Introduction

The field of conservation genetics is concerned with studying genetic and evolutionary processes in the context of biodiversity conservation (Frankham et al. 2010). Traditionally, a small number of neutral genetic markers were employed to study patterns of genetic variation of individuals and populations with the aim to explore underlying processes and their relevance to conservation. Marker-based measures provide insight into effective population sizes (N_e), recent demographic events (e.g. bottlenecks and expansions), genetic relatedness and the level of inbreeding. Genetic markers are also routinely employed in monitoring schemes (e.g. identification of individuals and capture–recapture modelling) and in breeding programs (Romanov et al. 2009) and have been extensively used to characterize population substructuring and genetic connectivity, to delineate conservation units and to infer interspecific admixture events (Höglund 2009; Allendorf et al. 2013). Under the premise of a causal relationship between neutral genetic variation and population viability, these data can inform practical conservation decisions (Frankham 1995).

Rapid advances in sequencing technology and bioinformatic tools during the last decade have initiated a transition from classical conservation genetics to conservation genomics (Fig. 1; Primmer 2009; Allendorf et al. 2010; Ouborg et al. 2010; Steiner et al. 2013). This development has two major implications. First, by significantly scaling-up the number of genetic markers, genomewide approaches enhance the power and resolution for the above-mentioned applications and improve the reliability of conclusions (Steiner et al. 2013). Second, the application of genomic technologies opens novel axes of investigation (Allendorf et al. 2010; Ouborg et al. 2010). Genome-scale data provide information beyond neutral genetic variation or candidate gene approaches (e.g. major histocompatibility complex genes; Hedrick 1999) and thus enable screening for selectively important variation and assessing the adaptive potential of populations (Primmer 2009). For example, approaches such as genomewide scans for selection, association mapping or quantitative trait loci (QTL) mapping can pinpoint loci of relevance for local adaptation of the target population (Steiner et al. 2013), with the potential to conserve

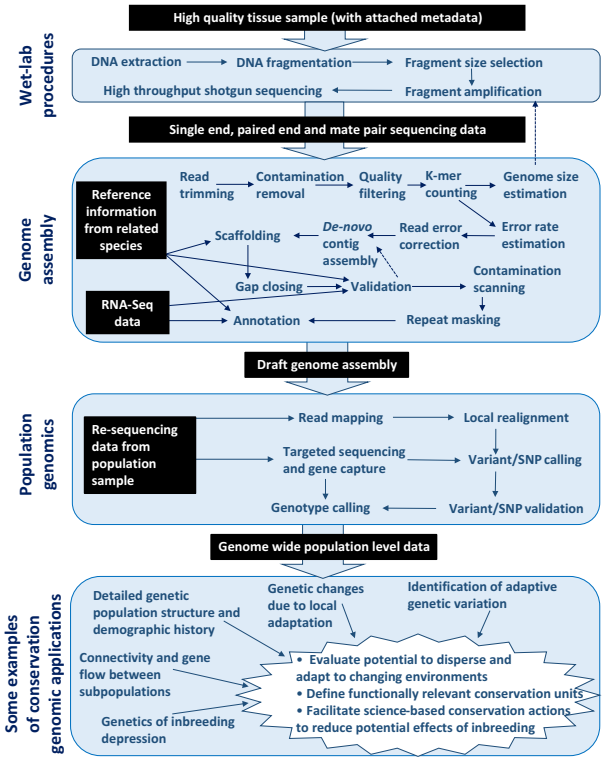

Figure 1 Workflow of a typical *de novo* whole-genome sequencing project. Black boxes with white text indicate genomic resources becoming available during the course of the project. From the top: wet-lab procedures, *de novo* assembly bioinformatic pipeline, postassembly analyses of additional population-wide sampling (population genomics), conservation genomic questions to address and analyses to perform (conservation genomic applications). Bullet points within the white star in the bottom part of the figures represent ultimate goals in conservation biology that can be addressed using genomic information combined with high-quality ecological data.

evolutionary processes – a long sought after goal in conservation biology (Crandall et al. 2000; Fraser and Bernatchez 2001). Genomewide analyses further allow addressing the poorly understood mechanistic basis of inbreeding depression (epistasis, directional dominance versus overdominance, many versus few loci), or assessing the impact of genetic variation on patterns of gene expression, and plastic response to environmental change. Genomic approaches can also be applied to highly fragmented DNA from ancient material (e.g. from museum specimens; Pääbo et al. 2004; Bi et al. 2013), to characterize environmental samples (Shokralla et al. 2012) and to understand how environmental perturbations affect microbial communities (Mardis 2008), representing largely unexplored terrain in conservation biology.

The above-mentioned applications do not necessarily require a reference genome sequence. Many analyses, including taxonomic delineation, characterization of demographic events, estimates of inbreeding or relatedness, can be successfully conducted in the absence of a genome reference. Instead, large-scale maker data such as genotyping-by-sequencing (Elshire et al. 2011), RAD-Seq (Narum et al. 2013), reduced representation sequencing (Van Tassell et al. 2008), amplicon sequencing (Zavodna et al. 2013) or transcriptome sequencing (Ekblom and Galindo 2011) can be effectively utilized without relying on a genome backbone. A complete and well-annotated genome sequence, however, provides the ultimate resource for genomic approaches. Whole-genome resequencing data with positional information along a genome sequence constitute the most complete account of individual genomic variation [e.g. structural rearrangements, copy number variation, insertion–deletion, single nucleotide polymorphisms (SNPs), sequence repeats] and will likely soon become the standard for genetic studies of natural populations (Ellegren et al. 2012; The Heliconius Genome Consortium 2012). It also provides the basis for haplotype information and genomewide estimates of linkage disequilibrium which have great power to reveal recent population histories (Li and Durbin 2011), timing of admixture events (Hellenthal et al. 2014) and to screen for signatures of selection (Hohenlohe et al. 2010). The study of selectively important variation strongly relies on annotated genome data to identify the functional genomic regions of interest. Reference sequences are further indispensable as a template for RNA-seq in detailed studies of (isoform-specific, allele-specific) gene expression (Vijay et al. 2013), epigenetic modifications (such as methylation; Herrera and Bazaga 2011) and DNA–protein interactions (Auerbach et al. 2013). These approaches are only accessible to genome-enabled taxa (Kohn et al. 2006) that enjoy the added benefit of using the latest bioinformatics tools developed in the biomedical sciences.

Here, we introduce the workflow of a typical whole-genome sequencing project conducted by an individual research group. This field guide aims at introducing principles and concepts to beginners in the field (Box 1) and offers practical guidance for the many steps involved (Fig. 1). It builds largely upon our own experience with vertebrate genome assembly. We limit the scope to genomic data, focusing on large and complex genomes, for transcriptome assembly we refer to Martin and Wang (2011) and Wolf (2013). We discuss sequencing, assembly and annotation, highlighting typical routines and analytical procedures. Our intention is not to provide a comprehensive review of sequencing technology, assembly algorithms or downstream downstream analyses, as this has already been performed. For these topics, we instead list exemplary literature and provide relevant entry points (Box 2).

Box 1: Glossary

Alignment	Similarity-based arrangement of DNA, RNA or protein sequences. In this context, subject and query sequence should be orthologous and reflect evolutionary, not functional or structural relationships
Annotation	Computational process of attaching biologically relevant information to genome sequence data
Assembly	Computational reconstruction of a longer sequence from smaller sequence reads
Barcode	Short-sequence identifier for individual labelling (barcoding) of sequencing libraries
BAC	(Bacterial artificial chromosome) DNA construct of various length (150–350 kb)
cDNA	Complementary DNA synthesized from an mRNA template
Contig	A contiguous linear stretch of DNA or RNA consensus sequence. Constructed from a number of smaller, partially overlapping, sequence fragments (reads)
Coverage	Also known as 'sequencing depth'. *Sequence coverage* refers to the average number of reads per locus and differs from *physical coverage*, a term often used in genome assembly referring to the cumulative length of reads or read pairs expressed as a multiple of genome size
De novo assembly	Refers to the reconstruction of contiguous sequences without making use of any reference sequence
EST library	Expressed sequence tag library. A short subsequence of cDNA transcript sequence
Fosmid	A vector for bacterial cloning of genomic DNA fragments that usually holds inserts of around 40 kb
GC content	The proportion of guanine and cytosine bases in a DNA/RNA sequence
Gene ontology (GO)	Structured, controlled vocabularies and classifications of gene function across species and research areas
InDel	Insertion/deletion polymorphism
Insert size	Length of randomly sheared fragments (from the genome or transcriptome) sequenced from both ends
K-mer	Short, unique element of DNA sequence of length k, used by many assembly algorithms
Library	Collection of DNA (or RNA) fragments modified in a way that is appropriate for downstream analyses, such as high-throughput sequencing in this case
Mapping	A term routinely used to describe alignment of short sequence reads to a longer reference sequence
Masking	Converting a DNA sequence [A,C,G,T] (usually repetitive or of low quality) to the uninformative character state N or to lower case characters [a,c,g,t] (*soft masking*)
Massively parallel (or next generation) sequencing	High-throughput sequencing nano-technology used to determine the base-pair sequence of DNA/RNA molecules at much larger quantities than previous end-termination (e.g. Sanger sequencing) based sequencing techniques
Mate-pair	Sequence information from two ends of a DNA fragment, usually several thousand base-pairs long
N50	A statistic of a set of contigs (or scaffolds). It is defined as the length for which the collection of all contigs of that length or longer contains at least half of the total of the lengths of the contigs
N90	Equivalent to the N50 statistic describing the length for which the collection of all contigs of that length or longer contains at least 90% of the total of the lengths of the contigs
Optical map	Genomewide, ordered, high-resolution restriction map derived from single, stained DNA molecules. It can be used to improve a genome assembly by matching it to the genomewide pattern of expected restriction sites, as inferred from the genome sequence
Paired-end sequencing	Sequence information from two ends of a short DNA fragment, usually a few hundred base pairs long
Read	Short base-pair sequence inferred from the DNA/RNA template by sequencing
RNA-Seq	High-throughput shotgun transcriptome (cDNA) sequencing. Usually not used synonymous to RNA-sequencing which implies direct sequencing of RNA molecules skipping the cDNA generation step
Scaffold	Two or more contigs joined together using read-pair information
Transcriptome	Set of all RNA molecules transcribed from a DNA template

Basic considerations

Genome assembly is a challenging problem that requires time, resources and expertise. Before engaging in a genome sequencing project, it should thus be carefully considered whether a genome reference sequence is strictly necessary for the purpose in question. Genome sequences are merely a resource and in many cases will contribute very little *per se* to a problem in conservation biology. In case a genome draft is judged to be of significant value to address the problem at hand, it needs to be considered whether sufficient financial and computational resources are available to produce a genome of satisfactory quality. If funding is not available to obtain the appropriate read depth, it is advisable to utilize alternative approaches where possible (such as genotyping-by-sequencing or transcriptome sequenc-

Box 2: Before you start

Some important points to consider

- Availability of appropriate computational resources
- Collaboration with sequencing facility and bioinformatics groups
- Plan for amount and type of sequencing data needed
- Does funding allow to produce sufficient sequence coverage? If not, alternative approaches should be considered rather than producing a poor, low coverage, assembly
- Familiarization with data handling pipelines and file formats (see below)
- High-quality DNA sample (with individual metadata)
- Plan for analyses and publication

• VCF	Variant calling

ing), rather than settle for low-coverage whole-genome sequencing data. The latter would be a waste of funding, effort and time.

One important limitation of the current shotgun genome sequencing approaches that may be of particular importance in conservation biology is the fact that core genes with high conservation relevance, like immune genes of the MHC or olfactory receptor (OR) genes, are highly polymorphic and have many paralogs, which makes them particularly difficult to assemble. More generally, rapidly evolving genes or members of large gene families are often poorly represented in the final assembly and annotated gene set. Such regions and genes constitute a challenge even for very large sequencing projects of model organisms. If the project is not carefully planned from the start, there is a risk that the regions of highest interest to conservation biology will not be correctly represented in the final draft of the genome. Manual annotation and use of additional data, such as targeted sequencing of bacterial artificial chromosome (BAC) clones, will often be necessary to include such genomic regions in the assembly. If information on such preidentified candidate genes is the main aim of the study, it might even be more efficient to focus only on those regions rather than trying to sequence and assemble the whole-genome (see for example Wang et al. 2012).

What does it mean to 'sequence a genome'?

Ideally, a genome draft would represent the complete nucleotide base sequence for all chromosomes in the species of interest, a 'physical map' of its genetic content (as opposed to the 'genetic or linkage map' which establishes the order and recombination distances among genetic markers). However, in reality, there are a number of complications with the concept of a 'genome sequence'. First, there is not one true sequence for a species because of individual genomic variation. In a single diploid individual, such variation will manifest itself in the form of heterozygous positions, insertion/deletion (InDel) polymorphism, copy number variation or small-scale rearrangements. Even cells from the same individual can differ in genomic content due to somatic mutations. The assembled genome sequence of an individual will also be only one representation of the total variation present in a species (paralleling

the use of 'type specimens' for taxonomic classification). Generally, only a single individual is sequenced (Wheeler et al. 2008), but sometimes (like in the HUGO project) the genome represents a 'consensus' of a number of pooled samples (International Human Genome Sequencing Consortium 2004). Note, however, that in diploid and polyploid organisms, the genome assembly already reflects a consensus sequence of several chromosome sets and fails to capture haplotypic variation (for most current short-read based methods). Second, it is essentially impossible to sequence and assemble all nucleotides in the genome (Ellegren 2014). Large parts of DNA sequence, especially the heterochromatic regions around centromeres and telomeres and other highly repetitive regions, are not well-characterized even in mature genome assemblies like human or mice. Third, there will always be some degree of error in the characterized genome sequence, both on the level of individual nucleotides (stemming from sequencing errors) and in the ordering of sequence blocks (stemming from assembly errors). Forth, every genome assembly is the result of a series of assembly heuristics and should accordingly be treated as a working hypothesis.

The principle of genome sequencing and assembly

Currently, most genome projects use a shotgun sequencing strategy for genome sequencing (Fig. 2). In a first step, genomic DNA is sheared into small random fragments. Depending on the technology, these are sequenced independently to a given length. Powerful computer algorithms are then utilized to piece the resulting sequence reads back together into longer continuous stretches of sequence (*contigs*), a process known as *de novo* assembly. For correct assembly, it is important that there is sufficient overlap between the sequence reads at each position in the genome, which requires high sequencing coverage (or read depth). Naturally, for longer sequence reads, more overlap can be expected, reducing the required raw read depth. Usually, longer fragments (several hundred base pairs) are sequenced from both ends (paired-end sequencing) to provide additional information on correct read placement in the assembly.

After the initial assembly, *contigs* are typically joined to form longer stretches of sequence (known as *scaffolds*). To achieve this, libraries from long DNA fragments spanning several kilobases (kb) of sequence in the genome are prepared and their endpoints sequenced. Depending on the technology and the specifics of the library preparation, these libraries are (somewhat confusingly) called, for example paired-end, mate-pair or jump libraries. If the endpoint sequences of several independent fragments come to lie on two different *contigs*, they are joined into a *scaffold*. The expected fragment length of the library provides information on the physical distance between the two *contigs*, and the created gap is filled with the uninformative base-pair character 'N'. Subsequent gap closing methods, ideally using long reads that read across repetitive sequences, help to fill in the missing base-pair information.

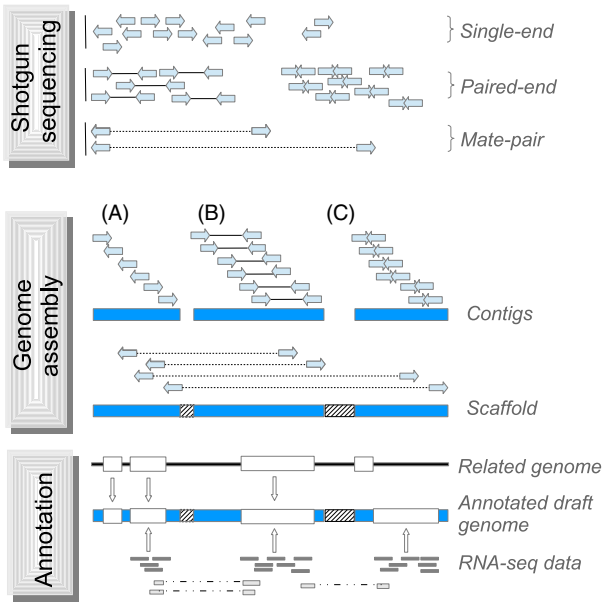

Figure 2 Simplified illustration of the assembly process and terminology. Shotgun sequencing: short fragments of DNA from the target organism are sequenced at random positions across the genome to a given depth of coverage. Fragments can consist of single reads (typically 50–1000 bp) or of paired-end reads of varying insert size (note that paired-end reads can even overlap). Mate-pair libraries span larger genomic regions (~2–20 kb inserts) with reads generally facing outwards and can be complemented with fosmid-end libraries (~40 kb inserts). Genome assembly: (A) short-read *de novo* assemblers extend the disperse sequence information from the reads into continuous stretches called *contigs*. *Contigs* usually reflect the consensus sequence and do not contain any polymorphisms. (B) Paired-end reads provide additional information on whether a read is supported for a given *contig*. (C) Some assemblers such as ALLPATHS-LG work with overlapping read pairs that are joined into a virtual longer read prior to the assembly. Read pairs from mate-pair or fosmid-end libraries can be used to order and orient *contigs* into *scaffolds*. Gap size between *contigs* is estimated from the expected length of mate-pairs and marked with 'N's (indicated by hatched grey boxes). Long reads from single molecule sequencing provide an alternative. Annotation: gene models can be inferred *in silico* by prediction algorithms, by lifting over information from genomes of related organisms and by using transcriptome data (RNA-seq, expressed sequence tag) from the target organism itself. Spliced reads from RNA-seq data as indicated at the bottom of the figure provide valuable evidence for splice junctions and various isoforms of a gene.

In a last step, the resulting *scaffolds* are often joined into linkage groups or placed on chromosomes (Ellegren 2014). Genetic maps constructed from pedigree data or crosses are arguably the best way for ordering and orienting *scaffolds* into longer sequence blocks (Ellegren et al. 2012). However,

© 2014 The Authors. *Evolutionary Applications* published by John Wiley & Sons Ltd

detailed genetic maps of species with conservation concern (usually not amendable to artificial crosses or half-sib breeding designs) require substantial genotyping effort, and deep pedigrees with a sufficient number of meioses are difficult to come by in most systems (Romanov et al. 2009). Given these difficulties, it is often not realistic to aim for a chromosome-level assembly, and this will also often not be necessary for most conservation biology applications. Most applications, including haplotype-based approaches that are powerful in revealing signatures of selection or depict recent demographic histories, generally work with high-quality *contigs*. As an alternative for placing and orienting the *scaffolds* onto putative chromosomes, synteny and gene order information from related species can be used. Note, however, that such information should be used with due caution as chromosomal rearrangements may have occurred even between very closely related species. There is also a risk that errors in the reference species assembly are transferred to the focal genome.

Genome sequencing

Sequencing technology and coverage considerations

Among the first decisions when starting, a genome sequencing project is the choice of sequencing platform, the type and amount of sequence data to generate. The latter is often limited by project funding, and the former may depend on which sequencing technology is promptly available. Judging from recently completed whole-genome sequencing projects (Table 1), there is a clear trend moving away from traditional Sanger sequencing (~1 kb sequence reads) and Roche 454 sequencing (up to 800 bp) towards short read technologies such as Illumina HiSeq (at present typically 150 bp) and SOLiD (typically 50 bp). Lately, there has been progress in producing longer reads at high throughput; several technologies offering this, such as Pacific Biosciences (up to 5 kb), IonTorrent (~500 bp) and Illumina Moleculo (up to 10 kb), are entering the market, and we expect to see a broader spectrum of read lengths. While this development blurs the initial dichotomy of short reads (e.g. 35 bp Illumina reads) versus long reads (~1 kb Sanger reads), read length still has important bioinformatic implications, as assembly algorithms optimized for long reads are fundamentally different from approaches targeting short reads. Recent studies begin to combine data of different read length and from several different sequencing platforms (Koren et al. 2012). This strategy makes intuitive sense as the drawbacks of each method can be counterbalanced, although the jury is still out whether such hybrid assemblies always outperform single data type approaches (Bradnam et al. 2013). Here, we follow the principle of current common practice and base our considerations largely on sequencing of Illumina libraries of different lengths (we loosely refer to short reads at sequence lengths below 500 bp and long reads above this length). Many of the following reflections, however, more generally relate to the assembly problem and do not depend on the specific choice of sequencing library.

For most downstream applications, obtaining long *contigs* is essential. With long-read data, from traditional Sanger sequencing of individual BAC clones, this is feasible even with a rather limited sequencing depth. However, when using only short-read technologies, high total read coverage (>100×) is needed. Too little data will result in a highly fragmented assembly and severe problems with downstream applications such as annotation and variant calling. For initial *contig* assembly, one usually starts out with a high amount of paired-end short-read data. To subsequently merge *contigs* into *scaffolds*, it is necessary to generate additional libraries with long-insert sizes in the range of 3–40 kb (Fig. 2). How much sequencing data are needed of each library types and insert size depends critically on a number of factors including the size and repeat content of the genome, the degree of heterozygosity and the target quality of the assembly (Sims et al. 2014). As these parameters will differ between sequencing projects and organisms of interest, the optimal resource allocation will be unique to every project. As a rough guideline for mammalian genomes, it has been proposed to use at least 45× coverage of short-insert paired-end libraries, 45× coverage of medium-sized insert libraries (3–10 kb) and 1–5× coverage of long-insert libraries (10–40 kb) (Nagarajan and Pop 2013). It should be noted that coverage can sometimes also be too high, as the absolute number of sequencing errors increases as a function of read number. According to our own experience, down-sampling from 100× to 50× coverage of a short-insert size library can significantly improve some steps in the assembly process.

To translate these recommendations into amount and type of sequencing needed for a specific project, basic knowledge on genome size, sequencing error rates, repeat content and the degree of genome duplications is needed. If no such information is available for the target species of interest at the start of the project, it is advisable to first perform a small pilot study using single-end or short-insert sequencing. The above-mentioned parameters can then be approximated using a k-mer counting approach (Marçais and Kingsford 2011; http://josephryan.github.com/estimate_genome_size.pl). Information on how to perform and interpret such k-mer counts can be found in web forums such as seqanswers (Box 2). Generally, a larger amount of long-insert data is needed for correct assembly if the genome has a high repeat content or a high degree of duplications. Genome size estimates for a large number of species are also available in online databases (Box 2).

Table 1. Some recently sequenced vertebrate genomes in species of conservation concern.

Red list categories: EX, extinct; CR, critically endangered; EN, endangered; VU, vulnerable, NT, near threatened; LC, least concern.
*Not red-listed, but likely to be affected by overfishing.
†Not red-listed, but endemic to a small geographic region.
‡Not currently red-listed but, subject to extensive exploitation or within group of endangered taxa.
§Not globally red-listed, but with several small and isolated regional populations.

Wet-lab procedures

The wet-lab part of the genome sequencing is often outsourced to sequencing centres, and we will only very briefly touch upon the basic steps of library preparation that are important to consider at the planning stage of the project and that affect downstream analytical procedures.

Genome individual

Heterozygous positions in the genome of the sequenced individual have adverse effects on the assembly. Highly polyploid species are particularly challenging for assembly and may necessitate specifically tailored assembly pipelines (Schatz et al. 2012). A general recommendation is to use inbred individuals, parthenogenetic or gynogenetic off-

© 2014 The Authors. *Evolutionary Applications* published by John Wiley & Sons Ltd

spring where available. Attached to the genome individual should be metadata that might be important for future referencing, such as the identity, age and sex of the individual, time and exact place of sampling, etc. (Genome 10K Community of Scientists 2009).

Tissue

Energetically active tissue (such as muscle) should be avoided, as there is a risk that the sequence data will contain a high proportion of mitochondrial DNA (mtDNA), which wastes sequencing effort and can cause problems in the assembly step due to the extreme read depth (as assembly pipelines often use read depth to identify duplicated genomic regions). We further recommend removing mtDNA sequence reads prior to assembly and use only a small fraction of this data to assemble the mitochondrial genome (which in itself may provide important information for conservation genetics) separately. It is also advisable to avoid tissues such as gut and skin which may have a high degree of nontarget DNA from xenobiotic organisms.

DNA quality

Whole-genome sequencing, particularly of long-insert size libraries, requires high-quality, intact, nondegraded DNA at a sufficient amount (Wong et al. 2012). For sequencing, a full genome using a set of different libraries requires ~1 mg of DNA as starting material (~6 μg for short-insert libraries, ~40 μg for 2–10 kb libraries, ~60 μg for >20 kb libraries). Before engaging in genome sequencing, it is thus essential to obtain a large amount of high-quality DNA of the target species. This can be a major obstacle for many species with conservation concern. If captive animals are available, such samples can often be utilized as a source of high-quality DNA, but note that genomic variation identified from such sources may not be representative of wild populations. Prior to submitting a DNA sample, its integrity should be checked on a high-resolution gel (e.g. pulse-field electrophoresis; a sample should typically show fragments of >100 kb).

Library preparation

When choosing the necessary raw read depth, one should be aware that currently most technologies include several PCR steps which can lead to a non negligible number of duplicated reads. While single reads can occur in duplicate by chance if coverage is high enough, duplication is bound to be an artefact for identical read pairs which are very unlikely to occur by chance (as they follow a length distribution). As duplicated reads are of no added value and duplication artefacts can impair coverage-based quality validation, they should be removed prior to the assembly. Duplicates generally constitute a few percentage of short-insert size libraries (<500 bp), but can reach over 95% for long-insert libraries (>10 kb).

Another central question refers to what insert sizes to use. Generally, it is advisable to have a good mix of sizes in the range of 0.2–40 kb with the shorter libraries being sequenced to significantly higher depth (Gnerre et al. 2011). Insert sizes of >20 kb make a large difference to the final contiguity and *scaffold* size of the assembly, but are not trivial to produce at high quality and currently constitute a limitation of many sequencing centres. Library preparations differ in quality and in how well they represent different parts of the genome. Therefore, more than one library should ideally be generated per size class. Note that some assembly programs (such as ALLPATHS-LG) expect a predefined mix of sequencing libraries as input data. Another important issue for downstream analyses that comes with library preparation is read orientation. Depending on the technology used, reads can face inwards (→ ←; e.g. Illumina paired-end sequencing) or outward (← →; e.g. Illumina mate-pair sequencing) in relation to the original DNA fragment. Mis-oriented reads with unexpectedly short insert sizes can arise due to sequencing of pairs from within the original DNA fragment rather than at its ends. Also, mate-pairs with aberrant insert sizes and orientation often represent chimeric sequences from nonadjacent genomic regions. For most assembly methods, such artefacts need to be filtered out during the preassembly steps, often leaving only a small fraction of usable, unique read pairs for assembly after trimming. To correctly process the data, the bioinformatician handling the data always needs to be 'library aware'.

Genome assembly

Data management

The amounts of data generated in a normal genome sequencing project is staggering. A vertebrate genome with 100× coverage means data files in the order of several hundred gigabytes. During the assembly procedure, temporary files easily cross the terabyte boundary. An adequate data management and backup strategy is thus needed already at the start of the project. Many universities are connected to local or national computing grids, including data storage facilities, and it is highly recommended to utilize these whenever possible. Having bioinformatics application experts working at the computing infrastructure provides a vital link between the biologist researchers and the computing grid system experts (Lampa et al. 2013). Such collaborations should already be established during the planning stage of the project. Sequencing centres often also offer assistance with data analyses and assembly. However, their automated pipelines are not likely to be optimized for data from nonmodel organisms and might not be usable from a conservation biology point of view. It is thus vital to explicitly discuss what kind of support can be

© 2014 The Authors. *Evolutionary Applications* published by John Wiley & Sons Ltd

provided by the facility before the start of the project. More generally, it should be considered whether enough expertise exists in the core research group to perform the computational steps of an assembly. Most data processing and genomic analyses of large-scale sequencing data are conducted on high-performance computing clusters running a UNIX-based operating system. One does not need to be a bioinformatics expert to handle whole-genome sequencing data, but is essential to have some familiarity with the UNIX environment and basic knowledge in command line software, writing shell scripts and applying scripts of commonly used languages for biological data analysis (such as Perl or Python).

Preassembly steps

Prior to the assembly, the quality of the sequencing data, overall GC content, repeat abundance or the proportion of duplicated reads should be assessed. Tools such as FastQC (http://www.bioinformatics.babraham.ac.uk/projects/fastqc) providing summary statistics are a useful starting point. Trimming low-quality data and reads resulting from PCR duplications can be performed with a variety of different software and scripts (e.g. ConDeTri; Smeds and Künstner 2011). Stand-alone error correcting, using a k-mer count approach (for example as applied in the SOAPdenovo pipeline), can also be a useful alternative for many datasets. Note, however, that the optimal stringency of quality filtering is specific to the individual project and the targeted assembly pipeline. Some assemblers, such as ALLPATHS-LG (Gnerre et al. 2011), where trimming and error correction are performed within the assembly pipeline, even require raw reads, without quality trimming as input.

Primer and vector sequences from the library preparation will most likely be present in the data (even if the sequencing facility claims to have removed them) and can be removed with simple scripts (like cutadapt; Martin 2011). Also, in Illumina sequencing, DNA from the PhiX phage is often added to the sequencing reaction, in order to calibrate sequence quality scores. Failure to remove such abundant contaminant sequences can disrupt the assembly process (due to the high read depth compared with the nuclear genome) and may result in the production of chimeric and contaminated *contigs*. The easiest way of removing known vector contamination from the raw data is to use a short read aligner (like BWA; Li and Durbin 2009) and delete all fragments mapping to the contamination sequence.

De novo assembly

Tools for genome assembly differ widely in their performance in terms of speed, scalability and the quality of the final genome sequence (Miller et al. 2010; Earl et al. 2011; Narzisi and Mishra 2011; Bradnam et al. 2013). While some assembly methods clearly outperform others, it is currently difficult to predict which of the tools might be most appropriate in a given situation. Every assembly project is unique in terms of generated data structure and the target genome differing, for instance, in size, base-composition, repeat content and polymorphism level. There are a number of software available for *de novo* assembly of shotgun whole-genome sequencing data, and new programs are constantly being added to the list. Some algorithms focus on minimizing mis-assemblies, while others mainly aim to improve contiguity (sometimes at the cost of accuracy). Most assembly algorithms perform optimally with a given distribution of library sizes, so it is important to consider the choice of assembly strategy already during the project planning and sequencing steps. Besides information from the primary literature and websites of assembly software, various web forums provide good entry points for up-to-date discussions and sharing the experiences of other researchers (see Box 2).

Most software implementations designed for long-read technologies such as traditional Sanger sequencing (for example the Celera assembler, Arachne and PCAP; Batzoglou et al. 2002; Huang et al. 2003; Denisov et al. 2008) or Roche 454 sequencing (for example Newbler) use an assembly approach known as overlap-layout-consensus (OLC). These algorithms are generally considered too computationally intensive (mainly in terms of runtime) for Illumina or SOLiD data. Still, a few assemblers such as Edena (Hernandez et al. 2008), SGA (Simpson and Durbin 2012) and FERMI (Li 2012) pursue the OLC strategy for such short-read data (Miller et al. 2010). Most other strategies for *de novo* assembly of short sequence reads can be broadly divided into two classes: extension-based methods and De Bruijn (or Eulerian) graph algorithms (Nagarajan and Pop 2013). Extension-based assemblers, such as SSAKE (Warren et al. 2007) and JR-Assembler (Chu et al. 2013) are usually computationally very efficient (in terms of both memory requirements and computational time), but are highly sensitive to sequencing errors, repeat regions and high levels of nucleotide polymorphism (Chu et al. 2013). The most commonly used approach for assembly of short-read data is therefore currently based on De Bruijn graphs, where reads are partitioned into k-mers (substrings of the read sequence of length k) that then form the nodes of the graph (network) and are linked when sharing a k-1 mer. Highly used assembly software, such as SOAPdenovo (Luo et al. 2012), ALLPATHS-LG (Gnerre et al. 2011), ABySS (Simpson et al. 2009) and Velvet (Zerbino and Birney 2008), all rely on De Bruijn graph algorithms. There are also 'hybrid' assembly approaches, for example Atlas (Havlak et al. 2004), Ray (Boisvert et al. 2010) and MaSuRCA

 © 2014 The Authors. *Evolutionary Applications* published by John Wiley & Sons Ltd

(Zimin et al. 2013), combining features of different algorithms and utilizing data from multiple sequencing technologies. In general, it is advisable to test several different assembly methods and evaluate which is most appropriate for the specific data at hand. Draft genome building should be treated as an iterative process with several rounds of assembly, evaluation and parameter tweaking. For a more comprehensive review of different assembly algorithms and software; see for example (Miller et al. 2010; Nagarajan and Pop 2013).

After the initial *contig* building, it is common to use read-pair information from long-insert (mate-pair, fosmid-end or jump) libraries (Zhang et al. 2012) to combine *contigs* into *scaffolds*. Additional short-insert paired-end libraries are also often useful, for example to bridge, short low-complexity regions. The lengths of sequence gaps between *contigs* are estimated from the expected insert sizes and are usually filled with a stretch of Ns. The scaffolding step is already included in many commonly used assembly programs, but there are also some stand-alone applications, for example SSPACE (Boetzer et al. 2011) and BESST (Nystedt et al. 2013), to perform this step independently. Some of the gaps (N's) emerging from this process can be removed a posteriori using the original read-pair information with software such as GapCloser (Li et al. 2010), GapFiller (Boetzer and Pirovano 2012) and iMAGE (Tsai et al. 2010). Long-read data (for example from PacBio) has also recently emerged as a way of filling N regions in *scaffolds* (English et al. 2012).

When choosing assembly software, it is important to consider both the amount of sequencing data and which computational resources are available (Schatz et al. 2010a). De Bruijn graph methods, such as SOAPdenovo and ALLPATHS-LG, generally require large amounts of computing memory (RAM). Depending on the amount of sequencing data, assembly of mammal-sized genomes (~3 Gb) can require terabytes of internal memory (Lampa et al. 2013). If large computer clusters are not available locally, it will be necessary to consider collaborative equipment purchases, joint projects with bioinformatics groups or utilization of commercially available computing clouds (Box 2; Schatz et al. 2010b).

Another consideration to make is whether to use freely available programs (most programs mentioned above fall in this category) or to invest in commercial software (such as CLC workbench or Lasergene from DNASTAR). Commercial software is usually more user-friendly than freely available programs and thus readily used by researchers with limited bioinformatics skills. The downside of commercial software, apart from the (often substantial) cost involved in purchase and licensing, is that these act even more like 'black box' solutions, where it is often near impossible to inspect or alter details about the algorithms. Some commonly used software applications are also distributed together with the sequencing instruments and may be available through the sequencing facilities.

For an increasing number of species with conservation concern, there are genomic information available for very closely related taxa (Kohn et al. 2006). In such cases, it is an attractive alternative to use as much information as possible from the related genome in the assembly process (Gnerre et al. 2009). Such a 'reference-assisted' assembly strategy has been utilized in several studies (Table 1), mainly using custom pipelines, and there is clearly great scope for development of more mature software in this field. The most common approach is to first produce *contigs de novo* and then align these to the genomic reference to aid in the scaffolding step. Assuming extensive synteny and gene order conservation, such an approach makes it possible to build large *scaffolds* even with low coverage data (Kim et al. 2013) or using very short sequence reads (Wang et al. 2014). An alternative approach is the so-called 'Align-Layout-Consensus' algorithm. Here, the overlap stage of the *de novo* assembly is replaced by alignment of reads to a closely related reference genome (which is computationally less intensive compared with the OLC approach). *Contigs* and *scaffolds* are then built *de novo*, using information from overlapping reads (Schneeberger et al. 2011).

Quality assessment and validation

Once an assembly has been successfully performed, users will want to assess its quality or compare several assemblies using different methods. Yet, as discussed above, every draft genome assembly constitutes merely a hypothesis of the true underlying genome sequence, and in the absence of knowing the truth, assessing its quality remains a challenge.

A variety of metrics reflecting different aspects of the assembly are available (Bradnam et al. 2013). They can be broadly divided into approaches that require additional information from external data and those solely based on information derived from the assembly itself. As external information is often not available in conservation genomics projects, intrinsic quality assessment of the assembly is a natural starting point. One basic metric is the proportion of the genome contained within the assembly. The expected genome size can either be inferred from *C*-value data (Box 2) or, alternatively, from k-mer frequency-based approaches. Another standard metric to evaluate assembly contiguity is the N50 statistic: by definition, 50% of the assembled nucleotides are found in *contigs* (contig N50) or *scaffolds* (scaffold N50) of at least this length. The N50 statistic thus describes a kind of median of assembled sequence lengths, giving greater weight to long sequences.

Recently, variations of this metric, for example the NG50 and 'NG Graph' (Bradnam et al. 2013), incorporating the expected genome size was introduced and provide effective means of visualizing and evaluating differences in contiguity between assemblies.

However, the N50 statistic and variations thereof need to be interpreted with caution. They merely indicate contiguity and contain no information on assembly accuracy. To detect errors in the assembly, information from remapped paired-end or mate-pair data can be used (as, e.g., implemented in the software REAPR; Hunt et al. 2013). Low-coverage regions or mis-orientation of read pairs suggests mis-assemblies, while aberrant insert sizes indicate small insertions or deletions. Exceedingly high sequence coverage, high local SNP densities or correlated SNPs, where most of the reads carry one character state (but multiple others show another character state), can indicate the presence of collapsed, near-identical repeats. Software applications performing these steps are numerous, and examples can be found in the current literature (Earl et al. 2011; Bradnam et al. 2013). The *amosvalidate* pipeline (Phillippy et al. 2008; Schatz et al. 2013) encompasses several genome assembly diagnostics in one pipeline, but works best for small- or medium-sized genomes.

Independent experimental data sets from the target species arguably provide the best source of external information. Data from optical maps, for instance, allow validating short- and large- scale accuracy of *scaffolds* and expanding them further to approach chromosome level. Similarly, separately assembled sequences from BAC or fosmid libraries can help to assess sequence accuracy and repeat content. Both approaches, however, rely on correct assembly themselves and are not readily available for smaller laboratories at present. Independent *de novo* assemblies from shotgun transcriptome sequencing data (RNA-seq) are more easily generated, and expressed sequence tag (EST) libraries might already exist for species of conservation concern (although getting access to fresh tissues for RNA extraction may be a serious limitation if captive populations are not available). Sequence content and exon structure of transcriptome data thus constitute an important additional resource for validating sequence accuracy and for correcting scaffolding in cases where genes span across *contigs*.

Comparative genomic approaches provide another avenue, which does not require the generation of additional data. For example, quantifying the presence and completeness of orthologous core eukaryotic protein sequences (Parra et al. 2007) provides first intuition on the comprehensiveness of the assembly. In cases where high-quality reference genomes of sister taxa exist, genome comparisons might be of guidance in detecting mis-assemblies and chimeric *contigs* under the assumption of broad-scale synteny and gene order conservation. Small-scale rearrangements, however, might be real and require in depth investigation.

DNA from other organisms are likely to have contaminated the genomic samples at various stages (during both sampling and laboratory procedures) and will be present in the sequencing data. Although mainly being a nuisance, contaminations at the sampling stage may actually be interesting from a conservation point of view, as they can carry information about parasites or other microorganisms related to the study species. External genomic resources aid in finding such contaminations that might have been assembled as separate *contigs* or are interspersed with target sequence in the same *contig*. Positive hits from a BLAST search or similar local alignment routines are often employed to find such traces of contamination, but results need to be interpreted with caution. Even correctly assembled sequences can lead to best hits from distantly related species with well-annotated genomes, particularly if taxon sampling within the target group of organisms is scarce. Likewise, small stretches of contamination in a large *contig* or *scaffold* may be missed entirely if other parts of the sequence yield significant hits on the target clade. Human contamination in other mammalian genome sequences will be particularly problematic, as such contamination is expected to be common due to handling of the samples. For parts of a *de novo*-sequenced mammalian genome, the best BLAST hit will be against a human or mouse sequence simply because the region in question has not been sequenced and annotated in any other mammal.

Genome annotation

To harness the full potential of a genome sequence, it needs to be annotated with biologically relevant information that can range from gene models and functional information, such as gene ontology (GO) terms (Gene Ontology Consortium 2004; Primmer et al. 2013) or 'Kyoto encyclopedia of genes and genomes' (KEGG) pathways (Kanehisa and Goto 2000), to microRNA and epigenetic modifications (The ENCODE Project Consortium 2012). In the context of genetic nonmodel organisms, annotation is often confined to protein-coding sequence (CDS) or transcripts more generally. Despite the considerable challenge to annotate genes in newly sequenced species where preexisting gene models are mostly lacking, automated gene annotation has in principle become possible for individual research groups (Yandell and Ence 2012). Still, a complete genome annotation constitutes a considerable effort and requires bioinformatic proficiency. We describe only the general workflow and refer the interested reader to a comprehensive review by Yandell and Ence (2012) for more details (Box 2). Before starting, it should be noted that

 © 2014 The Authors. *Evolutionary Applications* published by John Wiley & Sons Ltd

successful annotation strongly depends on the quality of the genome assembly. Only contiguous near-complete (~90%) genomes interrupted only by small gaps will yield satisfying results. As a rule of thumb, large genomes have longer genes and thus need more contiguous assemblies for successful annotation (cf. Figure 1 in Yandell and Ence 2012).

The annotation process can be conceptually divided into two phases: a 'computational phase' where several lines of evidence from other genomes or from species-specific transcriptome data are used in parallel to create initial gene and transcript predictions. In a second 'annotation phase', all (sometimes contradicting) information is then synthesized into a gene annotation, following a set of rules determined by the annotation pipeline.

Prior to gene prediction, it is of vital importance to mask repetitive sequences including low-complexity regions and transposable elements. As repeats are often poorly conserved across species, it is advisable to create a species-specific repeat library using tools like RepeatModeler or RepeatExplorer (Novák et al. 2013). Once repeats are masked (e.g. with RepeatMasker; http://www.repeatmasker.org), *ab initio* algorithms trained on gene models from related species can be used for baseline prediction of coding sequence (CDS) (e.g. AUGUSTUS; Stanke et al. 2006). Protein alignments (using e.g. tblastx) and syntenic protein lift-overs from a variety of other species provide a valuable resource to complement the predicted gene models. Arguably, the best evidence comes from detailed EST or RNA-seq data, which in addition to CDS, provides gene models with information on splice sites, transcription start sites and untranslated regions (UTRs). If possible, mRNA should be sequenced strand-specifically, as this helps resolve gene models, facilitates transcriptome assembly and eventually aids in the evaluation of the genome assembly.

In a next step, all the evidence from *ab initio* prediction and protein-, EST- or RNA-alignments need to be synthesized into a final set of gene annotations. As the evidence is mostly incomplete and sometimes contradicting, this is a difficult task that often benefits from manual curation. Still, several automated annotation tools like MAKER (Cantarel et al. 2008) or PASA (Haas et al. 2003) exist that incorporate, and weigh the evidence from, several sources. Although these tools generally provide good results, qualitative validation is important (e.g. by assessing the length of open-reading frames). Visual inspection of the annotation is another vital component to detect systematic issues such as intron leakage (introns being annotated as exons due to the presence of pre-mRNA) or gene fusion. Tools like WebApollo (Lee et al. 2013) from the GMOD project are particularly useful, as they allow the user to edit the annotation directly through the visual interface.

Publishing the genome

Draft genome sequences are now being produced at an ever-increasing rate. Traditional databases such as ENSEMBL from the European Molecular Biology Labs (EMBL) and the Wellcome Trust Sanger Institute, or genomic databases from the National Center for Biotechnology Information (NCBI) providing access to genomes and meta-information can no longer annotate and curate all incoming genomes. NCBI therefore already provides the possibility to upload draft genome sequences and user-generated annotation. To allow other users to improve the assembly and its annotation, all available raw data should be uploaded, together with the assembled genome and all relevant meta-data, for example as a BioProject on NCBI.

Perspectives

Conservation applications

We have summarized information on current methods for whole-genome sequencing, assembly and annotation, with the aim of providing practical guidance for conservation or ecology-oriented research groups moving into the field of genomics. The focus has been on large and complex genomes of nonmodel organisms relevant from a conservation perspective. In the introduction, we outlined a number different ways in which genomic resources in general, and a complete genome sequence, in particular, can be applied in a conservation biology setting (see also Fig. 1). Conservation genomics being a young field, examples where genomic resources have been put to the test in an applied conservation context are still limited, but a few such cases may be worth highlighting.

One of the first nonmodel genomes to be sequenced using the Illumina technology was the giant panda (Li et al. 2010). While the focus of the panda genome paper was not on conservation issues, follow-up studies have utilized the draft genome to make inferences about population structure, adaptive genetic variation and demography (Wei et al. 2012). Likewise in the Aye-Aye, resequencing data from twelve individuals from different parts of Madagascar were utilized to infer fine-scale genetic population structure and conduct landscape genetic analyses. The results were used to provide guidance for allocation of conservation resources towards preserving large and contiguous habitats in northern Madagascar (Perry et al. 2013). Genomic resources have further been utilized in breeding programs of the Tasmanian devil, which is endangered in the wild due to a contagious facial cancer. The generation of a reference genome sequence in combination with genomewide resequencing data has made it possible to investigate many details of this disease, including the identification of candidate genes involved in tumorigenesis (Murchison et al.

2012). Similarly, genomic resources have been utilized to limit the spread of a developmental disease causing mutation in breeding programs of the California condor (Romanov et al. 2009). Finally, genomewide SNP screening has been effective in several studies of fishery stock monitoring and management (Primmer 2009; Nielsen et al. 2012a).

Future directions

With rapid progress in sequencing nano-technology and further development of computational methods, we can expect that all steps of the workflow will continue to be improved. New library preparation protocols will enable sequencing from less starting material, producing libraries with longer and more precisely estimated insert sizes and generating longer reads with reduced error rates. The development of more efficient assembly algorithms and increasing computational power will make the bioinformatic data processing amenable to a larger spectrum of users. As the costs involved in genome sequencing and assembly continues to drop, the generation of a draft genome sequence will soon become routine, also for species with large genomes. This development will mean that even small research groups with limited funding will soon be expected to develop genomic resources for their species of choice, reinforcing the use of genomic approaches in conservation biology and related disciplines. The possible development of rapid and compact sequencing solutions that may be applied directly in the field situation would be particularly useful for many conservation applications. Another important area of progress lies in the usage of low-quality samples, obtained from noninvasive sampling or museum material that would allow monitoring of genomic diversity through time. Developing ways of storing and sharing genomic data will also be crucial, to make the most efficient use of these resources for conservation. In spite of these promising developments, we need to be aware that science alone is not sufficient to meet future conservation challenges. The technical transition from conservation genetics to genome-scale data therefore needs to be tightly accompanied by a discussion of how applied conservation biology can best benefit from genomic data (see for example McMahon et al., 2014). This discussion needs to be taken at the general level on a case-by-case basis and involves scientists and political decision makers alike.

Acknowledgements

We thank the organisers and participants of the 'Evolutionary conservation' symposium at ESEB 2013 for discussions, and Christophe Eizaguirre and Miguel Soares for inviting this contribution. Douglas Scofield, Aaron Shafer and three anonymous reviewers provided feedback on earlier drafts of this manuscript. We also wish to thank all participants of the EBC Next Generation Sequencing Journal Club (Uppsala University) for stimulating discussions on this subject over several years. RE was funded by the Swedish Environmental Protection Agency [grant number 235-12-11].

D.6 Genomes

Further explanations for Chapter 6.

D.6.1 Background: genes, genomes and cells

- Clark, Douglas, Choi (OpenStax) (2018a) — Open textbook chapter on the double helix, base pairing, replication and DNA repair, at introductory undergraduate level. Useful for revising the nucleic-acid basics assumed by the rest of the chapter. *(book chapter; CC BY-NC-SA 4.0)*

  Chapter 14: DNA Structure and Function (Biology 2e). Clark, Douglas, Choi (OpenStax) (2018). *OpenStax Biology 2e.* https://openstax.org/books/biology-2e/pages/14-introduction

- Clark, Douglas, Choi (OpenStax) (2018b) — Open textbook chapter on the genetic code, transcription, RNA processing and translation in prokaryotes and eukaryotes. Covers the central dogma at the level summarised in this section. *(book chapter; CC BY-NC-SA 4.0)*

  Chapter 15: Genes and Proteins (Biology 2e). Clark, Douglas, Choi (OpenStax) (2018). *OpenStax Biology 2e.* https://openstax.org/books/biology-2e/pages/15-introduction

- Heather and Chain (2016) — A short historical review of DNA sequencing, from Sanger and Maxam-Gilbert sequencing to second- and third-generation methods. Gives background for the experimental methods mentioned in this section. *(review; CC BY 4.0)*

  The sequence of sequencers: The history of sequencing DNA. Heather & Chain (2016). *Genomics.* doi:10.1016/j.ygeno.2015.11.003

  > Determining the order of nucleic acid residues in biological samples is an integral component of a wide variety of research applications. Over the last fifty years large numbers of researchers have applied themselves to the production of techniques and technologies to facilitate this feat, sequencing DNA and RNA molecules. This time-scale has witnessed tremendous changes, moving from sequencing short oligonucleotides to millions of bases, from struggling towards the deduction of the coding sequence of a single gene to rapid and widely available whole genome sequencing. This article traverses those years, iterating through the different generations of sequencing technology, highlighting some of the key discoveries, researchers, and sequences along the way.

D.6.2 From the first genome projects

- Taylor et al. (2024) — Reviews how the incomplete reference from the Human Genome Project was completed by the Telomere-to-Telomere assembly and extended by the Human Pangenome Reference. Connects the genome projects in this section with the pangenome discussion in the next. *(review; CC BY 4.0)*

  Beyond the Human Genome Project: The Age of Complete Human Genome Sequences and Pangenome References. Taylor et al. (2024). *Annual Review of Genomics and Human Genetics.* doi:10.1146/annurev-genom-021623-081639

  > The Human Genome Project was an enormous accomplishment, providing a foundation for countless explorations into the genetics and genomics of the human species. Yet for many years, the human genome reference sequence remained incomplete and lacked representation of human genetic diversity. Recently, two major advances have emerged to address these shortcomings: complete gap-free human genome sequences, such as the one developed by the Telomere-to-Telomere Consortium, and high-quality pangenomes, such as the one developed by the Human Pangenome Reference Consortium. Facilitated by advances in long-read DNA sequencing and genome assembly algorithms, complete human genome sequences resolve regions that have been historically difficult to sequence, including centromeres, telomeres, and segmental duplications. In parallel, pangenomes capture the extensive genetic diversity across populations worldwide. Together, these advances usher in a new era of genomics research,

enhancing the accuracy of genomic analysis, paving the path for precision medicine, and contributing to deeper insights into human biology.

- Birney (2021) — A brief perspective on why the Human Genome Project was organised internationally and kept its data freely available. Useful context for the Bermuda Principles and open data in genomics. *(perspective; CC BY 4.0)*

  The International Human Genome Project. Birney (2021). *Human Molecular Genetics*. doi:10.1093/hmg/ddab198

  > The human genome project was conceived and executed as an international project, due to both pragmatic and principled reasons. This internationality has served the project well, with the resulting human genome being freely available for all researchers in all countries. Over time the reference human genome will likely have to evolve to a graph genome, and tap into more diverse sequences worldwide. A similar international mindset underpins data analysis for the interpretation of the human genome from basic to clinical research.

- Pellicer et al. (2018) — Reviews the range of genome sizes in eukaryotes and especially land plants, and the roles of polyploidy and transposable elements in genome size change. Gives concrete examples for the C-value paradox. *(review; CC BY 4.0)*

  Genome Size Diversity and Its Impact on the Evolution of Land Plants. Pellicer et al. (2018). *Genes*. doi:10.3390/genes9020088

  > Genome size is a biodiversity trait that shows staggering diversity across eukaryotes, varying over 64,000-fold. Of all major taxonomic groups, land plants stand out due to their staggering genome size diversity, ranging ca. 2400-fold. As our understanding of the implications and significance of this remarkable genome size diversity in land plants grows, it is becoming increasingly evident that this trait plays not only an important role in shaping the evolution of plant genomes, but also in influencing plant community assemblages at the ecosystem level. Recent advances and improvements in novel sequencing technologies, as well as analytical tools, make it possible to gain critical insights into the genomic and epigenetic mechanisms underpinning genome size changes. In this review we provide an overview of our current understanding of genome size diversity across the different land plant groups, its implications on the biology of the genome and what future directions need to be addressed to fill key knowledge gaps.

D.6.3 Differences across the tree of life

- Youssef et al. (2019) — Open-access book chapter introducing genome structure and content across the tree of life, including how prokaryotic and eukaryotic genomes differ. A broad starting point for this section. *(book chapter; CC BY 4.0)*

  Introduction to Genome Biology and Diversity. Youssef et al. (2019). *Evolutionary Genomics*. doi:10.1007/978-1-4939-9074-0_1

  > Organisms display astonishing levels of cell and molecular diversity, including genome size, shape, and architecture. In this chapter, we review how the genome can be viewed as both a structural and an informational unit of biological diversity and explicitly define our intended meaning of genetic information. A brief overview of the characteristic features of bacterial, archaeal, and eukaryotic cell types and viruses sets the stage for a review of the differences in organization, size, and packaging strategies of their genomes. We include a detailed review of genetic elements found outside the primary chromosomal structures, as these provide insights into how genomes are sometimes viewed as incomplete informational entities. Lastly, we reassess the definition of the genome in light of recent advancements in our understanding of the diversity of genomic structures and the mechanisms by which genetic information is expressed within the cell. Collectively, these topics comprise a good introduction to genome biology for the newcomer to the field and provide a valuable reference for those developing new statistical or computation methods in genomics. This review also prepares the reader for anticipated transformations in thinking as the field of genome biology progresses.

- Bobay and Ochman (2017) — Short review of why bacterial genomes are compact and gene-dense while eukaryotic genomes accumulate non-functional sequence, explained by a deletion bias in bacteria and by genetic drift. Complements the subsection on prokaryotic genome organisation and the population-genetic arguments in the next section. *(review; CC BY 4.0)*

  The Evolution of Bacterial Genome Architecture. Bobay & Ochman (2017). *Frontiers in Genetics*. doi:10.3389/fgene.2017.00072

  > The genome architecture of bacteria and eukaryotes evolves in opposite directions when subject to genetic drift, a difference that can be ascribed to the fact that bacteria exhibit a mutational bias that deletes superfluous sequences, whereas eukaryotes are biased toward large insertions. Expansion of eukaryotic genomes occurs through the addition of non-functional sequences, such as repetitive sequences and transposable elements, whereas variation in bacterial genome size is largely due to the acquisition and loss of functional accessory genes. These properties create the situation in which eukaryotes with very similar numbers of genes can have vastly different genome sizes, while in bacteria, gene number scales linearly with genome size. Some bacterial genomes, however, particularly those of species that undergo bottlenecks due to recent association with hosts, accumulate pseudogenes and mobile elements, conferring them a low gene content relative to their genome size. These non-functional sequences are gradually eroded and eliminated after long-term association with hosts, with the result that obligate symbionts have the smallest genomes of any cellular organism. The architecture of bacterial genomes is shaped by complex and diverse processes, but for most bacterial species, genome size is governed by a non-adaptive process, i.e., genetic drift coupled with a mutational bias toward deletions. Thus, bacteria with small effective population sizes typically have the smallest genomes. Some marine bacteria counter this near-universal trend: despite having immense population sizes, selection, not drift, acts to reduce genome size in response to metabolic constraints in their nutrient-limited environment.

- Koonin (2015) — Discusses the origin of the eukaryotic cell from an archaeal host and a bacterial endosymbiont, from a comparative-genomics perspective. Relevant to the subsection on organelle genomes and endosymbiosis. *(review; CC BY 4.0)*

  Origin of eukaryotes from within archaea, archaeal eukaryome and bursts of gene gain: eukaryogenesis just made easier?. Koonin (2015). *Philosophical Transactions of the Royal Society B: Biological Sciences*. doi:10.1098/rstb.2014.0333

  > The origin of eukaryotes is a fundamental, forbidding evolutionary puzzle. Comparative genomic analysis clearly shows that the last eukaryotic common ancestor (LECA) possessed most of the signature complex features of modern eukaryotic cells, in particular the mitochondria, the endomembrane system including the nucleus, an advanced cytoskeleton and the ubiquitin network. Numerous duplications of ancestral genes, e.g. DNA polymerases, RNA polymerases and proteasome subunits, also can be traced back to the LECA. Thus, the LECA was not a primitive organism and its emergence must have resulted from extensive evolution towards cellular complexity. However, the scenario of eukaryogenesis, and in particular the relationship between endosymbiosis and the origin of eukaryotes, is far from being clear. Four recent developments provide new clues to the likely routes of eukaryogenesis. First, evolutionary reconstructions suggest complex ancestors for most of the major groups of archaea, with the subsequent evolution dominated by gene loss. Second, homologues of signature eukaryotic proteins, such as actin and tubulin that form the core of the cytoskeleton or the ubiquitin system, have been detected in diverse archaea. The discovery of this 'dispersed eukaryome' implies that the archaeal ancestor of eukaryotes was a complex cell that might have been capable of a primitive form of phagocytosis and thus conducive to endosymbiont capture. Third, phylogenomic analyses converge on the origin of most eukaryotic genes of archaeal descent from within the archaeal evolutionary tree, specifically, the TACK superphylum. Fourth, evidence has been presented that the origin of the major archaeal phyla involved massive acquisition of bacterial genes. Taken together, these findings make the symbiogenetic scenario for the origin of eukaryotes considerably more plausible and the origin of the organizational complexity of eukaryotic cells more readily explainable than they appeared until recently.

D.6.4 Genomes in populations

- Medini et al. (2020) — Opening chapter of an open-access book, written by the authors who introduced the pan-genome concept, describing how core and accessory genomes were defined

from multiple bacterial genomes. Other chapters of the same book cover pangenome ecology and selection. *(book chapter; CC BY 4.0)*

The Pangenome: A Data-Driven Discovery in Biology. Medini et al. (2020). *The Pangenome*. doi:10.1007/978-3-030-38281-0_1

> An early example of Big data in biology: how a mathematical model, developed to address a practical question in vaccinology, transformed established concepts, opening biology to the "unbounded."

- Wolf and Akey (2018) — Short review of what genome sequences have shown about Neanderthal and Denisovan admixture into modern humans, and which questions remain open. *(review; CC BY 4.0)*

  Outstanding questions in the study of archaic hominin admixture. Wolf & Akey (2018). *PLOS Genetics*. doi:10.1371/journal.pgen.1007349

  > The complete sequencing of archaic and modern human genomes has revolutionized the study of human history and evolution. The application of paleogenomics has answered questions that were beyond the scope of archaeology alone-definitively proving admixture between archaic and modern humans. Despite the remarkable progress made in the study of archaic-modern human admixture, many outstanding questions remain. Here, we review some of these questions, which include how frequent archaic-modern human admixture was in history, to what degree drift and selection are responsible for the loss and retention of introgressed sequences in modern human genomes, and how surviving archaic sequences affect human phenotypes.

- Ahlquist et al. (2021) — Reviews a decade of work on archaic introgression, including demographic history and the methods used to detect introgressed segments. Gives more methodological detail than the previous item. *(review; CC BY 4.0)*

  Our Tangled Family Tree: New Genomic Methods Offer Insight into the Legacy of Archaic Admixture. Ahlquist et al. (2021). *Genome Biology and Evolution*. doi:10.1093/gbe/evab115

  > The archaic ancestry present in the human genome has captured the imagination of both scientists and the wider public in recent years. This excitement is the result of new studies pushing the envelope of what we can learn from the archaic genetic information that has survived for over 50,000 years in the human genome. Here, we review the most recent ten years of literature on the topic of archaic introgression, including the current state of knowledge on Neanderthal and Denisovan introgression, as well as introgression from other as-yet unidentified archaic populations. We focus this review on four topics: 1) a reimagining of human demographic history, including evidence for multiple admixture events between modern humans, Neanderthals, Denisovans, and other archaic populations; 2) state-of-the-art methods for detecting archaic ancestry in population-level genomic data; 3) how these novel methods can detect archaic introgression in modern African populations; and 4) the functional consequences of archaic gene variants, including how those variants were co-opted into novel function in modern human populations. The goal of this review is to provide a simple-to-access reference for the relevant methods and novel data, which has changed our understanding of the relationship between our species and its siblings. This body of literature reveals the large degree to which the genetic legacy of these extinct hominins has been integrated into the human populations of today.

D.6.5 Repeats and the 3D genome

- Makałowski et al. (2019) — Open-access chapter describing the classes of transposable elements and the computational methods used to identify and annotate them. Useful for the subsection on transposable elements. *(book chapter; CC BY 4.0)*

  Transposable Elements: Classification, Identification, and Their Use As a Tool For Comparative Genomics. Makałowski et al. (2019). *Evolutionary Genomics*. doi:10.1007/978-1-4939-9074-0_6

> Most genomes are populated by hundreds of thousands of sequences originated from mobile elements. On the one hand, these sequences present a real challenge in the process of genome analysis and annotation. On the other hand, they are very interesting biological subjects involved in many cellular processes. Here we present an overview of transposable elements biodiversity, and we discuss different approaches to transposable elements detection and analyses.

- Garrido-Ramos (2017) — Reviews the structure, organisation, evolution and possible functions of satellite DNA, including how sequencing data are used to study it. Complements the subsection on tandem repeats. *(review; CC BY 4.0)*

  Satellite DNA: An Evolving Topic. Garrido-Ramos (2017). *Genes*. doi:10.3390/genes8090230

  > Satellite DNA represents one of the most fascinating parts of the repetitive fraction of the eukaryotic genome. Since the discovery of highly repetitive tandem DNA in the 1960s, a lot of literature has extensively covered various topics related to the structure, organization, function, and evolution of such sequences. Today, with the advent of genomic tools, the study of satellite DNA has regained a great interest. Thus, Next-Generation Sequencing (NGS), together with high-throughput in silico analysis of the information contained in NGS reads, has revolutionized the analysis of the repetitive fraction of the eukaryotic genomes. The whole of the historical and current approaches to the topic gives us a broad view of the function and evolution of satellite DNA and its role in chromosomal evolution. Currently, we have extensive information on the molecular, chromosomal, biological, and population factors that affect the evolutionary fate of satellite DNA, knowledge that gives rise to a series of hypotheses that get on well with each other about the origin, spreading, and evolution of satellite DNA. In this paper, I review these hypotheses from a methodological, conceptual, and historical perspective and frame them in the context of chromosomal organization and evolution.

- Pal et al. (2018) — Explains how Hi-C data are generated and analysed, from normalisation to the calling of compartments, TADs and loops. Useful for understanding the methods behind 3D genome organisation. *(review; CC BY 4.0)*

  Hi-C analysis: from data generation to integration. Pal et al. (2018). *Biophysical Reviews*. doi:10.1007/s12551-018-0489-1

  > In the epigenetics field, large-scale functional genomics datasets of ever-increasing size and complexity have been produced using experimental techniques based on high-throughput sequencing. In particular, the study of the 3D organization of chromatin has raised increasing interest, thanks to the development of advanced experimental techniques. In this context, Hi-C has been widely adopted as a high-throughput method to measure pairwise contacts between virtually any pair of genomic loci, thus yielding unprecedented challenges for analyzing and handling the resulting complex datasets. In this review, we focus on the increasing complexity of available Hi-C datasets, which parallels the adoption of novel protocol variants. We also review the complexity of the multiple data analysis steps required to preprocess Hi-C sequencing reads and extract biologically meaningful information. Finally, we discuss solutions for handling and visualizing such large genomics datasets.

D.6.6 RNA genes and regulatory elements

- Palazzo and Gregory (2014) — A readable argument, based on genome size variation, transposable elements and population genetics, for why much of the human genome is likely to be non-functional. Directly relevant to the debate after ENCODE discussed in this section. *(review; CC BY 4.0)*

  The Case for Junk DNA. Palazzo & Gregory (2014). *PLoS Genetics*. doi:10.1371/journal.pgen.1004351

  > With the advent of deep sequencing technologies and the ability to analyze whole genome sequences and transcriptomes, there has been a growing interest in exploring putative functions of the very large fraction of the genome that is commonly referred to as "junk DNA."Whereas this is an issue of considerable importance in genome biology, there is an unfortunate tendency for researchers and science writers to proclaim the demise of junk DNA on a regular basis without properly addressing some of the fundamental issues that first led to the rise of the concept.In this review, we provide an overview of the major arguments

that have been presented in support of the notion that a large portion of most eukaryotic genomes lacks an organism-level function.Some of these are based on observations or basic genetic principles that are decades old, whereas others stem from new knowledge regarding molecular processes such as transcription and gene regulation.

- Ponting and Haerty (2022) — A critical review of the evidence for lncRNA function, discussing the pitfalls of experimental and computational methods. Argues that most lncRNA transcripts are likely to be noise or to have minor regulatory roles. *(review; CC BY 4.0)*

  Genome-Wide Analysis of Human Long Noncoding RNAs: A Provocative Review. Ponting & Haerty (2022). *Annual Review of Genomics and Human Genetics*. doi:10.1146/annurev-genom-112921-123710

  > Do long noncoding RNAs (lncRNAs) contribute little or substantively to human biology? To address how lncRNA loci and their transcripts, structures, interactions, and functions contribute to human traits and disease, we adopt a genome-wide perspective. We intend to provoke alternative interpretation of questionable evidence and thorough inquiry into unsubstantiated claims. We discuss pitfalls of lncRNA experimental and computational methods as well as opposing interpretations of their results. The majority of evidence, we argue, indicates that most lncRNA transcript models reflect transcriptional noise or provide minor regulatory roles, leaving relatively few human lncRNAs that contribute centrally to human development, physiology, or behavior. These important few tend to be spliced and better conserved but lack a simple syntax relating sequence to structure and mechanism, and so resist simple categorization. This genome-wide view should help investigators prioritize individual lncRNAs based on their likely contribution to human biology.

- Marchese et al. (2017) — Reviews the proposed mechanisms by which lncRNAs act, through RNA sequence and structure, protein interactions and the act of transcription itself. A useful counterpoint to the more sceptical review above. *(review; CC BY 4.0)*

  The multidimensional mechanisms of long noncoding RNA function. Marchese et al. (2017). *Genome Biology*. doi:10.1186/s13059-017-1348-2

  > A major shift in our understanding of genome regulation has emerged recently. It is now apparent that the majority of cellular transcripts do not code for proteins, and many of them are long noncoding RNAs (lncRNAs). Increasingly, studies suggest that lncRNAs regulate gene expression through diverse mechanisms. We review emerging mechanistic views of lncRNAs in gene regulation in the cell nucleus. We discuss the functional interactions that lncRNAs establish with other molecules as well as the relationship between lncRNA transcription and function. While some of these mechanisms are specific to lncRNAs, others might be shared with other types of genes.

D.6.7 Gene order, synteny and genome rearrangements

- Liu et al. (2018) — Compares synteny-detection tools on real and simulated assemblies, and shows how assembly fragmentation and parameter choices change the inferred synteny blocks; a practical complement to the section. *(primary study; CC BY 4.0)*

  Inferring synteny between genome assemblies: a systematic evaluation. Liu et al. (2018). *BMC Bioinformatics*. doi:10.1186/s12859-018-2026-4

  > Background Genome assemblies across all domains of life are being produced routinely. Initial analysis of a new genome usually includes annotation and comparative genomics. Synteny provides a framework in which conservation of homologous genes and gene order is identified between genomes of different species. The availability of human and mouse genomes paved the way for algorithm development in large-scale synteny mapping, which eventually became an integral part of comparative genomics. Synteny analysis is regularly performed on assembled sequences that are fragmented, neglecting the fact that most methods were developed using complete genomes. It is unknown to what extent draft assemblies lead to errors in such analysis. Results We fragmented genome assemblies of model nematodes to various extents and conducted synteny identification and downstream analysis. We first show that synteny between species can be underestimated up to 40% and find disagreements between popular tools that infer synteny blocks. This inconsistency and further demonstration of erroneous gene ontology enrichment tests raise

questions about the robustness of previous synteny analysis when gold standard genome sequences remain limited. In addition, assembly scaffolding using a reference guided approach with a closely related species may result in chimeric scaffolds with inflated assembly metrics if a true evolutionary relationship was overlooked. Annotation quality, however, has minimal effect on synteny if the assembled genome is highly contiguous. Conclusions Our results show that a minimum N50 of 1 Mb is required for robust downstream synteny analysis, which emphasizes the importance of gold standard genomes to the science community, and should be achieved given the current progress in sequencing technology.

D.6.8 Pseudogenes, new genes and small proteins

- Van Oss and Carvunis (2019) — A short, clear review of how genes arise from non-coding DNA, proto-genes, and the methodological pitfalls in identifying de novo genes. *(review; CC BY 4.0)*

  De novo gene birth. Van Oss & Carvunis (2019). *PLOS Genetics*. doi:10.1371/journal.pgen.1008160

- Y.-W. Wang et al. (2020) — A worked example that weighs the different routes to new genes in one lineage, showing how each is detected. *(primary study; CC BY 4.0)*

  De Novo Gene Birth, Horizontal Gene Transfer, and Gene Duplication as Sources of New Gene Families Associated with the Origin of Symbiosis inAmanita. Wang et al. (2020). *Genome Biology and Evolution*. doi:10.1093/gbe/evaa193

  By introducing novel capacities and functions, new genes and gene families may play a crucial role in ecological transitions. Mechanisms generating new gene families include de novo gene birth, horizontal gene transfer, and neofunctionalization following a duplication event. The ectomycorrhizal (ECM) symbiosis is a ubiquitous mutualism and the association has evolved repeatedly and independently many times among the fungi, but the evolutionary dynamics enabling its emergence remain elusive. We developed a phylogenetic workflow to first understand if gene families unique to ECM Amanita fungi and absent from closely related asymbiotic species are functionally relevant to the symbiosis, and then to systematically infer their origins. We identified 109 gene families unique to ECM Amanita species. Genes belonging to unique gene families are under strong purifying selection and are upregulated during symbiosis, compared with genes of conserved or orphan gene families. The origins of seven of the unique gene families are strongly supported as either de novo gene birth (two gene families), horizontal gene transfer (four), or gene duplication (one). An additional 34 families appear new because of their selective retention within symbiotic species. Among the 109 unique gene families, the most upregulated gene in symbiotic cultures encodes a 1-aminocyclopropane-1-carboxylate deaminase, an enzyme capable of downregulating the synthesis of the plant hormone ethylene, a common negative regulator of plant-microbial mutualisms.

The Case for Junk DNA

Alexander F. Palazzo[1]*, T. Ryan Gregory[2]*

1 University of Toronto, Department of Biochemistry, Toronto, Ontario, Canada, **2** University of Guelph, Department of Integrative Biology, Guelph, Ontario, Canada

Overview

With the advent of deep sequencing technologies and the ability to analyze whole genome sequences and transcriptomes, there has been a growing interest in exploring putative functions of the very large fraction of the genome that is commonly referred to as "junk DNA." Whereas this is an issue of considerable importance in genome biology, there is an unfortunate tendency for researchers and science writers to proclaim the demise of junk DNA on a regular basis without properly addressing some of the fundamental issues that first led to the rise of the concept. In this review, we provide an overview of the major arguments that have been presented in support of the notion that a large portion of most eukaryotic genomes lacks an organism-level function. Some of these are based on observations or basic genetic principles that are decades old, whereas others stem from new knowledge regarding molecular processes such as transcription and gene regulation.

Introduction

The search for function in the genome

It has been known for several decades that only a small fraction of the human genome is made up of protein-coding sequences and that at least some noncoding DNA has important biological functions. In addition to coding exons, the genome contains sequences that are transcribed into functional RNA molecules (e.g., tRNA, rRNA, and snRNA), regulatory regions that control gene expression (e.g., promoters, silencers, and enhancers), origins of replication, and repeats that play structural roles at the chromosomal level (e.g., telomeres and centromeres).

New discoveries regarding potentially important sequences amongst the nonprotein-coding majority of the genome are becoming more prevalent. By far the best-known effort to identify functional regions in the human genome is the recently completed Encyclopaedia of DNA Elements (ENCODE) project [1], whose authors made the remarkable claim that a "biochemical function" could be assigned to 80% of the human genome [2]. Reports that ENCODE had refuted the existence of large amounts of junk DNA in the human genome received considerable media attention [3,4]. Criticisms that these claims were based on an extremely loose definition of "function" soon followed [5–8] (for a discussion of the relevant function concepts, see [9]), and debate continues regarding the most appropriate interpretation of the ENCODE results. Nevertheless, the excitement and subsequent backlash served to illustrate the widespread interest among scientists and nonspecialists in determining how much of the human genome is functionally significant at the organism level.

The origin of "junk DNA"

Although the term "junk DNA" was already in use as early as the 1960s [10–12], the term's origin is usually attributed to Susumu Ohno [13]. As Ohno pointed out, gene duplication can alleviate the constraint imposed by natural selection on changes to important gene regions by allowing one copy to maintain the original function as the other undergoes mutation. Rarely, these mutations will turn out to be beneficial, and a new gene may arise ("neofunctionalization") [14]. Most of the time, however, one copy sustains a mutation that eliminates its ability to encode a functional protein, turning it into a pseudogene. These sequences are what Ohno initially referred to as "junk" [13], although the term was quickly extended to include many types of noncoding DNA [15]. Today, "junk DNA" is often used in the broad sense of referring to any DNA sequence that does not play a functional role in development, physiology, or some other organism-level capacity. This broader sense of the term is at the centre of most current debate about the quantity—or even the existence—of "junk DNA" in the genomes of humans and other organisms.

It has now become something of a cliché to begin both media stories and journal articles with the simplistic claim that most or all noncoding DNA was "long dismissed as useless junk." The implication, of course, is that current research is revealing function in much of the supposed junk that was unwisely ignored as biologically uninteresting by past investigators. Yet, it is simply not true that potential functions for noncoding DNA were ignored until recently. In fact, various early commenters considered the notion that large swaths of the genome were nonfunctional to be "repugnant" [10,16], and possible functions were discussed each time a new type of nonprotein-coding sequence was identified (including pseudogenes, transposable elements, satellite DNA, and introns; for a compilation of relevant literature, see [17]).

Importantly, the concept of junk DNA was not based on ignorance about genomes. On the contrary, the term reflected *known* details about genome size variability, the mechanism of gene duplication and mutational degradation, and population genetics theory. Moreover, each of these observations and theoretical considerations remains valid. In this review, we examine several lines of evidence—both empirical and conceptual—that support the notion that a substantial percentage of the DNA in many eukaryotic genomes lacks an organism-level function and that the junk DNA concept remains viable post-ENCODE.

Genome Size and ''The Onion Test''

There are several key points to be understood regarding genome size diversity among eukaryotes and its relationship to the concept of junk DNA. First, genome size varies enormously among species [18,19]: at least 7,000-fold among animals and 350-fold even within vertebrates. Second, genome size varies independently of intuitive notions of organism complexity or presumed number of protein-coding genes (Figure 1). For example, a human genome contains eight times more DNA than that of a pufferfish but is 40 times smaller than that of a lungfish. Third, organisms that have very large genomes are not few in number or outliers—for example, of the >200 salamander genomes analyzed thus far, all are between four and 35 times larger than the human genome [18]. Fourth, even closely related species with very similar biological properties and the same ploidy level can differ significantly in genome size.

These observations pose an important challenge to any claim that most eukaryotic DNA is functional at the organism level. This logic is perhaps best illustrated by invoking ''the onion test'' [20]. The domestic onion, *Allium cepa*, is a diploid plant (2n = 16) with a haploid genome size of roughly 16 billion base pairs (16 Gbp), or about five times larger than humans. Although any number of species with large genomes could be chosen for such a comparison, the onion test simply asks: if most eukaryotic DNA is functional at the organism level, be it for gene regulation, protection against mutations, maintenance of chromosome structure, or any other such role, then why does an onion require five times more of it than a human? Importantly, the comparison is not restricted to onions versus humans. It could as easily be between pufferfish and lungfish, which differ by ~350-fold, or members of the genus *Allium*, which have more than a 4-fold range in genome size that is not the result of polyploidy [21].

In summary, the notion that the majority of eukaryotic noncoding DNA is functional is very difficult to reconcile with the massive diversity in genome size observed among species, including among some closely related taxa. The onion test is merely a restatement of this issue, which has been well known to genome biologists for many decades [18].

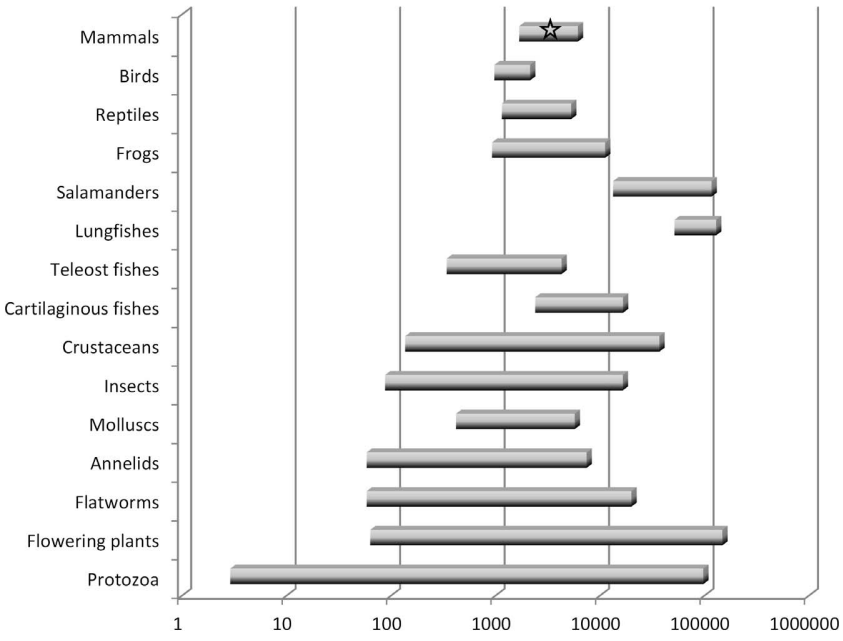

Figure 1. Summary of haploid nuclear DNA contents (''genome sizes'') for various groups of eukaryotes. This graph is based on data for about 10,000 species [18,19]. There is a wide range in genome sizes even among developmentally similar species, and there is no correspondence between genome size and general organism complexity. Humans, which have an average-sized genome for a mammal, are indicated by a star. Note the logarithmic scale.
doi:10.1371/journal.pgen.1004351.g001

Genome Composition

Another important consideration is the composition of eukaryotic genomes. Far from being composed of mysterious ''dark matter,'' the characteristics of the sequences constituting 98% or so of the human genome that is nonprotein-coding are generally well understood.

Transposable elements

By far the dominant type of nongenic DNA are transposable elements (TEs), including various well-described retroelements such as Short and Long Interspersed Nuclear Elements (SINEs and LINEs), endogenous retroviruses, and cut-and-paste DNA transposons. Because of their capacity to increase in copy number, transposable elements have long been described as ''parasitic'' or ''selfish'' [22,23]. However, the vast majority of these elements are inactive in humans, due to a very large fraction being highly degraded by mutation. Due to this degeneracy, estimates of the proportion of the human genome occupied by TEs has varied widely, between one-half and two-thirds [24,25]. Larger genomes, such as those of salamanders and lungfishes, almost certainly contain an even more enormous quantity of transposable element DNA [26,27].

Many examples have been found in which TEs have taken on regulatory or other functional roles in the genome [28]. In recognition of the more complex interactions between transposable elements and their hosts, Kidwell and Lisch proposed an expansion of the ''parasitism'' framework where each TE can be classified along a spectrum from parasitism to mutualism [29]. Nevertheless, there is evidence of organism-level function for only a tiny minority of TE sequences. It is therefore not obvious that functional explanations can be extrapolated from a small number of specific examples to all TEs within the genome.

Highly repetitive DNA

Another large fraction of the genome consists of highly repetitive DNA. These regions are extremely variable even amongst individuals of the same population (hence their use as ''DNA fingerprints'') and can expand or contract through processes such as unequal crossing over or replication slippage. Many repeats are thought to be derived from truncated TEs, but others consist of tandem arrays of di- and trinucleotides [30]. As with TEs, some highly repetitive sequences play a role in gene regulation

(for example, [31]). Others, such as telomeric- and centromeric-associated repeats [32,33], play critical roles in chromosomal maintenance. Despite this, there is currently no evidence that the majority of highly repetitive elements are functional.

Introns

According to Gencode v17, about 40% of the human genome is comprised of intronic regions; however, this figure is likely an overestimate as it includes all annotated events. It is also important to note that a large fraction of TEs and repetitive elements are found in introns. Although introns can increase the diversity of protein products by modulating alternative splicing, it is also clear that the vast majority of intronic sequence evolves in an unconstrained way, accumulating mutations at about the same rate as neutral regions. Although the median intron size in humans is ~1.5 kb [30], data suggest that most of the constrained sequence is confined to the first and last 150 nucleotides [34].

Pseudogenes

The human genome is also home to a large number of pseudogenes. Estimates of the total number range from 12,600 to 19,700 [35]. These include both "classical" pseudogenes (direct duplicates, of the sort imagined by Ohno [13]) and "processed" pseudogenes, which are reverse transcribed from mRNA [36]. Once again, although some pseudogenes have been co-opted for organism-level function (for example see [37]), most are simply evolving without selective constraints on their sequences and likely have no function [38].

Conserved sequences

Several analyses of sequence conservation between humans and other mammals have found that about 5% of the genome is conserved [1,39–42]. It is possible that an additional 4% of the human genome is under lineage-specific selection pressure [39]; however, this estimate appears to be somewhat questionable [43,44] (also see [45]). Ignoring these problems, the idea that 9% of the human genome shows signs of functionality is actually consistent with the results of ENCODE and other large-scale genome analyses.

Besides protein-coding sequences (including associated untranslated regions), which make up 1.5%–2.5% of the human genome [24], data from ENCODE suggest that conserved long noncoding RNAs (lncRNAs) are generated from about 9,000 loci that add up to less than an additional 0.4% [46,47]. Thus, even if a vast new untapped world of functional noncoding RNA is discovered, this will probably be transcribed from a small fraction of the human genome.

At first blush, sequences that are bound by transcription factors (TFs) appear to be very abundant, making up about 8.5% of the genome according to ENCODE [2]. This number, however, is an estimate of regions that are hypersensitive to DNase I treatment due to the displacement of nucleosomes by TFs. As pointed out by others [6], these regions are annotated as being several hundreds of nucleotides long and are thus much larger than the actual size of individual TF-binding motifs, which are typically 10 bp in length [48]. By ENCODE's own estimates, less than half of the nucleotide bases in these DNase I hypersensitivity regions contain actual TF recognition motifs [2], and only 60% of these are under purifying selection [49]. Others have found that weak and transient TF-binding events are routinely identified by chromatin IP experiments despite the fact that they do not significantly contribute to gene expression [50–53] and are poorly conserved [53]. Given that experiments performed in a diverse number of eukaryotic systems have found only a small correlation between TF-binding events and mRNA expression [54,51], it appears that in most cases only a fraction of TF-binding sites significantly impacts local gene expression.

In summary, most of the major constituents of the genome have been well characterized. The majority of human DNA consists of repetitive, mutationally degraded sequences. There are unambiguous examples of nonprotein-coding sequences of various types having been co-opted for organism-level functions in gene regulation, chromosome structure, and other roles, but at present evidence from the published literature suggests that these represent a small minority of the human genome.

Evolutionary Forces

To understand the current state of the human genome, we need to examine how it evolved, and as Michael Lynch once wrote, "Nothing in evolution makes sense except in the light of population genetics" [55]. Unfortunately, concepts that have been generated by this field have not been widely recognized in other domains of the life sciences. In particular, what is underappreciated by many nonevolution specialists is that much of molecular evolution in eukaryotes is primarily the result of genetic drift, or the fixation of neutral mutations. This view has been widely appreciated by molecular evolutionary biologists for the past 35 years.

The nearly neutral theory of molecular evolution

An important development in the understanding of how various evolutionary forces shape eukaryotic genes and genomes came with the theories developed by Kimura, Ohta, King, and Jukes. They demonstrated that alleles that were slightly beneficial or deleterious behaved like neutral alleles, provided that the absolute value of their selection coefficient was smaller than the inverse of the "effective" population size [56–59]. In other words, it is important to keep in mind population size when thinking about whether deleterious mutations are subjected to purifying selection.

It is also important to realize that the "effective" population size is dependent on many factors and is typically much lower than the total number of individuals in a species [55]. For humans it has been estimated that the historical effective population size is approximately 10,000, and this is on the low side in comparison to most metazoans [60]. Given the overall low figures for multicellular organisms in general, we would expect that natural selection would be powerless to stop the accumulation of certain genomic alterations over the entirety of metazoan evolution. One type of mutation that fits this description is intergenic insertions, be they transposable elements, pseudogenes, or random sequence [55]. The creation and loss of TF-binding motifs or cryptic transcriptional start sites in these same intergenic regions will equally be invisible to natural selection, provided that these do not drastically alter the expression of any nearby genes or cause the production of stable toxic transcripts. Thus, a central tenet of the nearly neutral theory of molecular evolution is that extraneous DNA sequences can be present within genomes, provided that they do not significantly impact the fitness of the organism.

Genetic load

It has long been appreciated that there is a limit to the number of deleterious mutations that an organism can sustain per generation [61,62]. The presence of these mutations is usually not harmful, because diploid organisms generally require only one functional copy of any given gene. However, if the rate at which these mutations are generated is higher than the rate at which natural selection can weed them out, then the collective

genomes of the organisms in the species will suffer a meltdown as the total number of deleterious alleles increases with each generation [63]. This rate is approximately one deleterious mutation per generation. In this context it becomes clear that the overall mutation rate would place an upper limit to the amount of functional DNA. Currently, the rate of mutation in humans is estimated to be anywhere from 70–150 mutations per generation [64,65]. By this line of reasoning, we would estimate that, at most, only 1% of the nucleotides in the genome are essential for viability in a strict sequence-specific way. However, more recent computational models have demonstrated that genomes could sustain multiple slightly deleterious mutations per generation [66]. Using statistical methods, it has been estimated that humans sustain 2.1–10 deleterious mutations per generation [66–68]. These data would suggest that at most 10% of the human genome exhibits detectable organism-level function and conversely that at least 90% of the genome consists of junk DNA. These figures agree with measurements of genome conservation (~9%, see above) and are incompatible with the view that 80% of the genome is functional in the sense implied by ENCODE. It remains possible that large amounts of noncoding DNA play structural or other roles independent of nucleotide sequence, but it far from obvious how this would be reconciled with "the onion test."

The evolution of the nucleus

When dealing with the evolution of any lineage, one must also keep in mind unique events, also known as historical contingencies, which constrain and shape subsequent evolutionary trajectories [69]. One of these key events in our own ancestry was the evolution of the eukaryotic nucleus. A further examination of why the nucleus evolved and how this altered cellular function may generate significant insights into the current shape of the eukaryotic genome.

One important event in early eukaryotic evolution was the development of a symbiotic relationship between the α-proteobacteria progenitor of mitochondria and an archaebacteria-like host [70,71]. As with most endosymbiotically derived organelles [72], DNA was transferred from mitochondria to the host. In this way, Group II introns, which are still found in both mitochondria and α-proteobacteria [73], invaded the host genome. Group II introns are parasitic DNA fragments that replicate when they are transcribed, typically as part of a larger transcript. The intron then folds into a catalytic ribozyme that splices itself out of the precursor transcript and then reinserts itself at a new genomic locus by reversing the splicing reaction. Importantly, functional fragments of Group II introns can splice out inactive versions in a trans-splicing reaction [74,75]. As described elsewhere, it is likely that Group II introns proliferated and evolved into two populations: inactivated copies that could be nonetheless spliced out in trans, and active fragments that promoted splicing of the former group. This latter group eventually evolved into the spliceosomal snRNAs [75–77]. This idea is supported by not only structural, catalytic, and functional similarities between Group II introns and snRNAs [78,79] but also by the fact that expression of the U5 snRNA rescues the splicing of Group II introns that lack the corresponding U5-like region [80].

It is likely that the proliferation of trans-splicing triggered the spatial segregation of RNA processing (the nucleoplasm) from the translation machinery (the cytoplasm) [77]. This subdivision ensured that mRNAs were properly spliced before they encountered the translation machinery. Not only would this segregation prevent translating ribosomes from interfering with the splicing reaction (and vice versa) but would also prevent the translation of incompletely processed mRNAs, which often encode toxic proteins [81,82]. Importantly, the segregation of translation from both transcription and RNA processing provided an opportunity for nuclear quality-control processes to eliminate misprocessed and spurious transcripts that did not meet the minimal requirements of "mRNA identity" (see below) before these RNAs ever encountered a ribosome. This in turn permitted intergenic DNA and cryptic transcriptional start sites to proliferate with minimal cost to the fitness of the organism. It should also be noted that the increase in ATP regeneration due to mitochondrial-derived metabolic pathways provided the surplus energy that is required to support an expansion not only in genome size and membranes [83,84] but also wasteful transcription. Thus, by several independent mechanisms, the acquisition of mitochondria likely allowed the expansion of nonfunctional intergenic DNA and the evolution of a noisy transcriptional system.

Gene Expression in Eukaryotes

Eukaryotic transcription is inherently noisy

One of the most widely discussed discoveries of the past decade of transcriptome analysis is that much of the metazoan genome is transcribed at some level (although this, too, was already recognized in rough outline in the 1970s [15]). When nascent transcripts from mouse have been analyzed by deep sequencing, the total number of reads that map to intergenic loci is almost equivalent to the number mapping to exonic regions (Figure 2A, reproduced from reference [85]). This is consistent with the observation that a large fraction of the cellular pool of RNA Polymerase II is associated with intergenic regions [86] and that transcription can be initiated at random sequences (see Figure S4 in [87]) and nucleosome-free regions [88,89]. Strikingly, when one examines the steady state level of polyadenylated RNA, very little maps to intergenic regions (Figure 2A, 2B, the latter reproduced from reference [46]; also see [85,90–92]). In fact, when one eliminates the ~9,000 transcript species that are thought to be derived from conserved lncRNA, then most of the annotated noncoding polyadenylated RNAs are present at levels below one copy per cell and are found exclusively in the nucleus (Figure 2B). The situation is no better in the unpolyadenylated pool, in which the amount of lncRNA and intergenic RNA is practically insignificant, especially in the cytoplasmic pool (Figure 2B). In aggregate, these data indicate that the majority of intergenic RNAs are degraded almost immediately after transcription. Consistent with this idea, the level of intergenic transcripts increase when RNA degradation machinery is inhibited [93–101]. Although pervasive transcription has been used as an argument against junk DNA [3,4], it is in fact entirely in line with the idea that intergenic regions are evolving under little-to-no constraint, especially when one considers that this intergenic transcription is unstable.

Identifying mRNA from intergenic transcription

A common theme that has emerged from the study of mRNA synthesis is that various steps in RNA synthesis and processing are biochemically coupled. In other words, cellular machineries that participate in one biochemical activity also promote subsequent steps. For example, during the splicing of the 5′most intron, the spliceosome collaborates with the 5′cap binding complex to deposit nuclear export factors onto the 5′end of the processed transcript [102,103], and this helps to explain why splicing enhances the nuclear export of mRNA [104–106]. Countless other examples of coupling exist (for reviews, see [107–111]).

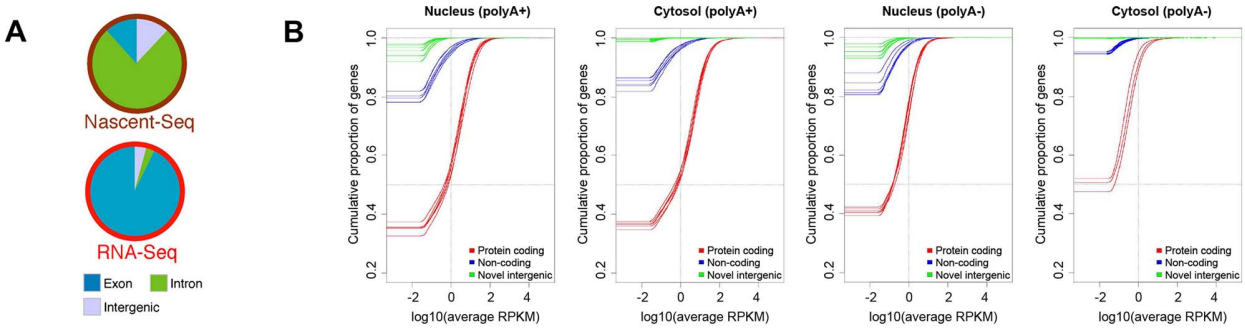

Figure 2. Levels of protein-coding and intergenic RNAs in mammalian cells. (A) Analysis of nascent and total poly(A)+ RNA levels from mouse liver nuclei. Nascent (i.e., polymerase-associated) RNA and poly(A)+ RNA were isolated from mouse liver nuclei and analyzed by high-throughput sequencing. Individual reads were categorized by their source. Exonic and intronic are from known referenced genes (i.e., "RefSeq" genes), while intergenic originate from nonreferenced loci (i.e., "non-RefSeq") in the mouse genome. Reproduced from [85]. (B) Empirical Cumulative Distribution Function (ECDF) of transcript expression in each cell compartment as determined by the ENCODE consortia. Results for RNA that either contain ("polyA+") or lack ("polyA−") a poly(A)-tail in the nucleus and cytosolic fractions are shown. Each human cell line that was analyzed is represented by three lines, one for each pool of RNA (red for protein-coding RNAs, blue for lncRNAs ["noncoding"], and green for intergenic transcripts ["novel intergenic"]). The lines indicate the cumulative fraction of RNAs in a given pool (y-axis) that are expressed at levels that are equal or less than the reads per kilobase per million mapped reads (RPKM) on the x-axis. Total numbers in each pool are as follows: reference protein coding genes: 20,679, loci producing lncRNAs: 9,277, and regions producing intergenic transcripts: 41,204. Transcripts with expression levels of 0 RPKM were adjusted to an artificial value of 10^{-6} RPKM so that the onset of each graph represents the fraction of nonexpressed genes or loci. Note that 1–4 RPKM is approximately equivalent to one copy per tissue culture cell [46,129]. Using this figure, one can easily deduce that the vast majority of intergenic transcripts are present at levels less than one copy per cell. Reproduced with permission from [46].
doi:10.1371/journal.pgen.1004351.g002

The ultimate goal of these coupling reactions is to sort protein-coding RNAs (i.e. mRNA) from intergenic transcripts [111,112]. Given that, on average, protein-coding genes have eight introns [30], while the majority of annotated ENCODE intergenic transcripts tend not to be spliced [46], introns help distinguish these two populations and thus serve as "mRNA identity" markers. These mRNA identity features activate coupling reactions, which in turn promote the further processing, nuclear export, and translation of a particular transcript. Likewise, other classes of functional RNAs (e.g., tRNAs and snRNAs) have their own identity elements [113]. In contrast, transcripts that lack identity elements are targeted for degradation. In agreement with this model, intronless RNA molecules that have a random sequence are poorly exported from the nucleus and have a very short half-life [114,115]. In contrast, intronless mRNAs have specialized motifs that promote their nuclear export [105,116–119].

In light of the fact that many functional lncRNAs serve a role in regulating chromatin structure or transcription, it is not surprising that most localise to the nucleoplasm [46]. One would predict that lncRNAs contain a differential set of identity elements that not only serve to prevent their decay but also retain them in the nucleus. This would especially be critical for lncRNAs that are spliced. Despite this, the elements that regulate the localization and stability of these RNAs have received little attention, but can be informed by the view that they may have their own identity markers.

It is also important to point out that eukaryotes have other mechanisms that either degrade aberrant mRNAs (e.g., nonsense-mediated decay) or limit the amount of intergenic transcription (e.g., heterochromatin). Nevertheless, eukaryotes appear to have evolved an intricate network of coupling reactions that are required to cope with a large burden of junk RNA. These findings are consistent with the idea that eukaryotic genomes are filled with junk DNA that is transcribed at a low level.

An alternative view of transcription and conservation?

In an attempt to counter the argument that sequence conservation is a prerequisite for functionality, it has been recently proposed that certain transcriptional events may serve some role in regulating cellular function, despite the fact that the sequence of the transcriptional product is unconstrained [120]. Indeed, this view is in line with the findings that the transcription of certain yeast genes is inhibited as a consequence of the production of cryptic unstable transcripts originating from upstream and/or downstream promoters (for a review see [121]). Other examples have linked the generation of cryptic unstable transcripts to chromatin modifications [101,122], DNA methylation [123], and DNA stability [124]. However, it remains unclear whether the majority of unstable noncoding RNAs have any effect on DNA or chromatin, let alone contribute to the fitness of the organism. In the cases where cryptic unstable transcriptional events impact gene expression, they usually consist of short transcripts that are synthesized from regions around the transcriptional start sites or within the gene itself [121]. Indeed most of the available data are consistent with the fact that transcriptional start sites are promiscuous, often generating bidirectional transcription [100,101], and that subsequent coupling processes, such as the interaction between promoter-associated complexes and 3′end processing factors, are required to enforce proper transcriptional directionality [125]. Other unstable transcripts function to promote or maintain heterochromatin formation in the vicinity of the transcriptional site, likely because these regions produce toxic transcripts [122]. Although this form of transcription has a function (viz., to maintain a repressive state), it is not clear that the elimination of these regions would have any effect on the organism [8]. The transcription of other short unstable transcripts, mostly produced from enhancer regions, has been shown to promote gene expression [126]; however, again these "enhancer RNAs" are transcribed from a small fraction of the total genome [127]. As stated by others [128], it is imperative that those who claim that the vast majority of intergenic transcription is functional test their hypotheses. In the absence of this evidence, the

declaration that we are in the midst of a paradigm shift with regards to eukaryotic genomes and gene expression [120] seems premature.

Concluding Remarks

For decades, there has been considerable interest in determining what role, if any, the majority of the DNA in eukaryotic genomes plays in organismal development and physiology. The ENCODE data are only the most recent contribution to a long-standing research program that has sought to address this issue. However, evidence casting doubt that most of the human genome possesses a functional role has existed for some time. This is not to say that none of the nonprotein-coding majority of the genome is functional—examples of functional noncoding sequences have been known for more than half a century, and even the earliest proponents of "junk DNA" and "selfish DNA" predicted that further examples would be found. Nevertheless, they also pointed out that evolutionary considerations, information regarding genome size diversity, and knowledge about the origins and features of genomic components do not support the notion that all of the DNA must have a function by virtue of its mere existence. Nothing in the recent research or commentary on the subject has challenged these observations.

Acknowledgments

We would like to thank L. Moran, S. Eddy, D. Graur, R. Hardison, J. Wan, and A. Akef for helpful comments on the manuscript.

D.7 Expression analysis

Further explanations for Chapter 7.

D.7.1 The first genome-wide methods: microarrays

- Lowe et al. (2017) — A short primer that compares microarrays and RNA-seq side by side, from sample preparation and normalisation to differential expression. Useful for seeing why RNA-seq replaced arrays and what the two technologies share. *(primer; CC BY 4.0)*

  Transcriptomics technologies. Lowe et al. (2017). *PLOS Computational Biology*. doi:10.1371/journal.pcbi.1005457

  > Transcriptomics technologies are the techniques used to study an organism's transcriptome, the sum of all of its RNA transcripts. The information content of an organism is recorded in the DNA of its genome and expressed through transcription. Here, mRNA serves as a transient intermediary molecule in the information network, whilst noncoding RNAs perform additional diverse functions. A transcriptome captures a snapshot in time of the total transcripts present in a cell. The first attempts to study the whole transcriptome began in the early 1990s, and technological advances since the late 1990s have made transcriptomics a widespread discipline. Transcriptomics has been defined by repeated technological innovations that transform the field. There are two key contemporary techniques in the field: microarrays, which quantify a set of predetermined sequences, and RNA sequencing (RNA-Seq), which uses high-throughput sequencing to capture all sequences. Measuring the expression of an organism's genes in different tissues, conditions, or time points gives information on how genes are regulated and reveals details of an organism's biology. It can also help to infer the functions of previously unannotated genes. Transcriptomic analysis has enabled the study of how gene expression changes in different organisms and has been instrumental in the understanding of human disease. An analysis of gene expression in its entirety allows detection of broad coordinated trends which cannot be discerned by more targeted assays.

- Slonim and Yanai (2009) — An introductory tutorial on the microarray analysis workflow: quality control, normalisation, differential expression, clustering and functional interpretation. Older, but it describes the classical array pipeline that the section summarises. *(tutorial; CC BY 4.0)*

  Getting Started in Gene Expression Microarray Analysis. Slonim & Yanai (2009). *PLoS Computational Biology*. doi:10.1371/journal.pcbi.1000543

  > Gene expression microarrays provide a snapshot of all the transcriptional activity in a biological sample. Unlike most traditional molecular biology tools, which generally allow the study of a single gene or a small set of genes, microarrays facilitate the discovery of totally novel and unexpected functional roles of genes. The power of these tools has been applied to a range of applications, including discovering novel disease subtypes, developing new diagnostic tools, and identifying underlying mechanisms of disease or drug response. However, this technology necessarily produces a large amount of data, challenging us to interpret it by exploiting modern computational and statistical tools. In this brief review, we aim to indicate the major issues involved in microarray analysis and provide a useful starting point for new microarray users. Figure 1 outlines the steps in a typical expression microarray experiment and maps them to the different sections of this review. Figure 1 Overview of steps in a typical gene expression microarray experiment.

D.7.2 RNA sequencing

- Law et al. (2018) — A complete worked analysis of a real RNA-seq data set in R, from count filtering and TMM normalisation to MDS plots, voom/limma testing and gene set tests. Shows in practice how the normalisation and modelling steps of the section fit together. *(tutorial; CC BY 4.0)*

  RNA-seq analysis is easy as 1-2-3 with limma, Glimma and edgeR. Law et al. (2018). *F1000Research*. doi:10.12688/f1000research.9005.3

> The ability to easily and efficiently analyse RNA-sequencing data is a key strength of the Bioconductor project. Starting with counts summarised at the gene-level, a typical analysis involves pre-processing, exploratory data analysis, differential expression testing and pathway analysis with the results obtained informing future experiments and validation studies. In this workflow article, we analyse RNA-sequencing data from the mouse mammary gland, demonstrating use of the popular edgeR package to import, organise, filter and normalise the data, followed by the limma package with its voom method, linear modelling and empirical Bayes moderation to assess differential expression and perform gene set testing. This pipeline is further enhanced by the Glimma package which enables interactive exploration of the results so that individual samples and genes can be examined by the user. The complete analysis offered by these three packages highlights the ease with which researchers can turn the raw counts from an RNA-sequencing experiment into biological insights using Bioconductor.

- Love et al. (2016) — A Bioconductor workflow from transcript quantification to DESeq2 testing, including size-factor normalisation, variance-stabilising transformations, exploratory PCA and batch handling. A useful complement to the limma/edgeR workflow above. *(tutorial; CC BY 4.0)*

  RNA-Seq workflow: gene-level exploratory analysis and differential expression. Love et al. (2016). *F1000Research*. doi:10.12688/f1000research.7035.2

  > Here we walk through an end-to-end gene-level RNA-Seq differential expression workflow using Bioconductor packages. We will start from the FASTQ files, show how these were aligned to the reference genome, and prepare a count matrix which tallies the number of RNA-seq reads/fragments within each gene for each sample.We will perform exploratory data analysis (EDA) for quality assessment and to explore the relationship between samples, perform differential gene expression analysis, and visually explore the results.

D.7.3 Testing and statistics

- Korthauer et al. (2019) — Explains and benchmarks Bonferroni, Benjamini–Hochberg, Storey's q-value and newer covariate-aware FDR methods on genomic examples. Helpful for understanding the multiple-testing part of the section and when the methods differ. *(review; CC BY 4.0)*

  A practical guide to methods controlling false discoveries in computational biology. Korthauer et al. (2019). *Genome Biology*. doi:10.1186/s13059-019-1716-1

  > Background In high-throughput studies, hundreds to millions of hypotheses are typically tested. Statistical methods that control the false discovery rate (FDR) have emerged as popular and powerful tools for error rate control. While classic FDR methods use only p values as input, more modern FDR methods have been shown to increase power by incorporating complementary information as informative covariates to prioritize, weight, and group hypotheses. However, there is currently no consensus on how the modern methods compare to one another. We investigate the accuracy, applicability, and ease of use of two classic and six modern FDR-controlling methods by performing a systematic benchmark comparison using simulation studies as well as six case studies in computational biology. Results Methods that incorporate informative covariates are modestly more powerful than classic approaches, and do not underperform classic approaches, even when the covariate is completely uninformative. The majority of methods are successful at controlling the FDR, with the exception of two modern methods under certain settings. Furthermore, we find that the improvement of the modern FDR methods over the classic methods increases with the informativeness of the covariate, total number of hypothesis tests, and proportion of truly non-null hypotheses. Conclusions Modern FDR methods that use an informative covariate provide advantages over classic FDR-controlling procedures, with the relative gain dependent on the application and informativeness of available covariates. We present our findings as a practical guide and provide recommendations to aid researchers in their choice of methods to correct for false discoveries.

- Nguyen and Holmes (2019) — Short practical advice on PCA and related methods: preprocessing, choosing the number of dimensions, interpreting axes and checking stability. Supports the clustering and dimensionality-reduction subsection. *(tutorial; CC BY 4.0)*

  Ten quick tips for effective dimensionality reduction. Nguyen & Holmes (2019). *PLOS Computational Biology*. doi:10.1371/journal.pcbi.1006907

- Kobak and Berens (2019) — Explains how t-SNE works and how initialisation, perplexity and exaggeration affect the global structure of the embedding. Useful background for the warnings in the section about over-interpreting t-SNE and UMAP plots. *(tutorial; CC BY 4.0)*

  The art of using t-SNE for single-cell transcriptomics. Kobak & Berens (2019). *Nature Communications*. doi:10.1038/s41467-019-13056-x

  > Single-cell transcriptomics yields ever growing data sets containing RNA expression levels for thousands of genes from up to millions of cells. Common data analysis pipelines include a dimensionality reduction step for visualising the data in two dimensions, most frequently performed using t-distributed stochastic neighbour embedding (t-SNE). It excels at revealing local structure in high-dimensional data, but naive applications often suffer from severe shortcomings, e.g. the global structure of the data is not represented accurately. Here we describe how to circumvent such pitfalls, and develop a protocol for creating more faithful t-SNE visualisations. It includes PCA initialisation, a high learning rate, and multi-scale similarity kernels; for very large data sets, we additionally use exaggeration and downsampling-based initialisation. We use published single-cell RNA-seq data sets to demonstrate that this protocol yields superior results compared to the naive application of t-SNE.

D.7.4 From gene lists to biology

- Wijesooriya et al. (2022) — Surveys how enrichment analysis is used in published studies and lists common errors, such as an inappropriate background gene list and missing correction for multiple testing. A practical guide to doing over-representation analysis correctly. *(perspective; CC BY 4.0)*

  Urgent need for consistent standards in functional enrichment analysis. Wijesooriya et al. (2022). *PLOS Computational Biology*. doi:10.1371/journal.pcbi.1009935

  > Gene set enrichment tests (a.k.a. functional enrichment analysis) are among the most frequently used methods in computational biology. Despite this popularity, there are concerns that these methods are being applied incorrectly and the results of some peer-reviewed publications are unreliable. These problems include the use of inappropriate background gene lists, lack of false discovery rate correction and lack of methodological detail. To ascertain the frequency of these issues in the literature, we performed a screen of 186 open-access research articles describing functional enrichment results. We find that 95% of analyses using over-representation tests did not implement an appropriate background gene list or did not describe this in the methods. Failure to perform p-value correction for multiple tests was identified in 43% of analyses. Many studies lacked detail in the methods section about the tools and gene sets used. An extension of this survey showed that these problems are not associated with journal or article level bibliometrics. Using seven independent RNA-seq datasets, we show misuse of enrichment tools alters results substantially. In conclusion, most published functional enrichment studies suffered from one or more major flaws, highlighting the need for stronger standards for enrichment analysis.

- Dam et al. (2017) — Reviews how co-expression networks are built and used to predict gene function and disease genes, including guilt by association, WGCNA-type modules and data requirements. Covers the co-expression part of the section. *(review; CC BY 4.0)*

  Gene co-expression analysis for functional classification and gene–disease predictions. van Dam et al. (2017). *Briefings in Bioinformatics*. doi:10.1093/bib/bbw139

  > Gene co-expression networks can be used to associate genes of unknown function with biological processes, to prioritize candidate disease genes or to discern transcriptional regulatory programmes. With recent advances in transcriptomics and next-generation sequencing, co-expression networks constructed from RNA sequencing data also enable the inference of functions and disease associations for non-coding genes and splice variants. Although gene co-expression networks typically do not provide information about causality, emerging methods for differential co-expression analysis are enabling the identification of regulatory genes underlying various phenotypes. Here, we introduce and guide researchers through a (differential) co-expression analysis. We provide an overview of methods and tools used to create and analyse co-expression networks constructed from gene expression data, and we explain how these can be used to identify genes with a regulatory role in disease. Furthermore, we discuss the integration of other data types with co-expression networks and offer future perspectives of co-expression analysis.

- Gibson et al. (2015) — Introduces cis- and trans-eQTL mapping and how eQTLs are used to interpret disease-associated variants from GWAS. Background for the regulatory-variation paragraph. *(review; CC BY 4.0)*

  Expression quantitative trait locus analysis for translational medicine. Gibson et al. (2015). *Genome Medicine*. doi:10.1186/s13073-015-0186-7

  > Expression quantitative trait locus analysis has emerged as an important component of efforts to understand how genetic polymorphisms influence disease risk and is poised to make contributions to translational medicine. Here we review how expression quantitative trait locus analysis is aiding the identification of which gene(s) within regions of association are causal for a disease or phenotypic trait; the narrowing down of the cell types or regulators involved in the etiology of disease; the characterization of drivers and modifiers of cancer; and our understanding of how different environments and cellular contexts can modify gene expression. We also introduce the concept of transcriptional risk scores as a means of refining estimates of individual liability to disease based on targeted profiling of the transcripts that are regulated by polymorphisms jointly associated with disease and gene expression.

D.7.5 Single-cell genomics

- Haque et al. (2017) — An accessible overview of single-cell RNA-seq: cell isolation, plate- and droplet-based protocols, UMIs, and the main analysis steps. Good for the technologies and properties-of-the-data subsections; the analysis tools have since moved on. *(review; CC BY 4.0)*

  A practical guide to single-cell RNA-sequencing for biomedical research and clinical applications. Haque et al. (2017). *Genome Medicine*. doi:10.1186/s13073-017-0467-4

  > RNA sequencing (RNA-seq) is a genomic approach for the detection and quantitative analysis of messenger RNA molecules in a biological sample and is useful for studying cellular responses. RNA-seq has fueled much discovery and innovation in medicine over recent years. For practical reasons, the technique is usually conducted on samples comprising thousands to millions of cells. However, this has hindered direct assessment of the fundamental unit of biology-the cell. Since the first single-cell RNA-sequencing (scRNA-seq) study was published in 2009, many more have been conducted, mostly by specialist laboratories with unique skills in wet-lab single-cell genomics, bioinformatics, and computation. However, with the increasing commercial availability of scRNA-seq platforms, and the rapid ongoing maturation of bioinformatics approaches, a point has been reached where any biomedical researcher or clinician can use scRNA-seq to make exciting discoveries. In this review, we present a practical guide to help researchers design their first scRNA-seq studies, including introductory information on experimental hardware, protocol choice, quality control, data analysis and biological interpretation.

  An introduction to spatial transcriptomics for biomedical research. Williams et al. (2022). *Genome Medicine*. doi:10.1186/s13073-022-01075-1

  > Single-cell transcriptomics (scRNA-seq) has become essential for biomedical research over the past decade, particularly in developmental biology, cancer, immunology, and neuroscience. Most commercially available scRNA-seq protocols require cells to be recovered intact and viable from tissue. This has precluded many cell types from study and largely destroys the spatial context that could otherwise inform analyses of cell identity and function. An increasing number of commercially available platforms now facilitate spatially resolved, high-dimensional assessment of gene transcription, known as 'spatial transcriptomics'. Here, we introduce different classes of method, which either record the locations of hybridized mRNA molecules in tissue, image the positions of cells themselves prior to assessment, or employ spatial arrays of mRNA probes of pre-determined location. We review sizes of tissue area that can be assessed, their spatial resolution, and the number and types of genes that can be profiled. We discuss if tissue preservation influences choice of platform, and provide guidance on whether specific platforms may be better suited to discovery screens or hypothesis testing. Finally, we introduce bioinformatic methods for analysing spatial transcriptomic data, including pre-processing, integration with existing scRNA-seq data, and inference of cell-cell interactions. Spatial -omics methods are already improving our

understanding of human tissues in research, diagnostic, and therapeutic settings. To build upon these recent advancements, we provide entry-level guidance for those seeking to employ spatial transcriptomics in their own biomedical research.

D.7.6 Single-cell sequencing and cancer evolution

  Cancer evolution: Darwin and beyond. Vendramin et al. (2021). *The EMBO Journal*. doi:10.15252/embj.2021108389

  > Clinical and laboratory studies over recent decades have established branched evolution as a feature of cancer. However, while grounded in somatic selection, several lines of evidence suggest a Darwinian model alone is insufficient to fully explain cancer evolution. First, the role of macroevolutionary events in tumour initiation and progression contradicts Darwin's central thesis of gradualism. Whole-genome doubling, chromosomal chromoplexy and chromothripsis represent examples of single catastrophic events which can drive tumour evolution. Second, neutral evolution can play a role in some tumours, indicating that selection is not always driving evolution. Third, increasing appreciation of the role of the ageing soma has led to recent generalised theories of age-dependent carcinogenesis. Here, we review these concepts and others, which collectively argue for a model of cancer evolution which extends beyond Darwin. We also highlight clinical opportunities which can be grasped through targeting cancer vulnerabilities arising from non-Darwinian patterns of evolution.

  Cancer Evolution: Mathematical Models and Computational Inference. Beerenwinkel et al. (2014). *Systematic Biology*. doi:10.1093/sysbio/syu081

  > Cancer is a somatic evolutionary process characterized by the accumulation of mutations, which contribute to tumor growth, clinical progression, immune escape, and drug resistance development. Evolutionary theory can be used to analyze the dynamics of tumor cell populations and to make inference about the evolutionary history of a tumor from molecular data. We review recent approaches to modeling the evolution of cancer, including population dynamics models of tumor initiation and progression, phylogenetic methods to model the evolutionary relationship between tumor subclones, and probabilistic graphical models to describe dependencies among mutations. Evolutionary modeling helps to understand how tumors arise and will also play an increasingly important prognostic role in predicting disease progression and the outcome of medical interventions, such as targeted therapy.

Abstract

Transcriptomics technologies are the techniques used to study an organism's transcriptome, the sum of all of its RNA transcripts. The information content of an organism is recorded in the DNA of its genome and expressed through transcription. Here, mRNA serves as a transient intermediary molecule in the information network, whilst noncoding RNAs perform additional diverse functions. A transcriptome captures a snapshot in time of the total transcripts present in a cell.

The first attempts to study the whole transcriptome began in the early 1990s, and technological advances since the late 1990s have made transcriptomics a widespread discipline. Transcriptomics has been defined by repeated technological innovations that transform the field. There are two key contemporary techniques in the field: microarrays, which quantify a set of predetermined sequences, and RNA sequencing (RNA-Seq), which uses high-throughput sequencing to capture all sequences.

Measuring the expression of an organism's genes in different tissues, conditions, or time points gives information on how genes are regulated and reveals details of an organism's biology. It can also help to infer the functions of previously unannotated genes. Transcriptomic analysis has enabled the study of how gene expression changes in different organisms and has been instrumental in the understanding of human disease. An analysis of gene expression in its entirety allows detection of broad coordinated trends which cannot be discerned by more targeted assays.

History

Transcriptomics has been characterised by the development of new techniques which have redefined what is possible every decade or so and render previous technologies obsolete (Fig 1). The first attempt at capturing a partial human transcriptome was published in 1991 and

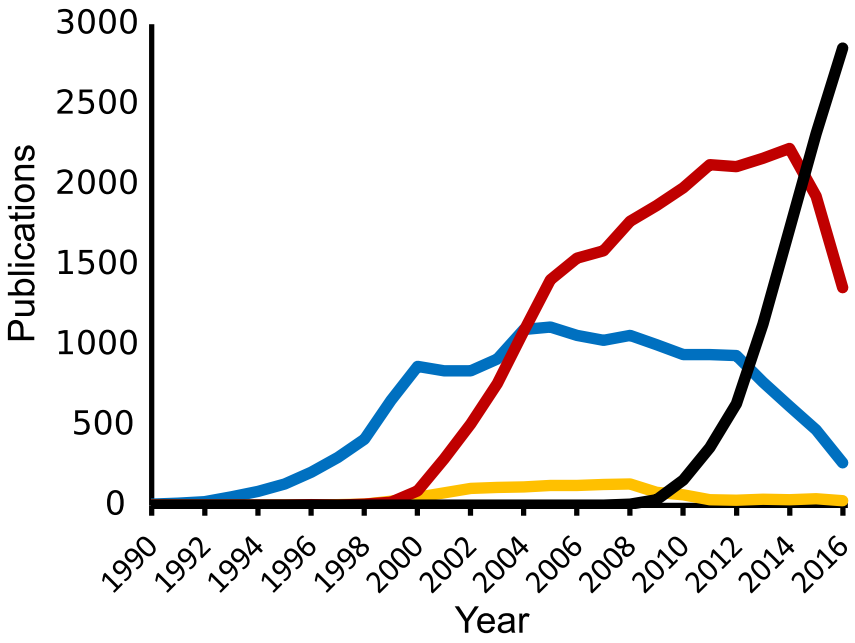

Fig 1. Transcriptomics method use over time. Published papers since 1990, referring to RNA sequencing (black), RNA microarray (red), expressed sequence tag (blue), and serial/cap analysis of gene expression (yellow)[12].

reported 609 mRNA sequences from the human brain [1]. In 2008, two human transcriptomes composed of millions of transcript-derived sequences covering 16,000 genes were published [2][3], and, by 2015, transcriptomes had been published for hundreds of individuals [4][5]. Transcriptomes of different disease states, tissues, or even single cells are now routinely generated [5][6][7]. This explosion in transcriptomics has been driven by the rapid development of new technologies with an improved sensitivity and economy (Table 1) [8][9][10][11].

Table 1. Comparison of contemporary methods [23] [24] [10].

Method	RNA-Seq	Microarray
Throughput	High [10]	Higher [10]
Input RNA amount	Low ~ 1 ng total RNA [25]	High ~ 1 μg mRNA [26]
Labour intensity	High (sample preparation and data analysis) [10][23]	Low [10][23]
Prior knowledge	None required, though genome sequence useful [23]	Reference transcripts required for probes [23]
Quantitation accuracy	~90% (limited by sequence coverage) [27]	>90% (limited by fluorescence detection accuracy) [27]
Sequence resolution	Can detect SNPs and splice variants (limited by sequencing accuracy of ~99%) [27]	Dedicated arrays can detect splice variants (limited by probe design and cross-hybridisation) [27]
Sensitivity	10^{-6} (limited by sequence coverage) [27]	10^{-3} (limited by fluorescence detection) [27]
Dynamic range	$>10^5$ (limited by sequence coverage) [28]	10^3–10^4 (limited by fluorescence saturation) [28]
Technical reproducibility	>99% [29][30]	>99% [31][32]

Before transcriptomics

Studies of individual transcripts were being performed several decades before any transcriptomics approaches were available. Libraries of silkmoth mRNAs were collected and converted to complementary DNA (cDNA) for storage using reverse transcriptase in the late 1970s [13]. In the 1980s, low-throughput Sanger sequencing began to be used to sequence random individual transcripts from these libraries, called expressed sequence tags (ESTs) [2][14][15][16]. The Sanger method of sequencing was predominant until the advent of high-throughput methods such as sequencing by synthesis (Solexa/Illumina, San Diego, CA). ESTs came to prominence during the 1990s as an efficient method to determine the gene content of an organism without sequencing the entire genome [16]. Quantification of individual transcripts by northern blotting, nylon membrane arrays, and later reverse transcriptase quantitative PCR (RT-qPCR) were also popular [17][18], but these methods are laborious and can only capture a tiny subsection of a transcriptome [12]. Consequently, the manner in which a transcriptome as a whole is expressed and regulated remained unknown until higher-throughput techniques were developed.

Early attempts

The word "transcriptome" was first used in the 1990s [19][20]. In 1995, one of the earliest sequencing-based transcriptomic methods was developed, serial analysis of gene expression (SAGE), which worked by Sanger sequencing of concatenated random transcript fragments [21]. Transcripts were quantified by matching the fragments to known genes. A variant of SAGE using high-throughput sequencing techniques, called digital gene expression analysis, was also briefly used [9][22]. However, these methods were largely overtaken by high throughput sequencing of entire transcripts, which provided additional information on transcript structure, e.g., splice variants [9].

Development of contemporary techniques

The dominant contemporary techniques, microarrays and RNA-Seq, were developed in the mid-1990s and 2000s [9][33]. Microarrays that measure the abundances of a defined set of transcripts via their hybridisation to an array of complementary probes were first published in 1995 [34][35]. Microarray technology allowed the assay of thousands of transcripts simultaneously at a greatly reduced cost per gene and labour saving [36]. Both spotted oligonucleotide arrays and Affymetrix (Santa Clara, California) high-density arrays were the method of choice for transcriptional profiling until the late 2000s [12][33]. Over this period, a range of microarrays were produced to cover known genes in model or economically important organisms. Advances in design and manufacture of arrays improved the specificity of probes and allowed for more genes to be tested on a single array. Advances in fluorescence detection increased the sensitivity and measurement accuracy for low abundance transcripts [35][37].

RNA-Seq refers to the sequencing of transcript cDNAs, in which abundance is derived from the number of counts from each transcript. The technique has therefore been heavily influenced by the development of high-throughput sequencing technologies [9][11]. Massively parallel signature sequencing (MPSS) was an early example based on generating 16–20 bp sequences via a complex series of hybridisations [38] and was used in 2004 to validate the expression of 10^4 genes in *Arabidopsis thaliana* [39]. The earliest RNA-Seq work was published in 2006 with 10^5 transcripts sequenced using the 454 technology [40]. This was sufficient coverage to quantify relative transcript abundance. RNA-Seq began to increase in popularity after 2008 when new Solexa/Illumina technologies (San Diego, CA) allowed 10^9 transcript

sequences to be recorded [4][10][41][42]. This yield is now sufficient for accurate quantitation of entire human transcriptomes.

Data gathering

Generating data on RNA transcripts can be achieved via either of two main principles: sequencing of individual transcripts (ESTs, or RNA-Seq), or hybridisation of transcripts to an ordered array of nucleotide probes (i.e., microarrays).

Isolation of RNA

All transcriptomic methods require RNA to first be isolated from the experimental organism before transcripts can be recorded. Although biological systems are incredibly diverse, RNA extraction techniques are broadly similar and involve the following: mechanical disruption of cells or tissues, disruption of RNase with chaotropic salts [43], disruption of macromolecules and nucleotide complexes, separation of RNA from undesired biomolecules including DNA, and concentration of the RNA via precipitation from solution or elution from a solid matrix [43][44]. Isolated RNA may additionally be treated with DNase to digest any traces of DNA [45]. It is necessary to enrich messenger RNA as total RNA extracts are typically 98% ribosomal RNA [46]. Enrichment for transcripts can be performed by poly-A affinity methods or by depletion of ribosomal RNA using sequence-specific probes [47]. Degraded RNA may affect downstream results; for example, mRNA enrichment from degraded samples will result in the depletion of 5′ mRNA ends and uneven signal across the length of a transcript. Snap-freezing of tissue prior to RNA isolation is typical, and care is taken to reduce exposure to RNase enzymes once isolation is complete [44].

EST

An EST is a short nucleotide sequence generated from a single RNA transcript. RNA is first copied as cDNA by a reverse transcriptase enzyme before the resultant cDNA is sequenced [16]. The Sanger method of sequencing was predominant until the advent of high-throughput methods such as sequencing by synthesis (Solexa/Illumina, San Diego, CA). Because ESTs don't require prior knowledge of the organism from which they come, they can also be made from mixtures of organisms or environmental samples [16]. Although higher-throughput methods are now used, EST libraries commonly provided sequence information for early microarray designs; for example, a barley GeneChip was designed from 350,000 previously sequenced ESTs [48].

Serial and Cap analysis of gene expression (SAGE/CAGE)

SAGE was a development of EST methodology to increase the throughput of the tags generated and allow some quantitation of transcript abundance (Fig 2) [21]. cDNA is generated from the RNA but is then digested into 11 bp "tag" fragments using restriction enzymes that cut at a specific sequence, and 11 base pairs along from that sequence. These cDNA tags are then concatenated head-to-tail into long strands (>500 bp) and sequenced using low-throughput, but long read length methods such as Sanger sequencing. Once the sequences are deconvoluted into their original 11 bp tags [21]. If a reference genome is available, these tags can sometimes be aligned to identify their corresponding gene. If a reference genome is unavailable, the tags can simply be directly used as diagnostic markers if found to be differentially expressed in a disease state.

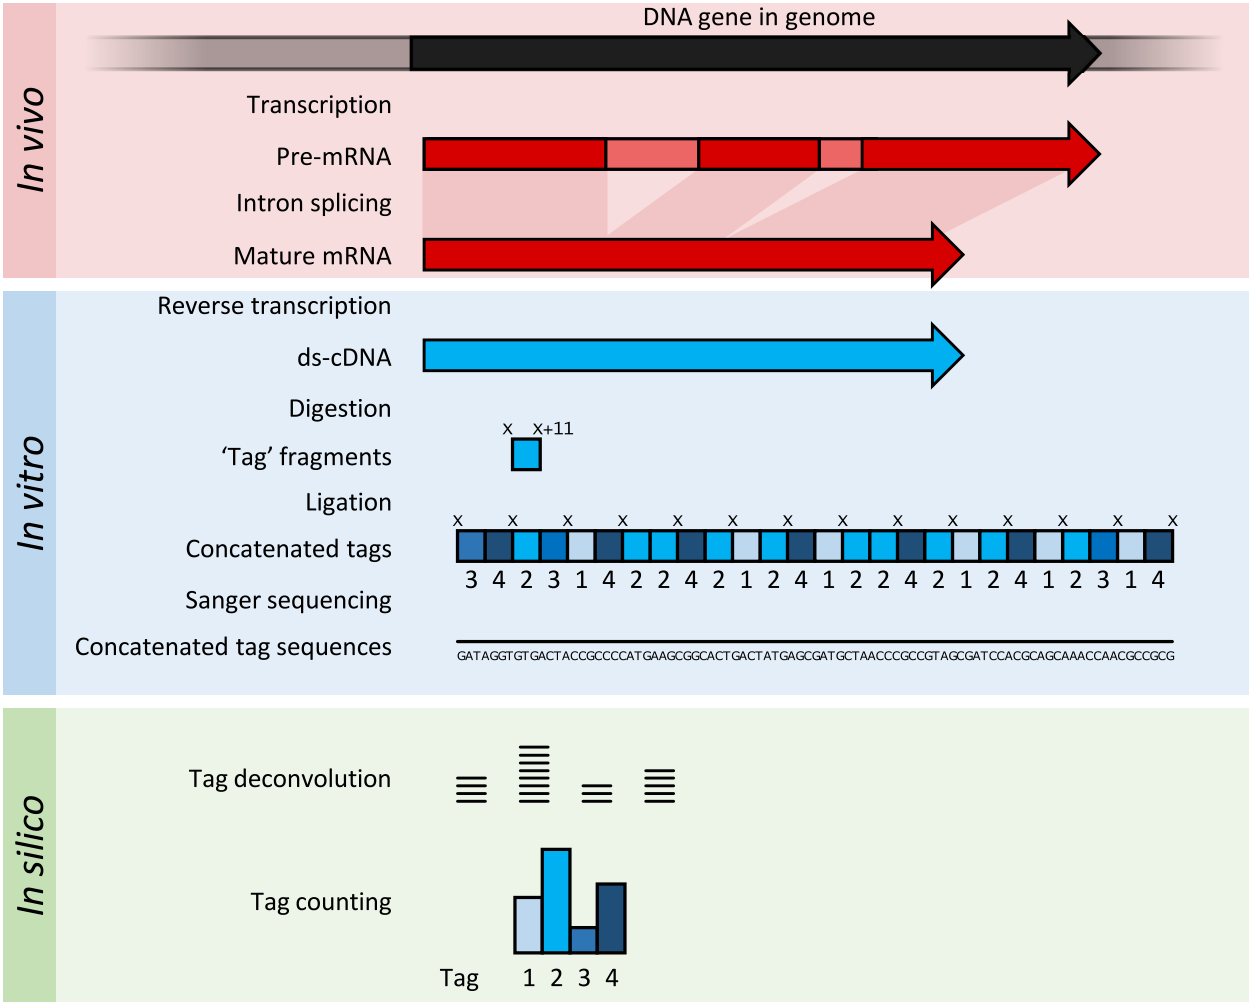

Fig 2. Summary of SAGE. Within the organisms, genes are transcribed and spliced (in eukaryotes) to produce mature mRNA transcripts (red). The mRNA is extracted from the organism, and reverse transcriptase is used to copy the mRNA into stable double-stranded–cDNA (ds-cDNA; blue). In SAGE, the ds-cDNA is digested by restriction enzymes (at location "X" and "X"+11) to produce 11-nucleotide "tag" fragments. These tags are concatenated and sequenced using long-read Sanger sequencing (different shades of blue indicate tags from different genes). The sequences are deconvoluted to find the frequency of each tag. The tag frequency can be used to report on transcription of the gene that the tag came from.

https://doi.org/10.1371/journal.pcbi.1005457.g002

The Cap analysis of gene expression (CAGE) method is a variant of SAGE that sequences tags from the 5′ end of an mRNA transcript only [49]. Therefore, the transcriptional start site of genes can be identified when the tags are aligned to a reference genome. Identifying gene start sites is of use for promoter analysis and for the cloning of full-length cDNAs.

SAGE and CAGE methods produce information on more genes than was possible when sequencing single ESTs, but the sample preparation and data analysis are typically more labour intensive.

Microarrays

Principles and advances. Microarrays consist of short nucleotide oligomers, known as "probes," which are arrayed on a solid substrate (e.g., glass) [50]. Transcript abundance is determined by hybridisation of fluorescently labelled transcripts to these probes (Fig 3) [51].

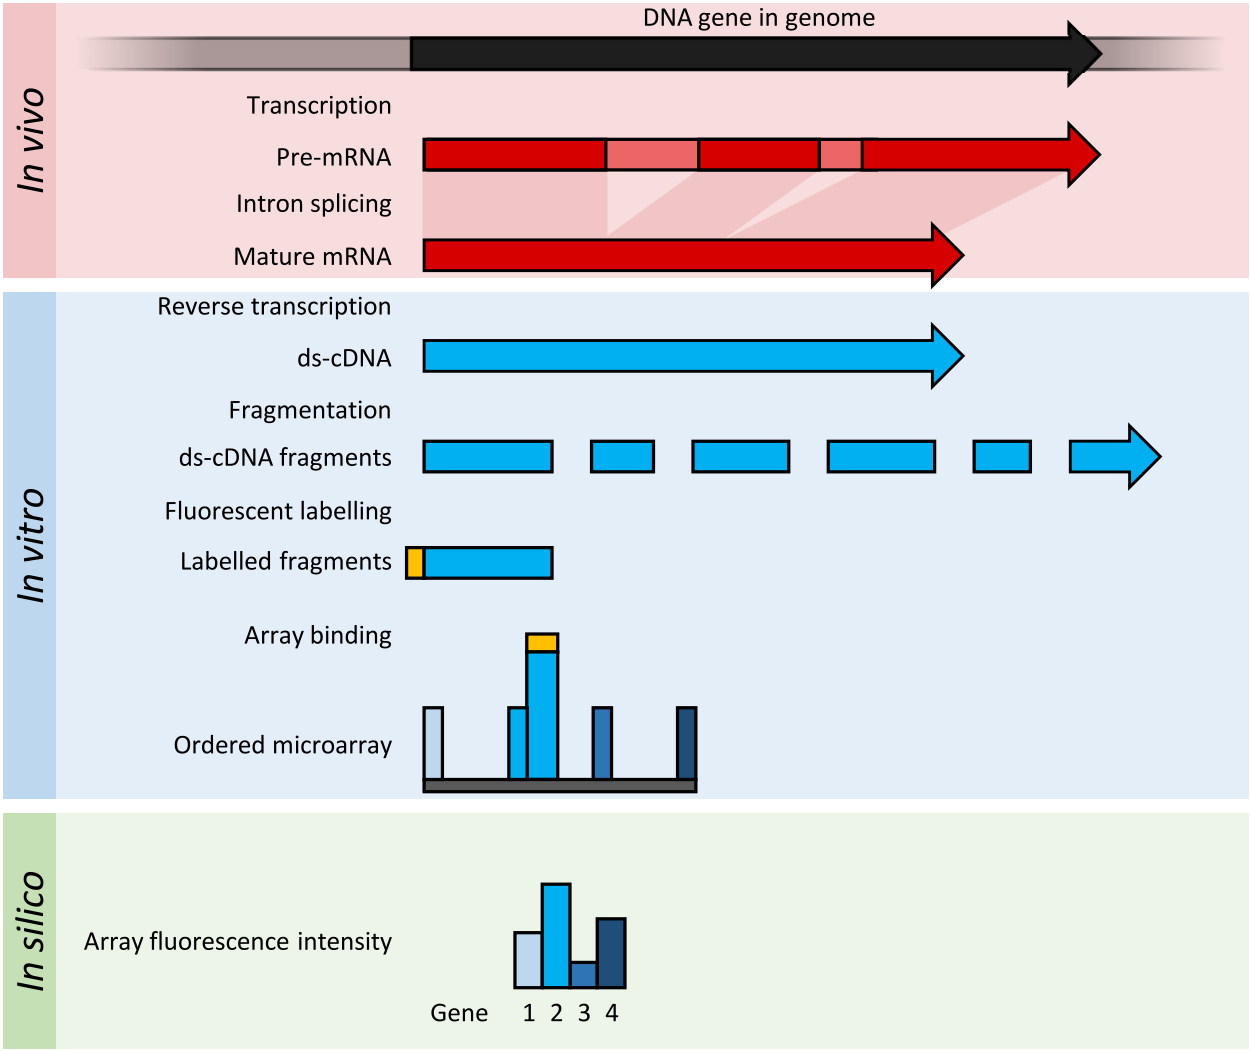

Fig 3. Summary of DNA microarrays. Within the organisms, genes are transcribed and spliced (in eukaryotes) to produce mature mRNA transcripts (red). The mRNA is extracted from the organism and reverse transcriptase is used to copy the mRNA into stable double-stranded–cDNA (ds-cDNA; blue). In microarrays, the ds-cDNA is fragmented and fluorescently labelled (orange). The labelled fragments bind to an ordered array of complementary oligonucleotides, and measurement of fluorescent intensity across the array indicates the abundance of a predetermined set of sequences. These sequences are typically specifically chosen to report on genes of interest within the organism's genome.

https://doi.org/10.1371/journal.pcbi.1005457.g003

The fluorescence intensity at each probe location on the array indicates the transcript abundance for that probe sequence [51]. Microarrays require some prior knowledge of the organism of interest, for example, in the form of an annotated genome sequence or in a library of ESTs that can be used to generate the probes for the array.

Methods. The manufacture of microarrays relies on micro and nanofabrication techniques. Microarrays for transcriptomics typically fall into one of the following two broad categories: low-density spotted arrays or high-density short probe arrays [36]. Transcript presence may be recorded with single- or dual-channel detection of fluorescent tags.

Spotted low-density arrays typically feature picolitre drops of a range of purified cDNAs arrayed on the surface of a glass slide [52]. The probes are longer than those of high-density

arrays and typically lack the transcript resolution of high-density arrays. Spotted arrays use different fluorophores for test and control samples, and the ratio of fluorescence is used to calculate a relative measure of abundance [53]. High-density arrays use single channel detection, and each sample is hybridised and detected individually [54]. High-density arrays were popularised by the Affymetrix GeneChip array (Santa Clara, CA), in which each transcript is quantified by several short 25-mer probes that together assay one gene [55].

NimbleGen arrays (Pleasanton, CA) are high-density arrays produced by a maskless-photochemistry method, which permits flexible manufacture of arrays in small or large numbers. These arrays have hundreds of thousands of 45- to 85-mer probes and are hybridised with a one-colour labelled sample for expression analysis [56]. Some designs incorporate up to 12 independent arrays per slide.

RNA-Seq

Principles and advances. RNA-Seq refers to the combination of a high-throughput sequencing methodology with computational methods to capture and quantify transcripts present in an RNA extract (Fig 4) [10]. The nucleotide sequences generated are typically around 100 bp in length, but can range from 30 bp to over 10,000 bp, depending on the sequencing method used. RNA-Seq leverages deep sampling of the transcriptome with many short fragments from a transcriptome to allow computational reconstruction of the original RNA transcript by aligning reads to a reference genome or to each other (de novo assembly) [9]. The typical dynamic range of 5 orders of magnitude for RNA-Seq is a key advantage over microarray transcriptomes. In addition, input RNA amounts are much lower for RNA-Seq (nanogram quantity) compared to microarrays (microgram quantity), which allowed finer examination of cellular structures, down to the single-cell level when combined with linear amplification of cDNA [25]. Theoretically, there is no upper limit of quantification in RNA-Seq, and background signal is very low for 100 bp reads in nonrepetitive regions [10].

RNA-Seq may be used to identify genes within a genome or identify which genes are active at a particular point in time, and read counts can be used to accurately model the relative gene expression level. RNA-Seq methodology has constantly improved, primarily through the development of DNA sequencing technologies to increase throughput, accuracy, and read length [57]. Since the first descriptions in 2006 and 2008 [40][58], RNA-Seq has been rapidly adopted and overtook microarrays as the dominant transcriptomics technique in 2015 [59].

The quest for transcriptome data at the level of individual cells has driven advances in RNA-Seq library preparation methods, resulting in dramatic advances in sensitivity. Single-cell transcriptomes are now well described and have even been extended to in situ RNA-Seq where transcriptomes of individual cells are directly interrogated in fixed tissues [60].

Methods. RNA-Seq was established in concert with the rapid development of a range of high-throughput DNA sequencing technologies [61]. However, before the extracted RNA transcripts are sequenced, several key processing steps are performed. Methods differ in the use of transcript enrichment, fragmentation, amplification, single or paired-end sequencing, and whether to preserve strand information.

The sensitivity of an RNA-Seq experiment can be increased by enriching classes of RNA that are of interest and depleting known abundant RNAs. The mRNA molecules can be separated by using oligonucleotides probes which bind their poly-A tails. Alternatively, ribo-depletion can be used to specifically remove abundant but uninformative ribosomal RNAs (rRNAs) by hybridisation to probes tailored to the taxon's specific rRNA sequences (e.g., mammal rRNA, plant rRNA). However, ribo-depletion can also introduce some bias via nonspecific

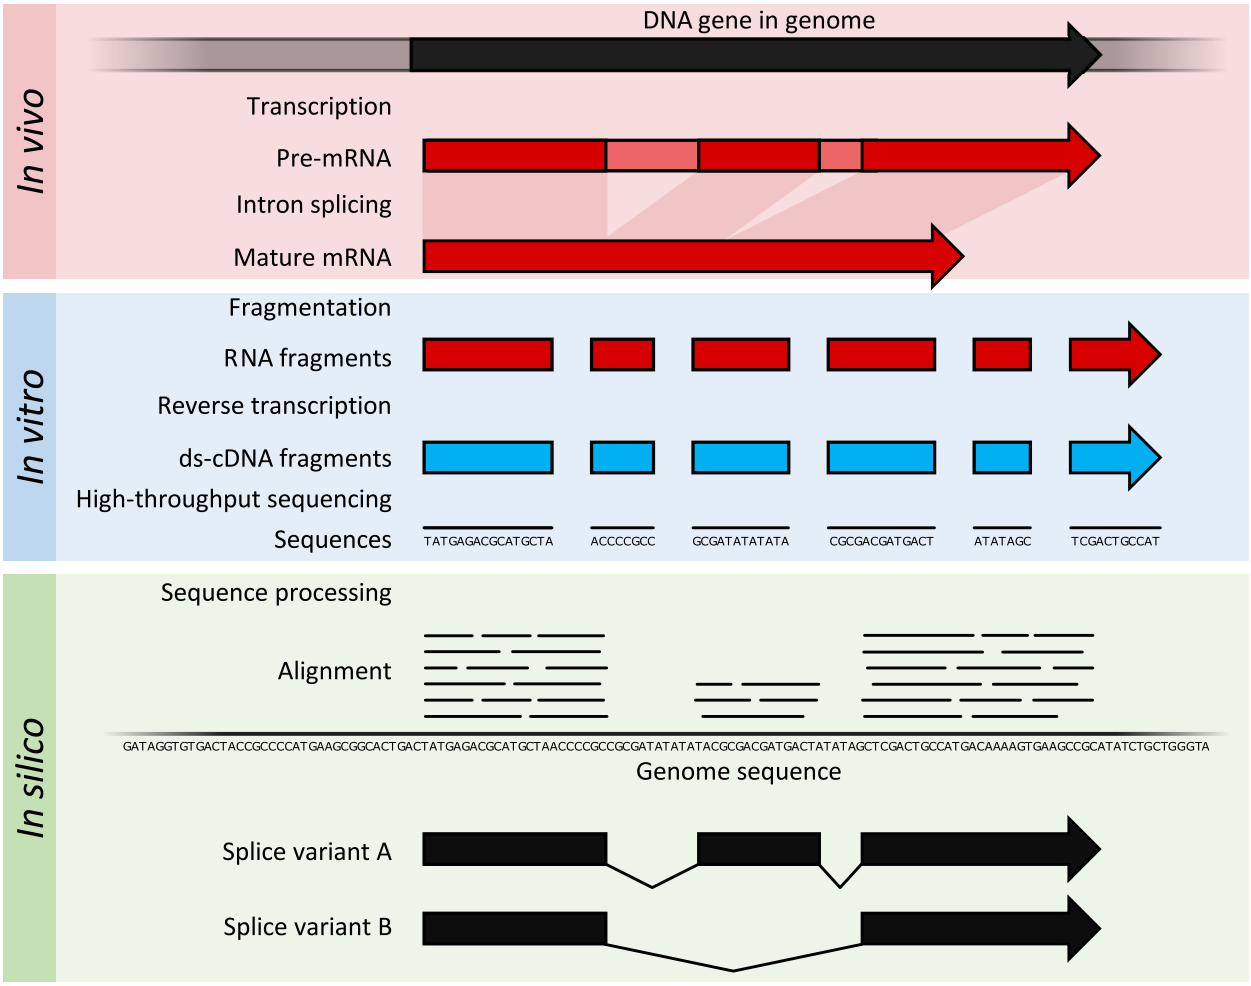

Fig 4. Summary of RNA sequencing. Within the organisms, genes are transcribed and spliced (in eukaryotes) to produce mature mRNA transcripts (red). The mRNA is extracted from the organism, fragmented and copied into stable double-stranded–cDNA (ds-cDNA; blue). The ds-cDNA is sequenced using high-throughput, short-read sequencing methods. These sequences can then be aligned to a reference genome sequence to reconstruct which genome regions were being transcribed. These data can be used to annotate where expressed genes are, their relative expression levels, and any alternative splice variants.

https://doi.org/10.1371/journal.pcbi.1005457.g004

depletion of off-target transcripts [62]. Small RNAs such as microRNAs, can be purified based on their size by gel electrophoresis and extraction.

Because mRNAs are longer than the read-lengths of typical high-throughput sequencing methods, transcripts are usually fragmented prior to sequencing. The fragmentation method is a key aspect of sequencing library construction [63]. It may incorporate chemical hydrolysis, nebulisation, or sonication of RNA, or utilise simultaneous fragmentation, and tagging of cDNA by transposase enzymes.

During preparation for sequencing, cDNA copies of transcripts may be amplified by PCR to enrich for fragments that contain the expected 5′ and 3′ adapter sequences [64]. Amplification is also used to allow sequencing of very low-input amounts of RNA, down to as little as 50 pg in extreme applications [65]. Spike-in controls can be used to provide quality control assessment of library preparation and sequencing, in terms of guanine-cytosine content, fragment length, as well as the bias due to fragment position within a transcript [66]. Unique molecular

identifiers (UMIs) are short random sequences that are used to individually tag sequence fragments during library preparation so that every tagged fragment is unique [67]. UMIs provide an absolute scale for quantification and the opportunity to correct for subsequent amplification bias introduced during library construction and accurately estimate the initial sample size. UMIs are particularly well-suited to single-cell RNA-Seq transcriptomics, in which the amount of input RNA is restricted and extended amplification of the sample is required [68][69][70].

Once the transcript molecules have been prepared, they can be sequenced in just one direction (single-end) or both directions (paired-end). A single-end sequence is usually quicker to produce, cheaper than paired-end sequencing, and sufficient for quantification of gene expression levels. Paired-end sequencing produces more robust alignments and/or assemblies, which is beneficial for gene annotation and transcript isoform discovery [10]. Strand-specific RNA-Seq methods preserve the strand information of a sequenced transcript [71]. Without strand information, reads can be aligned to a gene locus, but do not inform in which direction the gene is transcribed. Stranded-RNA-Seq is useful for deciphering transcription for genes that overlap in different directions, and to make more robust gene predictions in nonmodel organisms [71].

Currently, RNA-Seq relies on copying of RNA molecules into cDNA molecules prior to sequencing; hence, the subsequent platforms are the same for transcriptomic and genomic data (Table 2). Consequently, the development of DNA sequencing technologies has been a defining feature of RNA-Seq [73][75][76]. Direct sequencing of RNA using nanopore sequencing represents a current state-of-the-art RNA-Seq technique in its infancy (in prerelease beta testing as of 2016) [77][78]. However, nanopore sequencing of RNA can detect modified bases that would be otherwise masked when sequencing cDNA and also eliminates amplification steps that can otherwise introduce bias [11][79].

The sensitivity and accuracy of an RNA-Seq experiment are dependent on the number of reads obtained from each sample. A large number of reads are needed to ensure sufficient coverage of the transcriptome, enabling detection of low abundance transcripts. Experimental design is further complicated by sequencing technologies with a limited output range, the variable efficiency of sequence creation, and variable sequence quality. Added to those considerations is that every species has a different number of genes and therefore requires a tailored sequence yield for an effective transcriptome. Early studies determined suitable thresholds empirically, but as the technology matured, suitable coverage is predicted computationally by transcriptome saturation. Somewhat counterintuitively, the most effective way to improve detection of differential expression in low expression genes is to add more biological replicates, rather than adding

Table 2. Sequencing technology platforms commonly used for RNA-Seq [72][73].

Platform (Manufacturer)	Commercial release	Typical read length	Maximum throughput per run	Single read accuracy	RNA-Seq runs deposited in the NCBI SRA (Oct 2016) [74]
454 (Roche, Basel, Switzerland)	2005	700 bp	0.7 Gbp	99.9%	3548

https://doi.org/10.1371/journal.pcbi.1005457.t002

more reads [80]. The current benchmarks recommended by the Encyclopedia of DNA Elements (ENCODE) Project are for 70-fold exome coverage for standard RNA-Seq and up to 500-fold exome coverage to detect rare transcripts and isoforms [81][82][83].

Data analysis

Transcriptomics methods are highly parallel and require significant computation to produce meaningful data for both microarray and RNA-Seq experiments. Microarray data are recorded as high-resolution images, requiring feature detection and spectral analysis. Microarray raw image files are each about 750 MB in size, while the processed intensities are around 60 MB in size. Multiple short probes matching a single transcript can reveal details about the intron-exon structure, requiring statistical models to determine the authenticity of the resulting signal. RNA-Seq studies can produce $>10^9$ of short DNA sequences, which must be aligned to reference genomes comprised of millions to billions of base pairs. De novo assembly of reads within a dataset requires the construction of highly complex sequence graphs. RNA-Seq operations are highly repetitious and benefit from parallelised computation, but modern algorithms mean consumer computing hardware is sufficient for simple transcriptomics experiments that do not require de novo assembly of reads. A human transcriptome could be accurately captured by using RNA-Seq with 30 million 100 bp sequences per sample [84][85]. This example would require approximately 1.8 gigabytes of disk space per sample when stored in a compressed fastq format. Processed count data for each gene would be much smaller, equivalent to processed microarray intensities. Sequence data may be stored in public repositories, such as the Sequence Read Archive (SRA) [86]. RNA-Seq datasets can be uploaded via the Gene Expression Omnibus.

Image processing

Microarray image processing must correctly identify the regular grid of features within an image and independently quantify the fluorescence intensity for each feature (Fig 5). Image

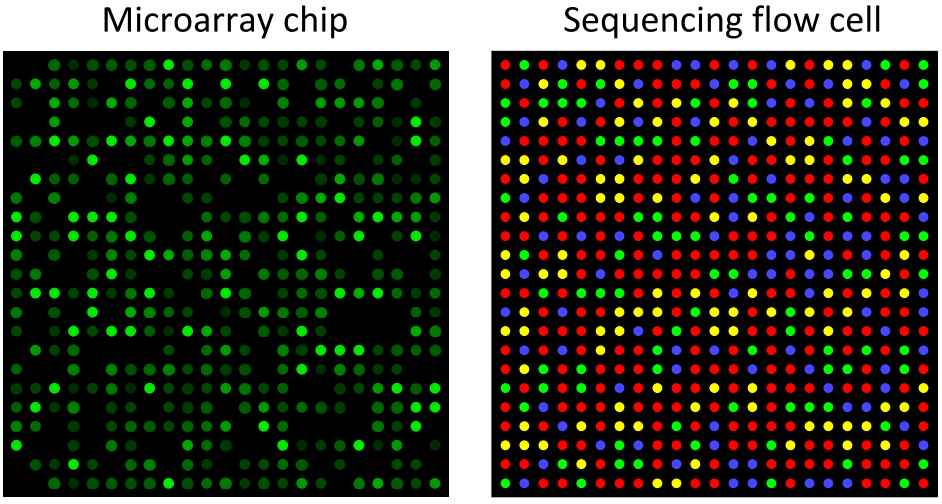

Fig 5. Microarray and sequencing flow cell. Microarrays and RNA sequencing (RNA-Seq) rely on image analysis in different ways. In a microarray chip, each spot on a chip is a defined oligonucleotide probe, and fluorescence intensity directly detects the abundance of a specific sequence (Affymetrix, Santa Clara, CA). In a high-throughput sequencing flow cell, spots are sequenced one nucleotide at a time, with the colour at each round indicating the next nucleotide in the sequence (Illumina Hiseq, San Diego, CA). Other variations of these techniques use more or fewer colour channels.

https://doi.org/10.1371/journal.pcbi.1005457.g005

artefacts must be additionally identified and removed from the overall analysis [87]. Fluorescence intensities directly indicate the abundance of each sequence because the sequence of each probe on the array is already known.

The first steps of RNA-seq also include similar image processing, however conversion of images to sequence data is typically handled automatically by the instrument software. The Illumina sequencing-by-synthesis method results in a random or ordered array of clusters distributed over the surface of a flow cell. The flow cell is imaged up to four times during each sequencing cycle, with tens to hundreds of cycles in total. Flow cell clusters are analogous to microarray spots and must be correctly identified during the early stages of the sequencing process. In Roche's Pyrosequencing method, the intensity of emitted light determines the number of consecutive nucleotides in a homopolymer repeat. There are many variants on these methods, each with a different error profile for the resulting data [88].

RNA-Seq data analysis

RNA-Seq experiments generate a large volume of raw sequence reads, which have to be processed to yield useful information. Data analysis usually requires a combination of bioinformatics software tools that vary according to the experimental design and goals. The process can be broken down into the following four stages: quality control, alignment, quantification, and differential expression [89]. Most popular RNA-Seq programs are run from a command-line interface, either in a Unix environment or within the R/Bioconductor statistical environment [90].

Quality control. Sequence reads are not perfect, so the accuracy of each base in the sequence needs to be estimated for downstream analyses. Raw data are examined for high quality scores for base calls, guanine-cytosine content matches the expected distribution, the over representation of particularly short sequence motifs (k-mers), and an unexpectedly high read duplication rate [85]. Several options exist for sequence quality analysis, including the FastQC and FaQCs software packages [91][92]. Abnormalities identified may be removed by trimming or tagged for special treatment during later processes.

Alignment. In order to link sequence read abundance to expression of a particular gene, transcript sequences are aligned to a reference genome, or de novo aligned to one another if no reference is available. The key challenges for alignment software include sufficient speed to permit $>10^9$ of short sequences to be aligned in a meaningful timeframe, flexibility to recognise and deal with intron splicing of eukaryotic mRNA, and correct assignment of reads that map to multiple locations. Software advances have greatly addressed these issues, and increases in sequencing read length are further reducing multimapping reads. A list of currently available high-throughput sequence aligners is maintained by the EBI [93][94].

Alignment of primary transcript mRNA sequences derived from eukaryotes to a reference genome requires specialised handling of intron sequences, which are absent from mature mRNA. Short read aligners perform an additional round of alignments specifically designed to identify splice junctions, informed by canonical splice site sequences and known intron splice site information. Identification of intron splice junctions prevents reads from being misaligned across splice junctions or erroneously discarded, allowing for more reads to be aligned to the reference genome and improving the accuracy of gene expression estimates. Because gene regulation may occur at the mRNA isoform level, splice-aware alignments also permit detection of isoform abundance changes that would otherwise be lost in a bulked analysis [95].

De novo assembly can be used to align reads to one another to construct full-length transcript sequences without the use of a reference genome (Table 3) [96]. Challenges particular to de novo assembly include larger computational requirements compared to a reference-based

Table 3. RNA-Seq de novo assembly software.

Software (Manufacturer)	Released	Last Updated	Resource load	Strengths and weaknesses
Velvet-Oases [100][101]	2008	2011	Heavy	The original short read assembler, now largely superseded.
SOAPdenovo-trans [102]	2011	2015	Moderate	Early short read assembler, updated for transcript assembly.
Trans-ABySS [103]	2010	2016	Moderate	Short reads, large genomes, MPI-parallel version available.
Trinity [104][105]	2011	2017	Moderate	Short reads, large genomes, memory intensive.
miraEST [106]	1999	2016	Moderate	Repetitive sequences, hybrid data input, wide range of sequence platforms accepted.
Newbler [107]	2004	2012	Heavy	Specialised for Roche 454 sequence, homo-polymer error handling.
CLC genomics workbench (Qiagen—Venlo, Netherlands) [108]	2008	2014	Light	Graphical user interface, hybrid data.

MPI, Message Passing Interface; RNA-Seq, RNA sequencing.

https://doi.org/10.1371/journal.pcbi.1005457.t003

transcriptome, additional validation of gene variants or fragments, additional annotation of assembled transcripts. The first metrics used to describe transcriptome assemblies, such as N50, have been shown to be misleading [97], and subsequently improved evaluation methods are now available [98][99]. Annotation-based metrics are better assessments of assembly completeness, such as contig reciprocal best hit count. Once assembled de novo, the assembly can be used as a reference for subsequent sequence alignment methods and quantitative gene expression analysis.

Quantification. Quantification of sequence alignments may be performed at the gene, exon, or transcript level. Typical outputs include a table of reads counts for each feature supplied to the software, for example, for genes in a general feature format file. Gene and exon read counts may be calculated easily using the HTSeq software package, for example [109]. Quantitation at the transcript level is more complicated and requires probabilistic methods to estimate transcript isoform abundance from short read information, for example, using cufflinks software [95]. Reads that align equally well to multiple locations must be identified and either removed, aligned to one of the possible locations, or aligned to the most probable location.

Some quantification methods can circumvent the need for an exact alignment of a read to a reference sequence all together. The kallisto method combines pseudoalignment and quantification into a single step that runs 2 orders of magnitude faster than comparable methods such as tophat/cufflinks, with less computational burden [110].

Differential expression. Once quantitative counts of each transcript are available, differential gene expression is then measured by normalising, modelling, and statistically analysing the data (Fig 6). Examples of dedicated software are described in Table 4. Most read a table of genes and read counts as their input, but some, such as cuffdiff, will accept binary alignment map format read alignments as input. The final outputs of these analyses are gene lists with associated pair-wise tests for differential expression between treatments and the probability estimates of those differences.

Validation

Transcriptomic analyses may be validated using an independent technique, for example, quantitative PCR (qPCR), which is recognisable and statistically assessable [115]. Gene expression is measured against defined standards both for the gene of interest and control genes. The

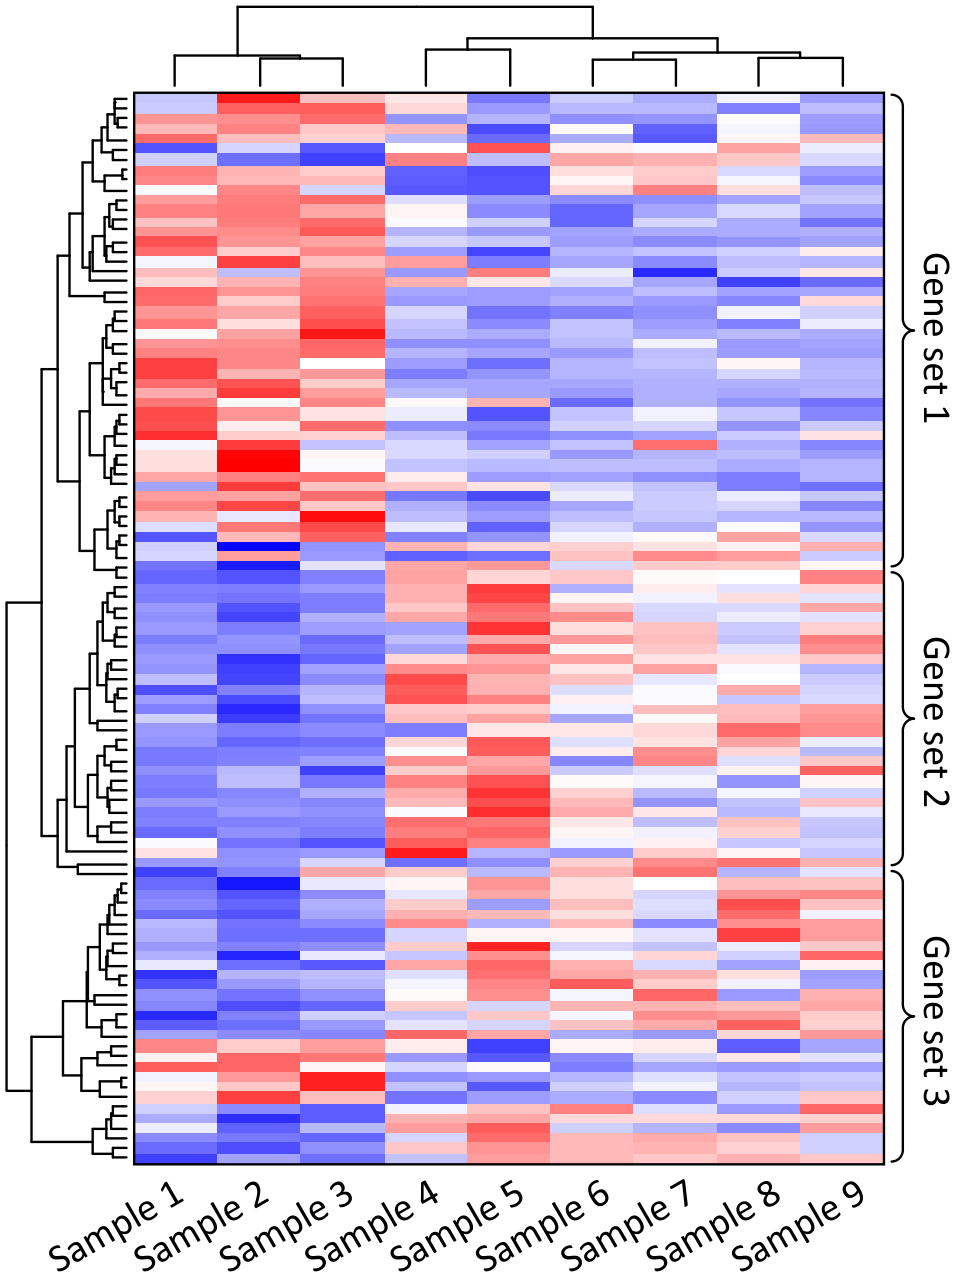

Fig 6. identification of gene co-expression patterns across different samples. Heatmap Each column contains the measurements for gene expression change for a single sample. Relative gene expression is indicated by colour: high-expression (red), median-expression (white) and low-expression (blue). Genes and samples with similar expression profiles can be automatically grouped (left and top trees). Samples may be different individuals, tissues, environments, or health conditions. In this example, expression of gene set 1 is high and expression of gene set 2 is low in samples 1, 2, and 3.

Table 4. RNA-Seq differential gene expression software.

Software	Environment	Specialisation
Cuffdiff2 [111]	Unix-based	Transcript analysis at isoform-level
EdgeR [112]	R/Bioconductor	Any count-based genomic data
DEseq2 [113]	R/Bioconductor	Flexible data types, low replication
Limma/Voom [114]	R/Bioconductor	Microarray or RNA-Seq data, isoform analysis, flexible experiment design

RNA-Seq, RNA sequencing.

https://doi.org/10.1371/journal.pcbi.1005457.t004

measurement by qPCR is similar to that obtained by RNA-Seq wherein a value can be calculated for the concentration of a target region in a given sample. qPCR is, however, restricted to amplicons smaller than 300 bp, usually toward the 3′ end of the coding region, avoiding the 3′ unstralated region (3′UTR) [116]. If validation of transcript isoforms is required, an inspection of RNA-Seq read alignments should indicate where qPCR primers might be placed for maximum discrimination. The measurement of multiple control genes along with the genes of interest produces a stable reference within a biological context [117]. qPCR validation of RNA-Seq data has generally shown that different RNA-Seq methods are highly correlated [58] [118][119].

Functional validation of key genes is an important consideration for post transcriptome planning. Observed gene expression patterns may be functionally linked to a phenotype by an independent knock-down/rescue study in the organism of interest.

Applications

Diagnostics and disease profiling

Transcriptomic strategies have seen broad application across diverse areas of biomedical research, including disease diagnosis and profiling [10]. RNA-Seq approaches have allowed for the large-scale identification of transcriptional start sites and uncovered alternative promoter usage and novel splicing alterations. These regulatory elements are important in human disease, and therefore, defining such variants is crucial to the interpretation of disease-association studies [120]. RNA-Seq can also identify disease-associated single nucleotide polymorphisms (SNP), allele-specific expression, and gene fusions, contributing to our understanding of disease causal variants [121].

Retrotransposons are transposable elements which proliferate within eukaryotic genomes through a process involving reverse transcription. RNA-Seq can provide information about the transcription of endogenous retrotransposons that may influence the transcription of neighbouring genes by various epigenetic mechanisms that lead to disease [122]. Similarly, the potential for using RNA-Seq to understand immune-related disease is expanding rapidly due to the ability to dissect immune cell populations and to sequence T cell and B cell receptor repertoires from patients [123][124].

Human and pathogen transcriptomes

RNA-Seq of human pathogens has become an established method for quantifying gene expression changes, identifying novel virulence factors, predicting antibiotic resistance, and unveiling host-pathogen immune interactions [125][126]. A primary aim of this technology is to develop optimised infection control measures and targeted, individualised treatment [124].

Transcriptomic analysis has predominantly focused on either the host or the pathogen. Dual RNA-Seq has recently been applied to simultaneously profile RNA expression in both the

pathogen and host throughout the infection process. This technique enables the study of the dynamic response and interspecies gene regulatory networks in both interaction partners from initial contact through to invasion and the final persistence of the pathogen or clearance by the host immune system [127][128].

Responses to environment

Transcriptomics allows for the identification of genes and pathways that respond to and counteract biotic and abiotic environmental stresses. The nontargeted nature of transcriptomics allows for the identification of novel transcriptional networks in complex systems. For example, comparative analysis of a range of chickpea lines at different developmental stages identified distinct transcriptional profiles associated with drought and salinity stresses, including identifying the role of transcript isoforms of Apetela 2 and Ethylene-Responsive Element Binding Protein (AP2-EREBP) [129]. Investigation of gene expression during biofilm formation by the fungal pathogen *Candida albicans* revealed a coregulated set of genes critical for biofilm establishment and maintenance [130].

Transcriptomic profiling also provides crucial information on mechanisms of drug resistance. Analysis of over a thousand *Plasmodium falciparum* isolates identified that upregulation of the unfolded protein response and slower progression through the early stages of the asexual intraerythrocytic developmental cycle were associated with artemisinin resistance in isolates from Southeast Asia [131].

Gene function annotation

All transcriptomic techniques have been particularly useful in identifying the functions of genes and identifying those responsible for particular phenotypes. Transcriptomics of *Arabidopsis* ecotypes that hyperaccumulate metals correlated genes involved in metal uptake, tolerance, and homeostasis with the phenotype [132]. Integration of RNA-Seq datasets across different tissues has been used to improve annotation of gene functions in commercially important organisms (e.g., cucumber) [133] or threatened species (e.g., koala) [134].

Assembly of RNA-Seq reads is not dependent on a reference genome [104], and it is so ideal for gene expression studies of nonmodel organisms with nonexisting or poorly developed genomic resources. For example, a database of SNPs used in Douglas fir breeding programs was created by de novo transcriptome analysis in the absence of a sequenced genome [135]. Similarly, genes that function in the development of cardiac, muscle, and nervous tissue in lobster were identified by comparing the transcriptomes of the various tissue types without use of a genome sequence [136]. RNA-Seq can also be used to identify previously unknown protein coding regions in existing sequenced genomes.

Noncoding RNA

Transcriptomics is most commonly applied to the mRNA content of the cell. However, the same techniques are equally applicable to noncoding RNAs that are not translated into a protein, but instead, have direct functions (e.g., roles in protein translation, DNA replication, RNA splicing, and transcriptional regulation) [137][138][139][140]. Many of these noncoding RNAs affect disease states, including cancer, cardiovascular, and neurological diseases [141].

Transcriptome databases

Transcriptomics studies generate large amounts of data that has potential applications far beyond the original aims of an experiment. As such, raw or processed data may be deposited

Table 5. Transcriptomic databases.

Name	Host	Data	Description
Gene Expression Omnibus [142]	NCBI	Microarray RNA-Seq	First transcriptomics database to accept data from any source. Introduced MIAME and MINSEQE community standards that define necessary experiment metadata to ensure effective interpretation and repeatability [143][144].
ArrayExpress [145]	ENA	Microarray	Imports datasets from the Gene Expression Omnibus and accepts direct submissions. Processed data and experiment metadata are stored at ArrayExpress, while the raw sequence reads are held at the ENA. Complies with MIAME and MINSEQE standards [144] [145].
Expression Atlas [146]	EBI	Microarray RNA-Seq	Tissue-specific gene expression database for animals and plants. Displays secondary analyses and visualisation, such as functional enrichment of Gene Ontology terms, InterPro domains, or pathways. Links to protein abundance data where available.
Genevestigator [147]	Privately curated	Microarray RNA-Seq	Contains manual curations of public transcriptome datasets, focusing on medical and plant biology data. Individual experiments are normalised across the full database, to allow comparison of gene expression across diverse experiments. Full functionality requires licence purchase, with free access to a limited functionality.
RefEx [148]	DDBJ	All	Human, mouse, and rat transcriptomes from 40 different organs. Gene expression visualised as heatmaps projected onto 3D representations of anatomical structures.
NONCODE [149]	noncode.org	RNA-Seq	ncRNAs excluding tRNA and rRNA.

DDBJ, DNA Data Bank of Japan; EBI, European Bioinformatics Institute; ENA, European Nucleotide Archive; MIAME, Minimum Information About a Microarray Experiment; MINSEQE, Minimum Information about a high-throughput nucleotide SEQuencing Experiment; NCBI, National Center for Biotechnology Information; ncRNAs, noncoding RNAs; RNA-Seq, RNA sequencing.

into public databases to ensure their utility for the broader scientific community (Table 5). For example, as of 2016, the Gene Expression Omnibus contained millions of experiments.

Conclusions

Transcriptomics has revolutionised our understanding of how genomes are expressed. Over the last three decades, new technologies have redefined what is possible to investigate, and integration with other omics technologies is giving an increasingly integrated view of the complexities of cellular life. The plummeting cost of transcriptomics studies have made them possible for small laboratories, and large-scale transcriptomics consortia are able to undertake experiments comparing transcriptomes of thousands of organisms, tissues, or environmental conditions. This trend is likely to continue as sequencing technologies improve.

Abstract
The ability to easily and efficiently analyse RNA-sequencing data is a key strength of the Bioconductor project. Starting with counts summarised at the gene-level, a typical analysis involves pre-processing, exploratory data analysis, differential expression testing and pathway analysis with the results obtained informing future experiments and validation studies. In this workflow article, we analyse RNA-sequencing data from the mouse mammary gland, demonstrating use of the popular **edgeR** package to import, organise, filter and normalise the data, followed by the **limma** package with its *voom* method, linear modelling and empirical Bayes moderation to assess differential expression and perform gene set testing. This pipeline is further enhanced by the **Glimma** package which enables interactive exploration of the results so that individual samples and genes can be examined by the user. The complete analysis offered by these three packages highlights the ease with which researchers can turn the raw counts from an RNA-sequencing experiment into biological insights using Bioconductor.

REVISED **Amendments from Version 2**

The updated workflow makes use of current versions of software: R version 3.5.1 and Bioconductor project version 3.8. The filtering strategy has been relaxed, using default settings in the filterByExpr function from the edgeR package which retains approximately 2500 more genes than the previous version. Output downstream of filtering has been updated, including adjustment to the vertical dotted line in Figure 1 marking the new log-CPM threshold. In "Transformations from the raw-scale" and "Removing genes that are lowly expressed", text has been added to give more details on log-CPM values that are calculated and gene filtering strategy. Glimma MD plot and heatmap now uses lcpm values to represent expression. The reference for Glimma has been updated, and the id.column argument in the glMDPlot function was renamed to side.main. Placement of some figures have been adjusted so that they appear around its associated text, which previously affected the pdf version of the article. Xueyi Dong and Luyi Tian are added as authors for translation of the article to Chinese which is available in the release version of the RNAseq123 workflow package from Bioconductor, http://bioconductor.org/packages/RNAseq123. Xueyi Dong also updated the workflow to Bioconductor 3.8. These changes have also been outlined in "Software availability" and "Author contributions".

See referee reports

Introduction

RNA-sequencing (RNA-seq) has become the primary technology used for gene expression profiling, with the genome-wide detection of differentially expressed genes between two or more conditions of interest one of the most commonly asked questions by researchers. The **edgeR**[1] and **limma** packages[2] available from the Bioconductor project[3] offer a well-developed suite of statistical methods for dealing with this question for RNA-seq data. In this article, we describe an **edgeR** - **limma** workflow for analysing RNA-seq data that takes gene-level counts as its input, and moves through pre-processing and exploratory data analysis before obtaining lists of differentially expressed (DE) genes and gene signatures. This analysis is enhanced through the use of interactive graphics from the **Glimma** package[4], that allows for a more detailed exploration of the data at both the sample and gene-level than is possible using static `R` plots.

The experiment analysed in this workflow is from Sheridan *et al.* (2015)[5] and consists of three cell populations (basal, luminal progenitor (LP) and mature luminal (ML)) sorted from the mammary glands of female virgin mice, each profiled in triplicate. RNA samples were sequenced across three batches on an Illumina HiSeq 2000 to obtain 100 base-pair single-end reads. The analysis outlined in this article assumes that reads obtained from an RNA-seq experiment have been aligned to an appropriate reference genome and summarised into counts associated with gene-specific regions. In this instance, reads were aligned to the mouse reference genome (mm10) using the `R` based pipeline available in the **Rsubread** package (specifically the `align` function[6] followed by `featureCounts`[7] for gene-level summarisation based on the in-built *mm10* RefSeq-based annotation). Count data for these samples can be downloaded from the Gene Expression Omnibus (GEO) `http://www.ncbi.nlm.nih.gov/geo/` using GEO Series accession number GSE63310. Further information on experimental design and sample preparation is also available from GEO under this accession number.

Data packaging

Reading in count data

To get started with this analysis, download the file `GSE63310_RAW.tar` available online from `http://www.ncbi.nlm.nih.gov/geo/download/?acc=GSE63310&format=file`, and extract the relevant files from this archive. Each of these text files contains the raw gene-level counts for a given sample. Note that our analysis only includes the basal, LP and ML samples from this experiment (see associated file names below).

```
files <- c("GSM1545535_10_6_5_11.txt", "GSM1545536_9_6_5_11.txt",
   "GSM1545538_purep53.txt", "GSM1545539_JMS8-2.txt",
   "GSM1545540_JMS8-3.txt", "GSM1545541_JMS8-4.txt",
   "GSM1545542_JMS8-5.txt", "GSM1545544_JMS9-P7c.txt",
   "GSM1545545_JMS9-P8c.txt")
read.delim(files[1], nrow=5)
```

```
##    EntrezID GeneLength Count
## 1    497097       3634     1
## 2 100503874       3259     0
## 3 100038431       1634     0
```

```
## 4      19888        9747      0
## 5      20671        3130      1
```

Whilst each of the nine text files can be read into R separately and combined into a matrix of counts, **edgeR** offers a convenient way to do this in one step using the readDGE function. The resulting DGEList-object contains a matrix of counts with 27,179 rows associated with unique Entrez gene identifiers (IDs) and nine columns associated with the individual samples in the experiment.

```
library(limma)
library(edgeR)
x <- readDGE(files, columns=c(1,3))
class(x)
```

```
## [1] "DGEList"
## attr(,"package")
## [1] "edgeR"
```

```
dim(x)
```

```
## [1] 27179     9
```

If the counts from all samples were stored in a single file, the data can be read into R and then converted into a DGE-List-object using the DGEList function.

Organising sample information

For downstream analysis, sample-level information related to the experimental design needs to be associated with the columns of the counts matrix. This should include experimental variables, both biological and technical, that could have an effect on expression levels. Examples include cell type (basal, LP and ML in this experiment), genotype (wild-type, knock-out), phenotype (disease status, sex, age), sample treatment (drug, control) and batch information (date experiment was performed if samples were collected and analysed at distinct time points) to name just a few.

Our DGEList-object contains a samples data frame that stores both cell type (or group) and batch (sequencing lane) information, each of which consists of three distinct levels. Note that within x$samples, library sizes are automatically calculated for each sample and normalisation factors are set to 1. For simplicity, we remove the GEO sample IDs (GSM*) from the column names of our DGEList-object x.

```
samplenames <- substring(colnames(x), 12, nchar(colnames(x)))
samplenames

Organising gene annotations

A second data frame named `genes` in the DGEList-object is used to store gene-level information associated with rows of the counts matrix. This information can be retrieved using organism specific packages such as **Mus.musculus**[8] for mouse (or **Homo.sapiens**[9] for human) or the **biomaRt** package[10,11] which interfaces the Ensembl genome databases in order to perform gene annotation. The type of information that can be retrieved includes gene symbols, gene names, chromosome names and locations, Entrez gene IDs, Refseq gene IDs and Ensembl gene IDs to name just a few. **biomaRt** primarily works off Ensembl gene IDs, whereas **Mus.musculus** packages information from various sources and allows users to choose between many different gene IDs as the key. The Entrez gene IDs available in our dataset were annotated using the **Mus.musculus** package to retrieve associated gene symbols and chromosome information.

```
library(Mus.musculus)
geneid <- rownames(x)
genes <- select(Mus.musculus, keys=geneid, columns=c("SYMBOL", "TXCHROM"),
                keytype="ENTREZID")
dim(genes)
```

```
## [1] 27220     3
```

```
head(genes)
```

```
##      ENTREZID   SYMBOL   TXCHROM
## 1      497097     Xkr4      chr1
## 2   100503874  Gm19938      <NA>
## 3   100038431  Gm10568      <NA>
## 4       19888      Rp1      chr1
## 5       20671    Sox17      chr1
## 6       27395   Mrpl15      chr1
```

As with any gene ID, Entrez gene IDs may not map one-to-one to the gene information of interest. It is important to check for duplicated gene IDs and to understand the source of duplication before resolving them. Our gene annotation contains 28 genes that map to multiple chromosomes (e.g. gene Gm1987 is associated with "chr4" and "chr4_JH584294_random" and microRNA Mir5098 is associated with "chr2", "chr5", "chr8", "chr11" and "chr17"). To resolve duplicate gene IDs one could combine all chromosome information from the multi-mapped genes, such that gene Gm1987 would be is assigned to "chr4 and chr4_JH584294_random", or select one of the chromosomes to represent the gene with duplicate annotation. For simplicity we do the latter, keeping only the first occurrence of each gene ID.

```
genes <- genes[!duplicated(genes$ENTREZID),]
```

In this example, the gene order is the same in both the annotation and the data object. If this is not the case due to missing and/or rearranged gene IDs, the `match` function can be used to order genes correctly. The data frame of gene annotations is then added to the data object and neatly packaged in a DGEList-object containing raw count data with associated sample information and gene annotations.

```
x$genes <- genes
x
```

```

Data pre-processing

Transformations from the raw-scale

For differential expression and related analyses, gene expression is rarely considered at the level of raw counts since libraries sequenced at a greater depth will result in higher counts. Rather, it is common practice to transform raw counts onto a scale that accounts for such library size differences. Popular transformations include counts per million (CPM), $\log_2$-counts per million (log-CPM), reads per kilobase of transcript per million (RPKM), and fragments per kilobase of transcript per million (FPKM).

In our analyses, CPM and log-CPM transformations are used regularly although they do not account for gene length differences as RPKM and FPKM values do. Whilst RPKM and FPKM values can just as well be used, CPM and log-CPM values can be calculated using a counts matrix alone and will suffice for the type of comparisons we are interested in. Assuming that there are no differences in isoform usage between conditions, differential expression analyses look at gene expression changes between conditions rather than comparing expression across multiple genes or drawing conclusions on absolute levels of expression. In other words, gene lengths remain constant for comparisons of interest and any observed differences are a result of changes in condition rather than changes in gene length.

Here raw counts are converted to CPM and log-CPM values using the `cpm` function in **edgeR**. RPKM values are just as easily calculated as CPM values using the `rpkm` function in **edgeR** if gene lengths are available.

```
cpm <- cpm(x)
lcpm <- cpm(x, log=TRUE)
```

A CPM value of 1 for a gene equates to having 20 counts in the sample with the lowest sequencing depth (JMS9-P8c, library size ≈20 million) or 76 counts in the sample with the greatest sequencing depth (JMS8-3, library size ≈76 million).

The log-CPM values will be used for exploratory plots. When `log=TRUE`, the `cpm` function adds an offset to the CPM values before converting to the log2-scale. By default, the offset is $2/L$ where 2 is the "prior count" and L is the average library size in millions, so the log-CPM values are related to the CPM values by $\log_2(\text{CPM} + 2/L)$. This calculation ensures that any two read counts with identical CPM values will also have identical log-CPM values. The prior count avoids taking the logarithm of zero, and also reduces spurious variability for genes

with very low counts by shrinking all the inter-sample log-fold-changes towards zero, something that is helpful for exploratory plotting. For this dataset, the average library size is about 45.5 million, so $L \approx 45.5$ and the minimum log-CPM value for each sample becomes $\log_2(2/45.5) = -4.51$. In other words, a count of zero for this data maps to a log-CPM value of −4.51 after adding the prior count or offset:

```
L <- mean(x$samples$lib.size) * 1e-6
M <- median(x$samples$lib.size) * 1e-6
c(L, M)
```

```
## [1] 45.5 51.4

```

Log-CPM values are also used in downstream linear modeling via **limma**'s `voom` function, although `voom` recomputes its own log-CPM values internally with a smaller prior count.

Removing genes that are lowly expressed

All datasets will include a mix of genes that are expressed and those that are not expressed. Whilst it is of interest to examine genes that are expressed in one condition but not in another, some genes are unexpressed throughout all samples. In fact, 19% of genes in this dataset have zero counts across all nine samples.

```
table(rowSums(x$counts==0)==9)
```

```
##
## FALSE  TRUE
## 22026  5153
```

Plotting the distribution log-CPM values shows that a sizeable proportion of genes within each sample are either unexpressed or lowly-expressed with log-CPM values that are small or negative (Figure 1A).

Genes that do not have a worthwhile number of reads in any sample should be filtered out of the downstream analyses. There are several reasons for this. From a biological point of view, genes that not expressed at a biologically meaningful level in any condition are not of interest and are therefore best ignored. From a statistical point of view, removing low count genes allows the mean-variance relationship in the data to be estimated with greater reliability and also reduces the number of statistical tests that need to be carried out in downstream analyses looking at differential expression.

The `filterByExpr` function in the **edgeR** package provides an automatic way to filter genes, while keeping as many genes as possible with worthwhile counts.

```
keep.exprs <- filterByExpr(x, group=group)
x <- x[keep.exprs,, keep.lib.sizes=FALSE]
dim(x)
```

```
## [1] 16624     9
```

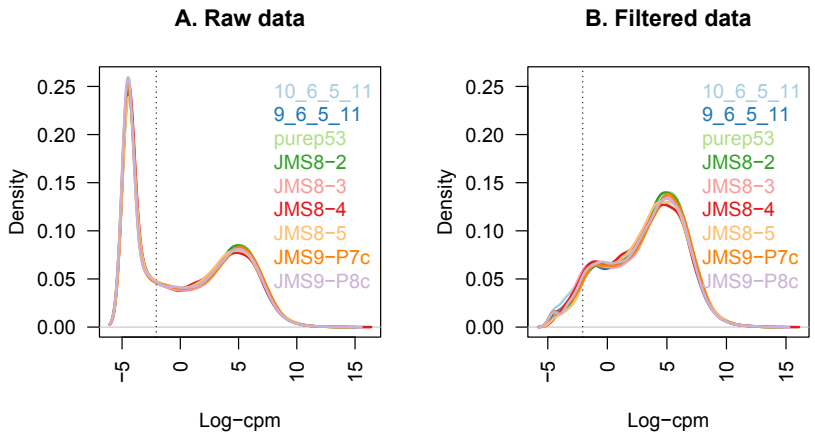

Figure 1. The density of log-CPM values for raw pre-filtered data (**A**) and post-filtered data (**B**) are shown for each sample. Dotted vertical lines mark the log-CPM threshold (equivalent to a CPM value of about 0.2) used in the filtering step.

By default, the function keeps genes with about 10 read counts or more in a minimum number of samples, where the number of samples is chosen according to the minimum group sample size. The actual filtering uses CPM values rather than counts in order to avoid giving preference to samples with large library sizes. For this dataset, the median library size is about 51 million and $10/51 \approx 0.2$, so the `filterByExpr` function keeps genes that have a CPM of 0.2 or more in at least three samples. A biologically interesting gene should be expressed in at least three samples because all the cell type groups have three replicates. The cutoffs used depend on the sequencing depth and on the experimental design. If the library sizes had been larger then a lower CPM cutoff would have been chosen, because larger library sizes provide better resolution to explore more genes at lower expression levels. Alternatively, smaller library sizes decrease our ability to explore marginal genes and hence would have led to a higher CPM cutoff.

Using this criterion, the number of genes is reduced to 16,624, about 60% of the number that we started with. The log-CPM values after filtering show a nearly unimodel distribution for each sample (Figure 1B). Note that subsetting the entire DGEList-object removes both the counts and the associated gene information for the filtered genes. The filtered DGEList-object keeps the gene information and the counts for the retained genes correctly associated.

Code to produce Figure 1 is given below:

```
lcpm.cutoff <- log2(10/M + 2/L)
library(RColorBrewer)
nsamples <- ncol(x)
col <- brewer.pal(nsamples, "Paired")
par(mfrow=c(1,2))
plot(density(lcpm[,1]), col=col[1], lwd=2, ylim=c(0,0.26), las=2, main="", xlab="")
title(main="A. Raw data", xlab="Log-cpm")
abline(v=lcpm.cutoff, lty=3)
for (i in 2:nsamples){
  den <- density(lcpm[,i])
  lines(den$x, den$y, col=col[i], lwd=2)
}
legend("topright", samplenames, text.col=col, bty="n")
lcpm <- cpm(x, log=TRUE)
plot(density(lcpm[,1]), col=col[1], lwd=2, ylim=c(0,0.26), las=2, main="", xlab="")
title(main="B. Filtered data", xlab="Log-cpm")
abline(v=lcpm.cutoff, lty=3)
for (i in 2:nsamples){
  den <- density(lcpm[,i])
  lines(den$x, den$y, col=col[i], lwd=2)
}
legend("topright", samplenames, text.col=col, bty="n")
```

Normalising gene expression distributions

During the sample preparation or sequencing process, external factors that are not of biological interest can affect the expression of individual samples. For example, samples processed in the first batch of an experiment can have higher expression overall when compared to samples processed in a second batch. It is assumed that all samples should have a similar range and distribution of expression values. Normalisation is required to ensure that the expression distributions of each sample are similar across the entire experiment.

Any plot showing the per sample expression distributions, such as a density or boxplot, is useful in determining whether any samples are dissimilar to others. Distributions of log-CPM values are similar throughout all samples within this dataset (Figure 1B).

Nonetheless, normalisation by the method of trimmed mean of M-values (TMM)[12] is performed using the `calcNormFactors` function in **edgeR**. The normalisation factors calculated here are used as a scaling factor for the library sizes. When working with DGEList-objects, these normalisation factors are automatically stored in `x$samples$norm.factors`. For this dataset the effect of TMM-normalisation is mild, as evident in the magnitude of the scaling factors, which are all relatively close to 1.

```
x <- calcNormFactors(x, method = "TMM")
x$samples$norm.factors
```

```
## [1] 0.894 1.025 1.046 1.046 1.016 0.922 0.996 1.086 0.984
```

To give a better visual representation of the effects of normalisation, the data was duplicated then adjusted so that the counts of the first sample are reduced to 5% of their original values, and in the second sample they are inflated to be 5-times larger.

```
x2 <- x
x2$samples$norm.factors <- 1
x2$counts[,1] <- ceiling(x2$counts[,1]*0.05)
x2$counts[,2] <- x2$counts[,2]*5
```

Figure 2 shows the expression distribution of samples for unnormalised and normalised data, where distributions are noticeably different pre-normalisation and are similar post-normalisation. Here the first sample has a small

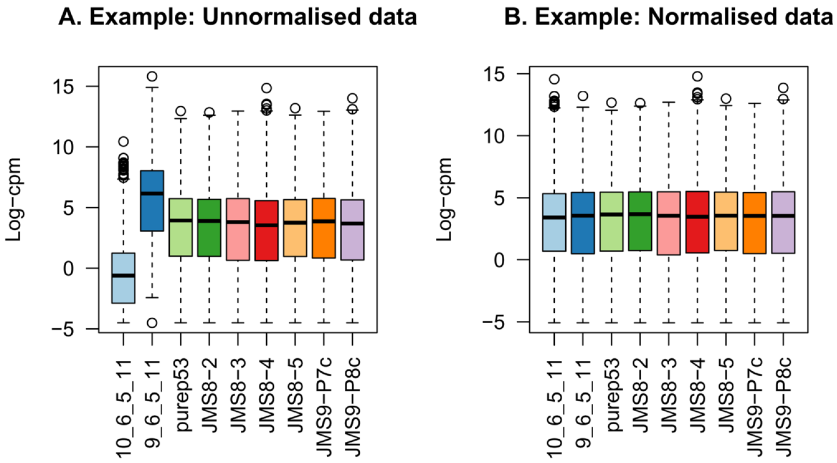

Figure 2. Example data: Boxplots of log-CPM values showing expression distributions for unnormalised data (**A**) and normalised data (**B**) for each sample in the modified dataset where the counts in samples 1 and 2 have been scaled to 5% and 500% of their original values respectively.

TMM scaling factor of 0.06, whereas the second sample has a large scaling factor of 6.08 – neither values are close to 1.

```
par(mfrow=c(1,2))

Unsupervised clustering of samples

In our opinion, one of the most important exploratory plots to examine for gene expression analyses is the multi-dimensional scaling (MDS) plot, or similar. The plot shows similarities and dissimilarities between samples in an unsupervised manner so that one can have an idea of the extent to which differential expression can be detected before carrying out formal tests. Ideally, samples would cluster well within the primary condition of interest, and any sample straying far from its group could be identified and followed up for sources of error or extra variation. If present, technical replicates should lie very close to one another.

Such a plot can be made in **limma** using the `plotMDS` function. The first dimension represents the leading-fold-change that best separates samples and explains the largest proportion of variation in the data, with subsequent dimensions having a smaller effect and being orthogonal to the ones before it. When experimental design involves multiple factors, it is recommended that each factor is examined over several dimensions. If samples cluster by a given factor in any of these dimensions, it suggests that the factor contributes to expression differences and is worth including in the linear modelling. On the other hand, factors that show little or no effect may be left out of downstream analysis.

In this dataset, samples can be seen to cluster well within experimental groups over dimension 1 and 2, and then separate by sequencing lane (sample batch) over dimension 3 (Figure 3). Keeping in mind that the first dimension explains the largest proportion of variation in the data, notice that the range of values over the dimensions become

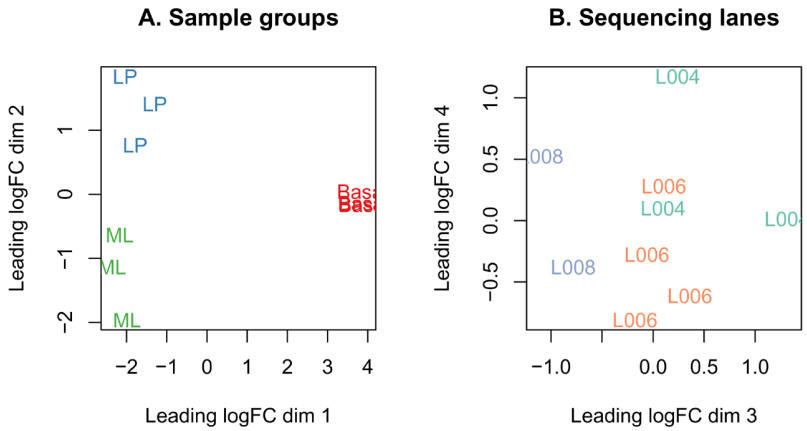

Figure 3. MDS plots of log-CPM values over dimensions 1 and 2 with samples coloured and labeled by sample groups (**A**) and over dimensions 3 and 4 with samples coloured and labeled by sequencing lane (**B**). Distances on the plot correspond to the leading fold-change, which is the average (root-mean-square) $\log_2$-fold-change for the 500 genes most divergent between each pair of samples by default.

smaller as we move to higher dimensions. Whilst all samples cluster by groups, the largest transcriptional difference is observed between basal and LP, and basal and ML over dimension 1. For this reason, it is expected that pairwise comparisons between cell populations will result in a greater number of DE genes for comparisons involving basal samples, and relatively small numbers of DE genes when comparing ML to LP. Datasets where samples do not cluster by experimental group may show little or no evidence of differential expression in the downstream analysis.

To create the MDS plots, we assign different colours to the factors of interest. Dimensions 1 and 2 are examined using the colour grouping defined by cell types.

```
lcpm <- cpm(x, log=TRUE)
par(mfrow=c(1,2))
col.group <- group
levels(col.group) <-  brewer.pal(nlevels(col.group), "Set1")
col.group <- as.character(col.group)
col.lane <- lane
levels(col.lane) <-  brewer.pal(nlevels(col.lane), "Set2")
col.lane <- as.character(col.lane)
plotMDS(lcpm, labels=group, col=col.group)
title(main="A. Sample groups")
```

Dimensions 3 and 4 are examined using the colour grouping defined by sequencing lanes (batch).

```
plotMDS(lcpm, labels=lane, col=col.lane, dim=c(3,4))
title(main="B. Sequencing lanes")
```

Alternatively, the **Glimma** package offers the convenience of an interactive MDS plot where multiple dimensions can be explored. The `glMDSPlot` function generates an html page (that is opened in a browser if `launch=TRUE`) with an MDS plot in the left panel and a barplot showing the proportion of variation explained by each dimension in the right panel. Clicking on the bars of the bar plot changes the pair of dimensions plotted in the MDS plot, and hovering over the individual points reveals the sample label. The colour scheme can be changed as well to highlight cell population or sequencing lane (batch). An interactive MDS plot of this dataset can be found at http://bioinf.wehi.edu.au/folders/limmaWorkflow/glimma-plots/MDS-Plot.html

```
library(Glimma)
glMDSPlot(lcpm, labels=paste(group, lane, sep="_"), groups=x$samples[,c(2,5)],
          launch=FALSE)
```

Differential expression analysis

Creating a design matrix and contrasts

In this study, it is of interest to see which genes are expressed at different levels between the three cell populations profiled. In our analysis, linear models are fitted to the data with the assumption that the underlying data is normally distributed. To get started, a design matrix is set up with both the cell population and sequencing lane (batch) information.

```
design <- model.matrix(~0+group+lane)
colnames(design) <- gsub("group", "", colnames(design))
design
```

```
##   Basal LP ML laneL006 laneL008
## 1     0  1  0        0        0
## 2     0  0  1        0        0
## 3     1  0  0        0        0
## 4     1  0  0        1        0
## 5     0  0  1        1        0
## 6     0  1  0        1        0
## 7     1  0  0        1        0
## 8     0  0  1        0        1
## 9     0  1  0        0        1
```

```
## attr(,"assign")
## [1] 1 1 1 2 2
## attr(,"contrasts")
## attr(,"contrasts")$group
## [1] "contr.treatment"
##
## attr(,"contrasts")$lane
## [1] "contr.treatment"
```

For a given experiment, there are usually several equivalent ways to set up an appropriate design matrix. For example, `~0+group+lane` removes the intercept from the first factor, `group`, but an intercept remains in the second factor `lane`. Alternatively, `~group+lane` could be used to keep the intercepts in both `group` and `lane`. Understanding how to interpret the coefficients estimated in a given model is key here. We choose the first model for our analysis, as setting up model contrasts is more straight forward in the absence of an intercept for `group`. Contrasts for pairwise comparisons between cell populations are set up in **limma** using the `makeContrasts` function.

```
contr.matrix <- makeContrasts(
   BasalvsLP = Basal-LP,
   BasalvsML = Basal - ML,
   LPvsML = LP - ML,
   levels = colnames(design))
contr.matrix
```

```
##           Contrasts
## Levels     BasalvsLP BasalvsML LPvsML
##   Basal            1         1      0
##   LP              -1         0      1
##   ML               0        -1     -1
##   laneL006         0         0      0
##   laneL008         0         0      0
```

A key strength of **limma**'s linear modelling approach is the ability accommodate arbitrary experimental complexity. Simple designs, such as the one in this workflow, with cell type and batch, through to more complicated factorial designs and models with interaction terms can be handled relatively easily. Where experimental or technical effects can be modelled using a random effect, another possibility in **limma** is to estimate correlations using `duplicateCorrelation` by specifying a `block` argument for both this function and in the `lmFit` linear modelling step.

Removing heteroscedascity from count data

It has been shown that for RNA-seq count data, the variance is not independent of the mean[13] – this is true of raw counts or when transformed to log-CPM values. Methods that model counts using a Negative Binomial distribution assume a quadratic mean-variance relationship. In **limma**, linear modelling is carried out on the log-CPM values which are assumed to be normally distributed and the mean-variance relationship is accommodated using precision weights calculated by the `voom` function.

When operating on a DGEList-object, `voom` converts raw counts to log-CPM values by automatically extracting library sizes and normalisation factors from `x` itself. Additional normalisation to log-CPM values can be specified within `voom` using the `normalize.method` argument.

The mean-variance relationship of log-CPM values for this dataset is shown in Figure 4A. Typically, the "voom-plot" shows a decreasing trend between the means and variances resulting from a combination of technical variation in the sequencing experiment and biological variation amongst the replicate samples from different cell populations. Experiments with high biological variation usually result in flatter trends, where variance values plateau at high expression values. Experiments with low biological variation tend to result in sharp decreasing trends.

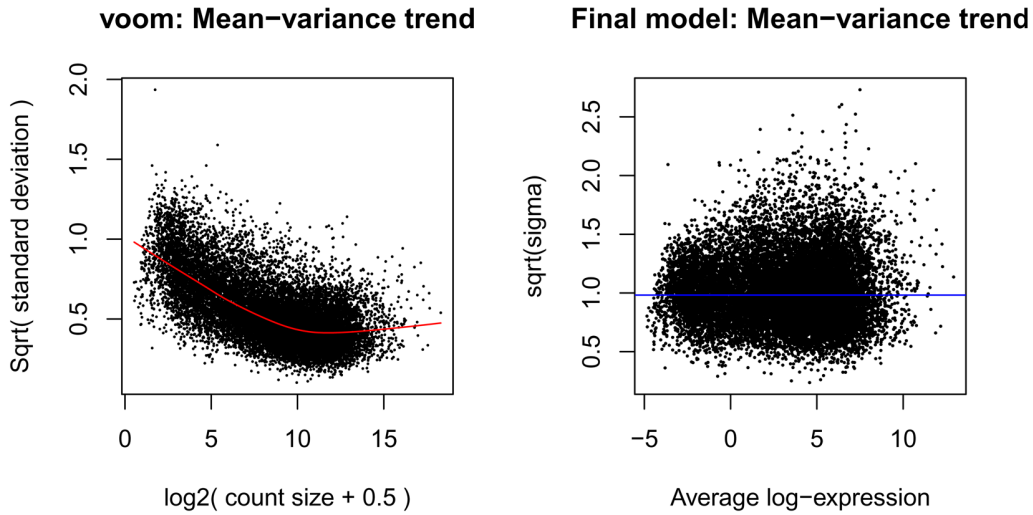

Figure 4. Means (x-axis) and variances (y-axis) of each gene are plotted to show the dependence between the two before `voom` is applied to the data (**A**) and how the trend is removed after `voom` precision weights are applied to the data (**B**). The plot on the left is created within the `voom` function which extracts residual variances from fitting linear models to log-CPM transformed data. Variances are then rescaled to quarter-root variances (or square-root of standard deviations) and plotted against the mean expression of each gene. The means are $\log_2$-transformed mean-counts with an offset of 2. The plot on the right is created using `plotSA` which plots $\log_2$ residual standard deviations against mean log-CPM values. The average $\log_2$ residual standard deviation is marked by a horizontal blue line. In both plots, each black dot represents a gene and a red curve is fitted to these points.

Moreover, the voom-plot provides a visual check on the level of filtering performed upstream. If filtering of lowly-expressed genes is insufficient, a drop in variance levels can be observed at the low end of the expression scale due to very small counts. If this is observed, one should return to the earlier filtering step and increase the expression threshold applied to the dataset.

Where sample-level variation is evident from earlier inspections of the MDS plot, the `voomWithQualityWeights` function can be used to simultaneously incorporate sample-level weights together with the abundance dependent weights estimated by `voom`[14]. For an example of this approach, see Liu *et al.* (2016)[15].

```
v <- voom(x, design, plot=TRUE)
v
```

Note that the other data frames stored within the DGEList-object that contain gene- and sample-level information, are retained in the EList-object `v` created by `voom`. The `v$genes` data frame is equivalent to `x$genes`, `v$targets` is equivalent to `x$samples`, and the expression values stored in `v$E` is analogous to `x$counts`, albeit on a transformed scale. In addition to this, the `voom` EList-object has a matrix of precision weights `v$weights` and stores the design matrix in `v$design`.

Fitting linear models for comparisons of interest

Linear modelling in **limma** is carried out using the `lmFit` and `contrasts.fit` functions originally written for application to microarrays. The functions can be used for both microarray and RNA-seq data and fit a separate model to the expression values for each gene. Next, empirical Bayes moderation is carried out by borrowing information across all genes to obtain more precise estimates of gene-wise variability[16]. The model's residual variances are plotted against average expression values in Figure 4B. It can be seen from this plot that the variance is no longer dependent on the mean expression level.

```
vfit <- lmFit(v, design)
vfit <- contrasts.fit(vfit, contrasts=contr.matrix)
efit <- eBayes(vfit)
plotSA(efit)
```

Examining the number of DE genes

For a quick look at differential expression levels, the number of significantly up- and down-regulated genes can be summarised in a table. Significance is defined using an adjusted *p*-value cutoff that is set at 5% by default. For the comparison between expression levels in basal and LP, 4,648 genes are found to be down-regulated in basal relative to LP and 4,863 genes are up-regulated in basal relative to LP – a total of 9,511 DE genes. A total of 9,598 DE genes are found between basal and ML (4,927 down- and 4,671 up-regulated genes), and a total of 5,652 DE genes are found between LP and ML (3,135 down- and 2,517 up-regulated). The larger numbers of DE genes observed for comparisons involving the basal population are consistent with our observations from the MDS plots.

```
summary(decideTests(efit))
```

```
##        BasalvsLP BasalvsML LPvsML
## Down        4648      4927   3135

## Up          4863      4671   2517
```

Some studies require more than an adjusted *p*-value cutoff. For a stricter definition on significance, one may require log-fold-changes (log-FCs) to be above a minimum value. The *treat* method[17] can be used to calculate *p*-values from empirical Bayes moderated *t*-statistics with a minimum log-FC requirement. The number of differentially expressed genes are reduced to a total of 3,648 DE genes for basal versus LP, 3,834 DE genes for basal versus ML, and 414 DE genes for LP versus ML when testing requires genes to have a log-FC that is significantly greater than 1 (equivalent to a 2-fold difference between cell types on the original scale).

```
tfit <- treat(vfit, lfc=1)
dt <- decideTests(tfit)
summary(dt)
```

```

Genes that are DE in multiple comparisons can be extracted using the results from `decideTests`, where 0s represent genes that are not DE, 1s represent genes that are up-regulated, and -1s represent genes that are down-regulated. A total of 2,784 genes are DE in both basal versus LP and basal versus ML (Figure 5), twenty of which are listed below. The `write.fit` function can be used to extract and write results for all three comparisons to a single output file.

```

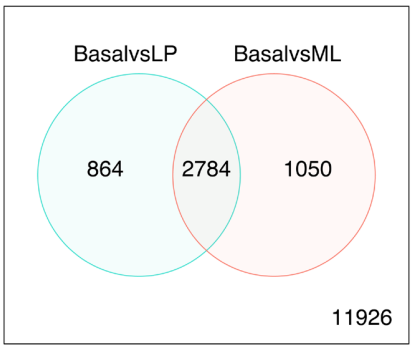

Figure 5. Venn diagram showing the number of genes DE in the comparison between basal versus LP only (left), basal versus ML only (right), and the number of genes that are DE in both comparisons (center). The number of genes that are not DE in either comparison are marked in the bottom-right.

Examining individual DE genes from top to bottom

The top DE genes can be listed using `topTreat` for results using `treat` (or `topTable` for results using `eBayes`). By default `topTreat` arranges genes from smallest to largest adjusted *p*-value with associated gene information, log-FC, average log-CPM, moderated *t*-statistic, raw and adjusted *p*-value for each gene. The number of top genes displayed can be specified, where `n=Inf` includes all genes. Genes *Cldn7* and *Rasef* are amongst the top DE genes for both basal versus LP and basal versus ML.

```
basal.vs.lp <- topTreat(tfit, coef=1, n=Inf)
basal.vs.ml <- topTreat(tfit, coef=2, n=Inf)
head(basal.vs.lp)
```

Useful graphical representations of differential expression results

To summarise results for all genes visually, mean-difference plots, which display log-FCs from the linear model fit against the average log-CPM values can be generated using the `plotMD` function, with the differentially expressed genes highlighted.

```
plotMD(tfit, column=1, status=dt[,1], main=colnames(tfit)[1], xlim=c(-8,13))
```

Glimma extends this functionality by providing an interactive mean-difference plot via the `glMDPlot` function. The output of this function is an html page, with summarised results in the left panel (similar to what is output by `plotMD`), and the log-CPM values from individual samples for a selected gene in the right panel, with a table of results below the plots (Figure 6). This interactive display allows the user to search for particular genes based on the annotation provided (e.g. Gene symbol identifier), which is not possible in a static `R` plot.

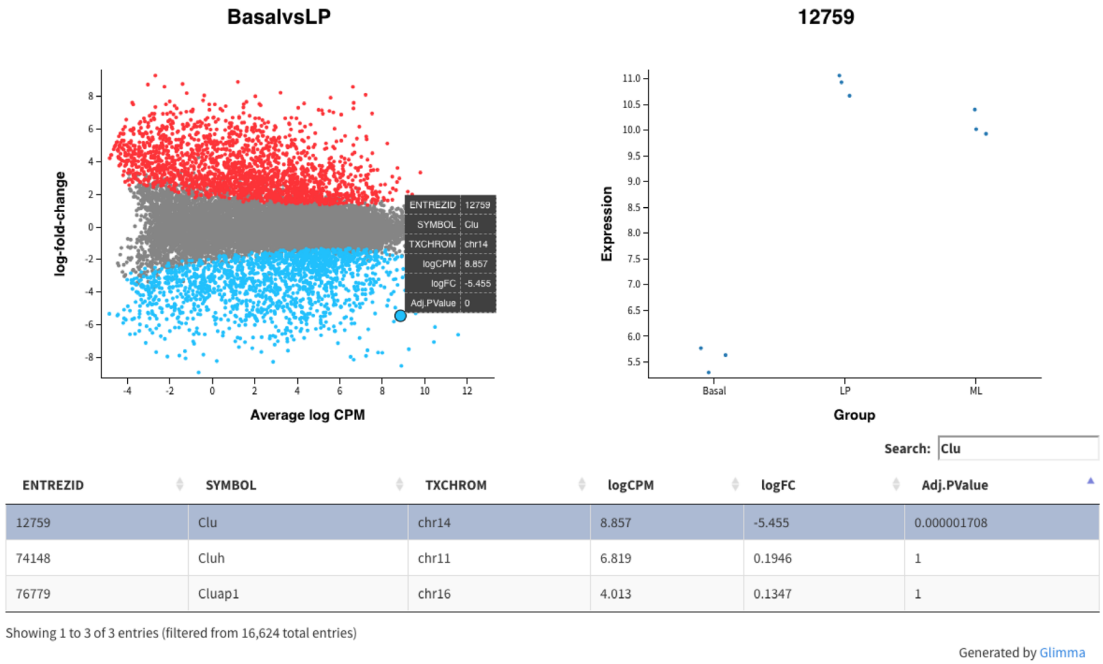

Figure 6. Interactive mean-difference plot generated using Glimma. Summary data (log-FCs versus log-CPM values) are shown in the left panel which is linked to the individual values per sample for a selected gene in the right panel. A table of results is also displayed below these figures, along with a search bar to allow users to look up a particular gene using the annotation information available, e.g. the Gene symbol identifier *Clu*.

```
glMDPlot(tfit, coef=1, status=dt, main=colnames(tfit)[1],
         side.main="ENTREZID", counts=lcpm, groups=group, launch=FALSE)
```

The mean-difference plot generated by the command above is available online (see http://bioinf.wehi.edu.au/folders/limmaWorkflow/glimma-plots/MD-Plot.html). The interactivity provided by the **Glimma** package allows additional information to be presented in a single graphical window. **Glimma** is implemented in `R` and Javascript, with the `R` code generating the data which is converted into graphics using the Javascript library D3 (`https://d3js.org`), with the Bootstrap library handling layouts and Datatables generating the interactive searchable tables. This allows plots to be viewed in any modern browser, which is convenient for including them as linked files from an Rmarkdown report of the analysis.

Plots shown previously include either all of the genes that are expressed in any one condition (such as the Venn diagram of common DE genes or mean-difference plot) or look at genes individually (log-CPM values shown in right panel of the interactive mean-difference plot). Heatmaps allow users to look at the expression of a subset of genes. This can give useful insight into the expression of individual groups and samples without losing perspective of the overall study when focusing on individual genes, or losing resolution when examining patterns averaged over thousands of genes at the same time.

A heatmap is created for the top 100 DE genes (as ranked by adjusted *p*-value) from the basal versus LP contrast using the `heatmap.2` function from the **gplots** package (Figure 7). The heatmap correctly clusters samples by cell type and reorders the genes into blocks with similar expression patterns. From the heatmap, we observe that the expression of ML and LP samples are very similar for the top 100 DE genes between basal and LP.

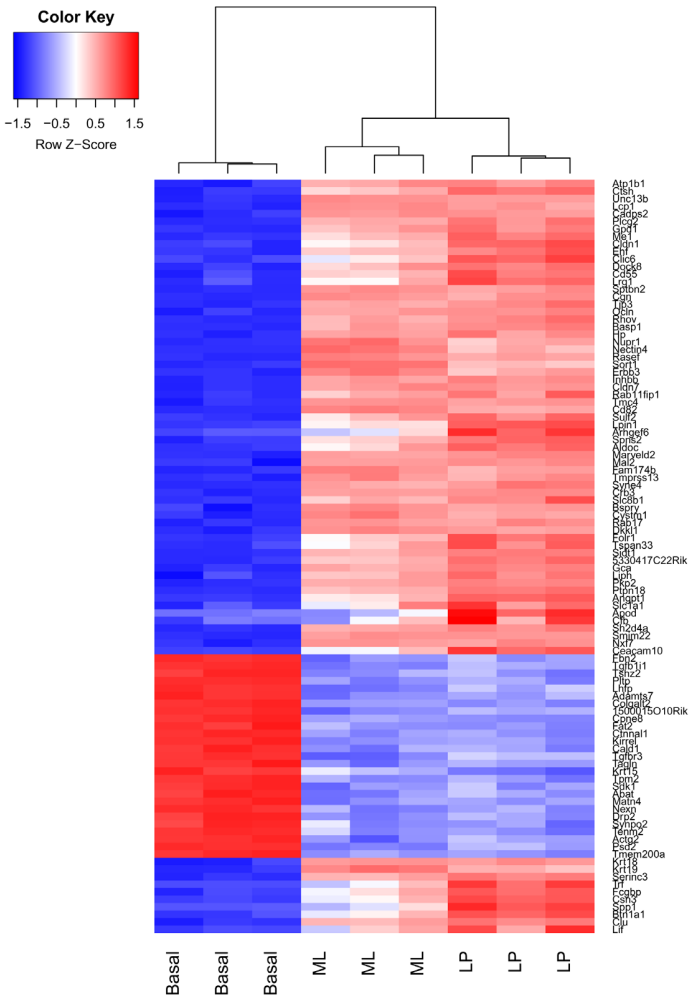

Figure 7. Heatmap of log-CPM values for top 100 genes DE in basal versus LP. Expression across each gene (or row) have been scaled so that mean expression is zero and standard deviation is one. Samples with relatively high expression of a given gene are marked in red and samples with relatively low expression are marked in blue. Lighter shades and white represent genes with intermediate expression levels. Samples and genes have been reordered by the method of hierarchical clustering. A dendrogram is shown for the sample clustering.

```
library(gplots)
basal.vs.lp.topgenes <- basal.vs.lp$ENTREZID[1:100]
i <- which(v$genes$ENTREZID %in% basal.vs.lp.topgenes)
mycol <- colorpanel(1000,"blue","white","red")

heatmap.2(lcpm[i,], scale="row",
   labRow=v$genes$SYMBOL[i], labCol=group,
   col=mycol, trace="none", density.info="none",
   margin=c(8,6), lhei=c(2,10), dendrogram="column")
```

Gene set testing with camera

We finish off this analysis with some gene set testing by applying the *camera* method[18] to the *c2* gene signatures from the Broad Institute's MSigDB c2 collection[19] that have been adapted for mouse and are available as Rdata objects from http://bioinf.wehi.edu.au/software/MSigDB/. Other useful gene sets derived from MSigDB for both human and mouse, such as the hallmark gene sets, are also available from this site. C2 gene sets have been curated

from online databases, publications and domain experts, and hallmark gene sets are selected from MSigDB to have well-defined biological states or processes.

```
load(url("http://bioinf.wehi.edu.au/software/MSigDB/mouse_c2_v5p1.rdata"))
idx <- ids2indices(Mm.c2,id=rownames(v))
cam.BasalvsLP <- camera(v,idx,design,contrast=contr.matrix[,1])
head(cam.BasalvsLP,5)
```

```

```

The `camera` function performs a competitive test to assess whether the genes in a given set are highly ranked in terms of differential expression relative to genes that are not in the set. It uses **limma**'s linear model framework, taking both the design matrix and contrast matrix (if present) and accommodates the observational-level weights from *voom* in the testing procedure. After adjusting the variance of the resulting gene set test statistic by a variance inflation factor that depends on the gene-wise correlation (which is set to 0.01 by default, but can be estimated from the data) and the size of the set, a *p*-value is returned and adjusted for multiple testing.

This experiment is the RNA-seq equivalent of the dataset generated by Lim *et al.* (2010)[20], who used Illumina microarrays to profile the same sorted cell populations, so it is reassuring to see the gene signatures from this earlier publication coming up at the top of the list for each contrast. We make a barcodeplot of the Lim *et al.* (2010) Mature Luminal gene sets (Up and Down) in the LP versus ML contrast. Note that these sets go in the opposite direction in our dataset due to our parameterization which compares LP against ML rather than the other way around (if the contrast were reversed, the directions would be consistent).

```
barcodeplot(efit$t[,3], index=idx$LIM_MAMMARY_LUMINAL_MATURE_UP,
            index2=idx$LIM_MAMMARY_LUMINAL_MATURE_DN, main="LPvsML")
```

Other gene set tests are available in **limma**, such as the self-contained tests by *mroast*[21]. Whilst *camera* is ideal for testing a large database of gene sets and observing which of them rank highly relative to others (as shown above), self-contained tests are better for focused testing of one or a few specifically chosen sets to see if they are DE in their own right. In other words, *camera* is more appropriate when "fishing" for gene sets of interest, whereas *mroast* tests sets that are already of interest for significance.

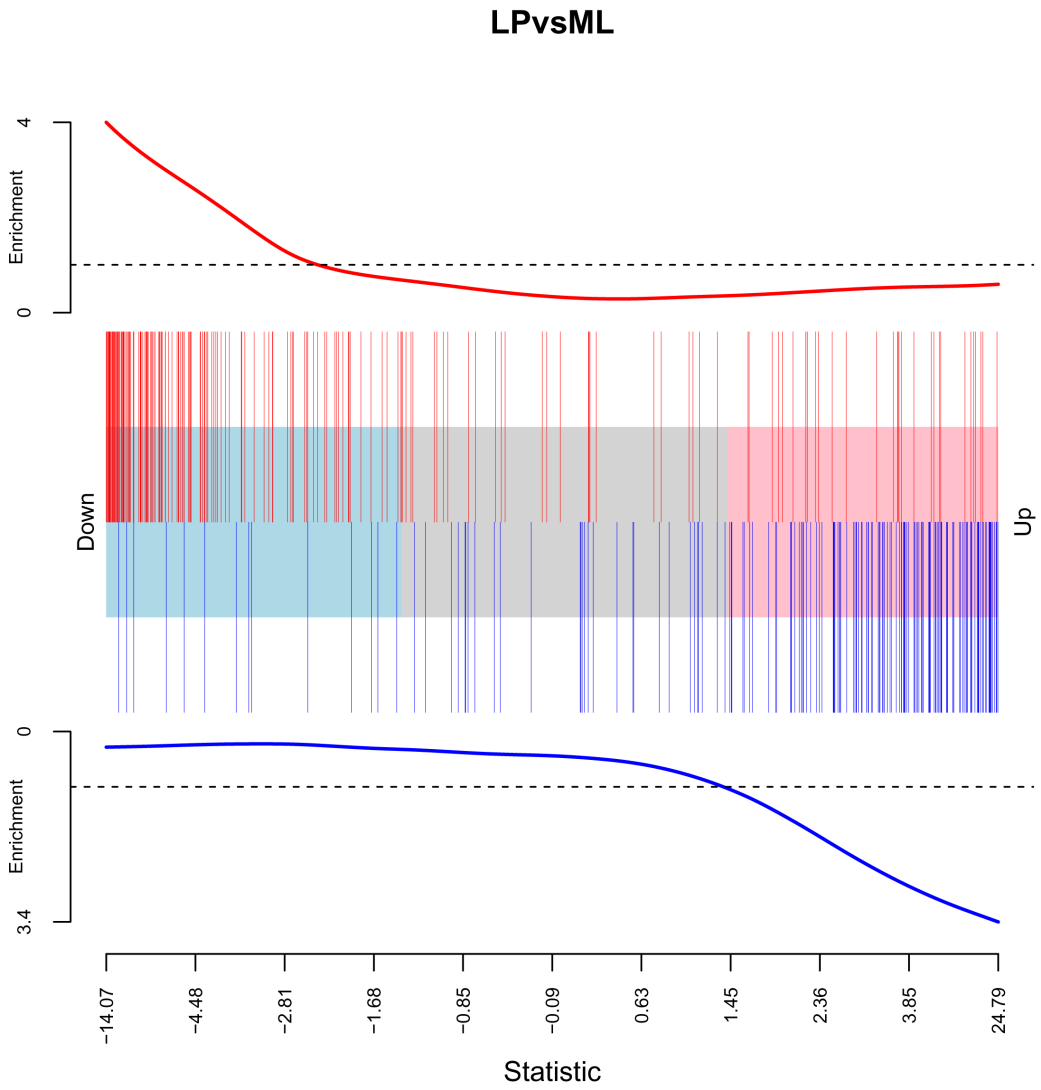

Figure 8. Barcode plot of LIM_MAMMARY_LUMINAL_MATURE_UP (red bars, top of plot) and LIM_MAMMARY_LUMINAL_MATURE_DN (blue bars, bottom of plot) gene sets in the LP versus ML contrast. For each set, an enrichment line that shows the relative enrichment of the vertical bars in each part of the plot is displayed. The experiment of Lim *et al.* (2010) is very similar to the current one, with the same sorting strategy used to obtain the different cell populations, except that microarrays were used instead of RNA-seq to profile gene expression. Note that the inverse correlation (the up gene set is down and the down gene set is up) is a result of the way the contrast has been set up (LP versus ML) – if reversed, the directionality would agree.

Software availability

This RNA-seq workflow makes use of various packages available from version 3.8 of the Bioconductor project, running on R[22] version 3.5.1. Besides the software highlighted in this article (**limma**, **Glimma** and **edgeR**) it requires a number of other packages, including **gplots**[23] and **RColorBrewer** and the gene annotation package **Mus.musculus**. This document was compiled using **knitr**[24–26]. Version numbers for all packages used are shown below. The **RNAseq123** Bioconductor workflow package available from `https://bioconductor.org/packages/RNAseq123` contains both an English and Chinese (Mandarin) vignette of this article along with code to perform the complete analysis. Installation of this package manages all of the above-mentioned dependencies and is a useful resource for delivering hands-on training on RNA-seq data analysis.

Author contributions

CWL, GKS and MER developed the workflow and wrote the article with input from MA (gene set testing), SS (Glimma interactive plotting), XD (Chinese translation of vignette and all code and figure updates required for Bioconductor 3.8) and LT (Chinese translation of vignette).

Grant information

This worked was funded by the National Health and Medical Research Council (NHMRC) (Fellowship GNT1058892 and Program GNT1054618 to GKS, Project GNT1050661 to MER and GKS and Fellowship GNT1104924 to

MER), Victorian State Government Operational Infrastructure Support and Australian Government NHMRC IRIISS.

The funders had no role in study design, data collection and analysis, decision to publish, or preparation of the manuscript.

Acknowledgements

We thank Dr Julie Sheridan for generating this dataset and for advice on its analysis.

Referee Report 06 July 2016

https://doi.org/10.5256/f1000research.9688.r14437

✔ **Jovana Maksimovic**
Bioinformatics research group, Murdoch Childrens Research Institute, Murdoch Children's Research Institute, Parkville, Vic, Australia

This workflow outlines a step-by-step differential expression analysis of a publicly available RNA-seq dataset using several well-established Bioconductor packages such as limma and edgeR and the novel Glimma package. The workflow describes in detail the key steps that are generally performed as part of most standard, count-based RNAseq analyses: pre-processing, exploratory data analysis, differential expression testing and pathway analysis. Each of the steps is carefully explained and broken down into a series of logical substeps, which also include R code and example output. Furthermore, this workflow is a good example of how multiple Bioconductor packages can be applied in a real-world RNAseq analysis.

Overall, I think this is a very clearly written and well-explained workflow that not only highlights the utility of combining Bioconductor packages for RNAseq analysis but also demystifies the process for those who may be interested in learning what an RNAseq analysis involves. Although some familiarity with R and statistical concepts would be advantageous, they are not necessary to be able to follow the logic behind the steps and what each step is trying to achieve.

I have tested the R code under R 3.3.0 and Bioconductor 3.0 and it ran without errors.

Minor comments:

- As this workflow will be of particular use for those who are very new to RNAseq analysis, I think it should be explained why 1 CPM is chosen as the cutoff for lowly expressed genes. In addition, it may be useful to show the relationship between CPM and raw counts and how the selected cutoff relates to numbers of reads.
- In the gene set testing section, it is worth mentioning that the Hallmark gene sets (also available from the Broad MSigDB) may be a good starting point for pathway analysis as they “summarise and represent specific well-defined, states or processes”.
- Also, for those who are new to RNAseq analysis, it may be worth mentioning that there are other gene set testing methods available in limma e.g. roast etc. and a very brief explanation of when the different methods are appropriate.
- General comment regarding Glimma plots: it would be handy to see the gene symbol (if available) as well as EntrezID in the title of the scatter plot next to the MD plot.

Competing Interests: Matthew E. Ritchie and I are both organisers of the Bioconductor Asia-Pacific Developer meeting, which is to be held in Brisbane in November 2016.

I have read this submission. I believe that I have an appropriate level of expertise to confirm that it is of an acceptable scientific standard.

Author Response 30 Nov 2016

Charity Law, The Walter and Eliza Hall Institute of Medical Research, Australia

Dear Jovana, thank-you for the helpful suggestions. We have added extra text to explain why a CPM value of 1 was chosen and how this value relates to raw counts. We have also given more detail on c2 and Hallmark gene sets, as well as mentioning roast and when one might chose to use roast over camera.

Referee Report 06 July 2016

https://doi.org/10.5256/f1000research.9688.r14439

Maria A. Doyle
Research Computing Facility, Peter MacCallum Cancer Centre, Melbourne, Vic, Australia

Editorial Note from F1000Research - 7th July 2016:

the status of this review was changed after publication from "Approved with Reservations" to "Approved". The referee's reservation was caused by using the current release (Bioconductor 3.3) as opposed to the development release (Bioconductor 3.4) as used in the article.

The following text has been removed:

My only reservation to approving the article is that I encountered these two errors when running the Glimma code in the article. I used R 3.3.0 and the most recent version of Glimma from Bioconductor (Glimma 1.0.0) but the sessionInfo() in the article shows Glimma 1.1.1 was used which may account for the errors:

1) With this line of code no plot was produced and it gave the error below:

```
glMDSPlot(lcpm, labels=paste(group, lane, sep="_"),
+         groups=x$samples[,c(2,5)], launch=TRUE)
Error in glScatter.default(points, xval = "dim1", yval = "dim2", xlab = "Dimension 1",  :
  group does not correspond to a column
```

2) With this line of code the table (shown in Fig 6.) didn't appear, just the 2 plots:

```
glMDPlot(tfit, coef=1, status=dt[,1], main=colnames(tfit)[1],
   counts=x$counts, samples=colnames(x), anno=x$genes, groups=group,
   id.column="ENTREZID", display.columns=c("SYMBOL", "ENTREZID"),
   search.by="SYMBOL", launch=FALSE)
```

This article is a very nice description (nicely written, nicely explained) of an RNA-seq workflow, starting from gene counts and proceeding through a standard differential expression analysis, using 3

complementary Bioconductor packages edgeR, limma & Glimma. It explains clearly how to perform the steps of a differential expression analysis and also how to generate useful plots for visualising the data e.g. MDSplot, MDplot, barcodeplot, heatmap etc.

Two of the packages, edgeR and limma, are well established while Glimma is the new kid on the block. It's a tool along the lines of the web-based Degust (http://www.vicbioinformatics.com/degust/), in that it enables interactive exploration of RNA-seq data. It would seem to be a very useful addition to R RNA-seq workflows as the interactive html plots it can generate (MDS, MD etc) make exploring the results easier (especially by non-R savvy collaborators) and it could help save an analyst's time and effort through not having to reproduce static plots e.g. to highlight different genes. With the Glimma MDplot I like that you can search for a gene and see a plot of the log-cpm counts for that gene in the samples.

It was great to be able to try out the workflow really easily by downloading the data file linked to in the paper (from GEO), with no processing required other than unzipping the files, and the code in the article all worked, giving the same results shown in the paper with the exception of two errors described below.

Minor comments:

The article says the workflow is available from Bioconductor here http://www.bioconductor.org/help/workflows/ but it doesn't seem to be there, however it is available at the other location mentioned http://bioinf.wehi.edu.au/folders/limmaWorkflow/

The section title "Removing genes that are not expressed" suggests only genes with no expression are removed, however the paragraph then explains that genes lowly expressed are also removed so for greater clarity maybe that could be changed to something like "Removing genes that are not sufficiently expressed".

In the section "Organising gene annotations" I think it's good the authors point out to check for duplicated genes, however in this case the duplication appears to be due to extracting the TXCHROM column (as some genes are reported as being present on more than one chromosome) but the TXCHROM information is not used in this workflow and if the TXCHROM column is omitted then there are no duplicates so it might be worth mentioning that.

With this bit "Differential expression analyses look at gene expression differences between conditions, rather than comparing expression across multiple genes or drawing conclusions on absolute levels of expression. In other words, gene lengths remain constant for comparisons of interest and any observed differences are a result of changes in condition rather than changes in gene length." Wouldn't one caveat to this be if there was a significant change in the length of the isoform(s) expressed from a gene (e.g. from expression of a long isoform to a short isoform) as then the assumption of no change in gene length would no longer be valid.

In the online version Fig.7 is in the middle of a code block could it be moved below.

Figs 5-8 have bold headings but Figs 1-4 don't is that an error.

Could perhaps modify title to reflect the order in which the tools are used - edger, limma & Glimma.

It would be nice for consistency if the colours in the Glimma interactive MDS plots matched the colours used in the static MDS plots in Fig 3.

Competing Interests: No competing interests were disclosed.

I have read this submission. I believe that I have an appropriate level of expertise to confirm that it is of an acceptable scientific standard.

Referee Response 06 Jul 2016

Maria A. Doyle, Peter MacCallum Cancer Centre, Australia

I've just requested that the status of this article be changed to Approved as the code works fine with the development release of Bioconductor 3.4 but could it be made clearer in the article that 3.4 must be used for the code to work as shown.

Competing Interests: No competing interests were disclosed.

Author Response 30 Nov 2016

Charity Law, The Walter and Eliza Hall Institute of Medical Research, Australia

Dear Maria, we have made changes according to your suggestions, including a change in the section title to "Removing genes that are lowly expressed", and we have added comments to point out that our analysis assumes no differential isoform usage. We have also simplified our example in the "Organising gene annotations" section.

Thanks for pointing out the inconsistencies in the figure captions. They have now been addressed.

Indeed, it would be nice to make the colours consistent between the interactive and static MDS plots. We like the colours used in the static plot and can have the interactive version of the plot updated once color specification becomes available to the MDS plotting function in Glimma.

Competing Interests: None

Referee Report 23 June 2016

https://doi.org/10.5256/f1000research.9688.r14436

James W. MacDonald
Department of Environmental and Occupational Health Sciences, University of Washington, Seattle, WA, USA

In this manuscript the authors perform a step-by-step analysis of a public RNA-Seq data set, using the Bioconductor packages edgeR, limma, and Glimma. The analysis proceeds through four stages (data preparation, preprocessing, univariate analyses, and gene set testing), with each stage broken up into several discrete steps. Each step is clearly explained and is accompanied by R code and output, so the reader can follow along if desired.

The target audience for this paper appears to be someone with passing familiarity with both R and statistics, without requiring expertise in either. Most of the code should be easy to understand, and any

complex sections are clearly explained in the text. Similarly, the authors outline the analytic choices they make (e.g., filtering out unexpressed genes, specifying model coefficients, etc) at a more accessible level.

While both edgeR and limma are well known, popular Bioconductor packages, Glimma is a new package that was released in April 2016. This package uses the d3.js JavaScript library to generate interactive HTML documents that can be viewed locally, rather than needing to be accessed from a server running R (as, say a shiny app requires). This is an exciting development, and is unfortunately not as compelling as it could be, if the Glimma plots were part of the HTML version of the manuscript rather than provided as links.

This is a well written paper, and is a useful contribution to the literature; while each package has either an extensive user's guide or vignette, by necessity these documents pertain only to the package at hand. Most RNA-Seq analyses require a combination of multiple packages to complete, and this paper provides a clear example.

Major comments

None.

Minor comments

In the section 'Organising gene annotations', the code used to subset the one-to-many mappings is needlessly complex. Simply doing something like

genes <- genes[!duplicated(genes[,1]),]

will accomplish the same thing, in a more straightforward way.

In the section 'Removing heteroscedasticity from count data', the authors state:

"When operating on a DGEList-object, voom converts raw counts to log-CPM values by automatically extracting library sizes and normalisation factors stored in the object. For a matrix of counts, the method of normalisation can be specified within voom using the normalize.method (by default no normalisation is performed)."

This is confusing; the authors already showed in an earlier section ('Normalising gene expression distributions') that converting to log-CPM using TMM normalization factors will do a shift-normalization (which is what voom will do in this instance). The normalize.method argument to voom specifies **additional** normalization methods that can be applied to the matrix of TMM normalized log-CPM values.

Competing Interests: No competing interests were disclosed.

I have read this submission. I believe that I have an appropriate level of expertise to confirm that it is of an acceptable scientific standard.

Author Response 30 Nov 2016

Charity Law, The Walter and Eliza Hall Institute of Medical Research, Australia

Dear James, thank-you for your comments. We have considered your suggestions and made changes to simplify the section on 'Organising gene annotations' and to clarify that voom offers additional normalisation ontop of the TMM-normsalisation that is carried out.

Competing Interests: None

Version 2

Reader Comment 15 Feb 2017

Marc Teunis, University of Applied Sciences, Utrecht, The Netherlands

Dear authors,

I am testing the workflow on a CentOS RStudio Server (see session info below). I just wanted to point out a minor glitch in the code for downloading the files for this workflow.

I have installed the workflow from BIOCONDUCTOR using:

source("http://bioconductor.org/workflows.R")
workflowInstall("RNAseq123")

The current code chunck for downloading the file should be changed to

utils::download.file(url, destfile="GSE63310_RAW.tar", mode="wb", method = "wget")

Not setting method to "wget" results in an incomplete download of the RAW.tar archive.

Hoping to have aided future users with this comment.

Sincerely,
Marc

D.8 Proteomics

Further explanations for Chapter 8.

D.8.1 Mass spectrometry methods

- Dupree et al. (2020) — Walks through the bottom-up workflow from sample preparation and digestion to LC-MS/MS, acquisition and quantification, and discusses its limitations. A readable overview of the section's experimental side. *(review; CC BY 4.0)*

  A Critical Review of Bottom-Up Proteomics: The Good, the Bad, and the Future of This Field. Dupree et al. (2020). *Proteomes*. doi:10.3390/proteomes8030014

  > Proteomics is the field of study that includes the analysis of proteins, from either a basic science prospective or a clinical one. Proteins can be investigated for their abundance, variety of proteoforms due to post-translational modifications (PTMs), and their stable or transient protein-protein interactions. This can be especially beneficial in the clinical setting when studying proteins involved in different diseases and conditions. Here, we aim to describe a bottom-up proteomics workflow from sample preparation to data analysis, including all of its benefits and pitfalls. We also describe potential improvements in this type of proteomics workflow for the future.

- Wang et al. (2024) — Tutorial on multiplex isotope labelling for quantification (precursor-based labels such as SILAC, mass-defect labels and reporter-ion labels such as TMT), with their principles, advantages and limitations such as ratio distortion. Useful background for the quantification subsection. *(tutorial; CC BY 4.0)*

  A Tutorial Review of Labeling Methods in Mass Spectrometry-Based Quantitative Proteomics. Wang et al. (2024). *ACS Measurement Science Au*. doi:10.1021/acsmeasuresciau.4c00007

  > Recent advancements in mass spectrometry (MS) have revolutionized quantitative proteomics, with multiplex isotope labeling emerging as a key strategy for enhancing accuracy, precision, and throughput. This tutorial review offers a comprehensive overview of multiplex isotope labeling techniques, including precursor-based, mass defect-based, reporter ion-based, and hybrid labeling methods. It details their fundamental principles, advantages, and inherent limitations along with strategies to mitigate the limitation of ratio-distortion. This review will also cover the applications and latest progress in these labeling techniques across various domains, including cancer biomarker discovery, neuroproteomics, post-translational modification analysis, cross-linking MS, and single-cell proteomics. This Review aims to provide guidance for researchers on selecting appropriate methods for their specific goals while also highlighting the potential future directions in this rapidly evolving field.

- Jiang et al. (2024) — Long, comprehensive review covering instruments, fragmentation, acquisition modes, data analysis and quantification in bottom-up proteomics. Useful as a reference to dip into; licence allows linking only. *(review; CC BY-NC-ND 4.0 (link only))*

  Comprehensive Overview of Bottom-Up Proteomics Using Mass Spectrometry. Jiang et al. (2024). *ACS Measurement Science Au*. doi:10.1021/acsmeasuresciau.3c00068

  > Proteomics is the large scale study of protein structure and function from biological systems through protein identification and quantification. "Shotgun proteomics" or "bottom-up proteomics" is the prevailing strategy, in which proteins are hydrolyzed into peptides that are analyzed by mass spectrometry. Proteomics studies can be applied to diverse studies ranging from simple protein identification to studies of proteoforms, protein-protein interactions, protein structural alterations, absolute and relative protein quantification, post-translational modifications, and protein stability. To enable this range of different experiments, there are diverse strategies for proteome analysis. The nuances of how proteomic workflows differ may be challenging to understand for new practitioners. Here, we provide a comprehensive overview of different proteomics methods. We cover from biochemistry basics and protein extraction to biological interpretation and orthogonal validation. We expect this Review will serve as a handbook for researchers who are new to the field of bottom-up proteomics.

D.8.2 Algorithms for peptide identification

- McHugh and Arthur (2008) — Short introductory review of peptide mass fingerprinting, database search, de novo sequencing and their scoring, written for computational readers. Older, but the basic algorithms it explains have not changed. *(review; CC BY 4.0)*

  Computational Methods for Protein Identification from Mass Spectrometry Data. McHugh & Arthur (2008). *PLoS Computational Biology*. doi:10.1371/journal.pcbi.0040012

  > Protein identification using mass spectrometry is an indispensable computational tool in the life sciences. A dramatic increase in the use of proteomic strategies to understand the biology of living systems generates an ongoing need for more effective, efficient, and accurate computational methods for protein identification. A wide range of computational methods, each with various implementations, are available to complement different proteomic approaches. A solid knowledge of the range of algorithms available and, more critically, the accuracy and effectiveness of these techniques is essential to ensure as many of the proteins as possible, within any particular experiment, are correctly identified. Here, we undertake a systematic review of the currently available methods and algorithms for interpreting, managing, and analyzing biological data associated with protein identification. We summarize the advances in computational solutions as they have responded to corresponding advances in mass spectrometry hardware. The evolution of scoring algorithms and metrics for automated protein identification are also discussed with a focus on the relative performance of different techniques. We also consider the relative advantages and limitations of different techniques in particular biological contexts. Finally, we present our perspective on future developments in the area of computational protein identification by considering the most recent literature on new and promising approaches to the problem as well as identifying areas yet to be explored and the potential application of methods from other areas of computational biology.

- Angelis et al. (2025) — Introduction to deep-learning models that predict fragment spectra, retention times and other peptide properties, and how they are used in rescoring and library generation. Matches the subsection on predicting spectra and retention times. *(tutorial; CC BY 4.0)*

  Peptide Property Prediction for Mass Spectrometry Using AI: An Introduction to State of the Art Models. Angelis et al. (2025). *PROTEOMICS*. doi:10.1002/pmic.202400398

  > This review explores state of the art machine learning and deep learning models for peptide property prediction in mass spectrometry-based proteomics, including, but not limited to, models for predicting digestibility, retention time, charge state distribution, collisional cross section, fragmentation ion intensities, and detectability. The combination of these models enables not only the in silico generation of spectral libraries but also finds many additional use cases in the design of targeted assays or data-driven rescoring. This review serves as both an introduction for newcomers and an update for experienced researchers aiming to develop accessible and reproducible models for peptide property predictions. Key limitations of the current models, including difficulties in handling diverse post-translational modifications and instrument variability, highlight the need for large-scale, harmonized datasets, and standardized evaluation metrics for benchmarking.

- Wen et al. (2020) — Overview of deep-learning applications in proteomics, including spectrum and retention-time prediction and de novo peptide sequencing. Gives a broader context for the machine-learning methods in this section. *(review; CC BY 4.0)*

  Deep Learning in Proteomics. Wen et al. (2020). *PROTEOMICS*. doi:10.1002/pmic.201900335

  > Proteomics, the study of all the proteins in biological systems, is becoming a data-rich science. Protein sequences and structures are comprehensively catalogued in online databases. With recent advancements in tandem mass spectrometry (MS) technology, protein expression and post-translational modifications (PTMs) can be studied in a variety of biological systems at the global scale. Sophisticated computational algorithms are needed to translate the vast amount of data into novel biological insights. Deep learning automatically extracts data representations at high levels of abstraction from data, and it thrives in data-rich scientific research domains. Here, a comprehensive overview of deep learning applications in proteomics, including retention time prediction, MS/MS spectrum prediction, de novo peptide sequencing, PTM prediction, major histocompatibility complex-peptide binding prediction, and protein structure prediction, is provided. Limitations and the future directions of deep learning in proteomics are also

discussed. This review will provide readers an overview of deep learning and how it can be used to analyze proteomics data.

D.8.3 Statistics and error control

- Noble and MacCoss (2012) — A chapter of the PLoS Computational Biology 'Translational Bioinformatics' collection that explains peptide identification, target–decoy FDR estimation, q-values, posterior error probabilities, protein inference and quantification. Written by researchers behind Percolator and Skyline, it is a clear statistical introduction to the whole section. *(book chapter; CC BY 4.0)*

  Computational and Statistical Analysis of Protein Mass Spectrometry Data. Noble & MacCoss (2012). *PLoS Computational Biology*. doi:10.1371/journal.pcbi.1002296

  > High-throughput proteomics experiments involving tandem mass spectrometry produce large volumes of complex data that require sophisticated computational analyses. As such, the field offers many challenges for computational biologists. In this article, we briefly introduce some of the core computational and statistical problems in the field and then describe a variety of outstanding problems that readers of PLoS Computational Biology might be able to help solve.

- Wen et al. (2025) — Explains how entrapment experiments can test whether a pipeline's reported FDR is valid, and shows that some widely used tools do not control the FDR as claimed. Useful for understanding the assumptions behind target–decoy estimates. *(perspective; CC BY 4.0)*

  Assessment of false discovery rate control in tandem mass spectrometry analysis using entrapment. Wen et al. (2025). *Nature Methods*. doi:10.1038/s41592-025-02719-x

  > A critical challenge in mass spectrometry proteomics is accurately assessing error control, especially given that software tools employ distinct methods for reporting errors. Many tools are closed-source and poorly documented, leading to inconsistent validation strategies. Here we identify three prevalent methods for validating false discovery rate (FDR) control: one invalid, one providing only a lower bound, and one valid but under-powered. The result is that the proteomics community has limited insight into actual FDR control effectiveness, especially for data-independent acquisition (DIA) analyses. We propose a theoretical framework for entrapment experiments, allowing us to rigorously characterize different approaches. Moreover, we introduce a more powerful evaluation method and apply it alongside existing techniques to assess existing tools. We first validate our analysis in the better-understood data-dependent acquisition setup, and then, we analyze DIA data, where we find that no DIA search tool consistently controls the FDR, with particularly poor performance on single-cell datasets.

- Hutchings et al. (2023) — Step-by-step Bioconductor workflow for TMT and label-free data, covering import, pre-processing, quality control, aggregation to proteins and differential abundance testing. A practical complement to the statistics of quantification. *(tutorial; CC BY 4.0)*

  A Bioconductor workflow for processing, evaluating, and interpreting expression proteomics data. Hutchings et al. (2023). *F1000Research*. doi:10.12688/f1000research.139116.1

  > Background: Expression proteomics involves the global evaluation of protein abundances within a system. In turn, differential expression analysis can be used to investigate changes in protein abundance upon perturbation to such a system. Methods: Here, we provide a workflow for the processing, analysis and interpretation of quantitative mass spectrometry-based expression proteomics data. This workflow utilizes open-source R software packages from the Bioconductor project and guides users end-to-end and step-by-step through every stage of the analyses. As a use-case we generated expression proteomics data from HEK293 cells with and without a treatment. Of note, the experiment included cellular proteins labelled using tandem mass tag (TMT) technology and secreted proteins quantified using label-free quantitation (LFQ). Results: The workflow explains the software infrastructure before focusing on data import, pre-processing and quality control. This is done individually for TMT and LFQ datasets. The application of statistical differential expression analysis is demonstrated, followed by interpretation via gene ontology enrichment analysis. Conclusions: A comprehensive workflow for the processing, analysis and interpretation of expression proteomics is presented. The workflow is a valuable resource for the

proteomics community and specifically beginners who are at least familiar with R who wish to understand and make data-driven decisions with regards to their analyses.

D.8.4 Proteomics beyond protein abundance

- Richards et al. (2021) — Reviews affinity purification–MS, proximity labelling, co-fractionation and cross-linking MS for mapping interaction networks, including scoring and quality control. Covers the interaction proteomics subsection. *(review; CC BY 4.0)*

  Mass spectrometry-based protein–protein interaction networks for the study of human diseases. Richards et al. (2021). *Molecular Systems Biology*. doi:10.15252/msb.20188792

  > A better understanding of the molecular mechanisms underlying disease is key for expediting the development of novel therapeutic interventions. Disease mechanisms are often mediated by interactions between proteins. Insights into the physical rewiring of protein-protein interactions in response to mutations, pathological conditions, or pathogen infection can advance our understanding of disease etiology, progression, and pathogenesis and can lead to the identification of potential druggable targets. Advances in quantitative mass spectrometry (MS)-based approaches have allowed unbiased mapping of these disease-mediated changes in protein-protein interactions on a global scale. Here, we review MS techniques that have been instrumental for the identification of protein-protein interactions at a system-level, and we discuss the challenges associated with these methodologies as well as novel MS advancements that aim to address these challenges. An overview of examples from diverse disease contexts illustrates the potential of MS-based protein-protein interaction mapping approaches for revealing disease mechanisms, pinpointing new therapeutic targets, and eventually moving toward personalized applications.

- Savage and Zhang (2020) — Guide to bioinformatics resources for phosphoproteomics: phosphosite and kinase knowledge bases, prediction of sites and their kinases, and kinase activity inference. Useful for the post-translational modifications subsection. *(review; CC BY 4.0)*

  Using phosphoproteomics data to understand cellular signaling: a comprehensive guide to bioinformatics resources. Savage & Zhang (2020). *Clinical Proteomics*. doi:10.1186/s12014-020-09290-x

  > Mass spectrometry-based phosphoproteomics is becoming an essential methodology for the study of global cellular signaling. Numerous bioinformatics resources are available to facilitate the translation of phosphopeptide identification and quantification results into novel biological and clinical insights, a critical step in phosphoproteomics data analysis. These resources include knowledge bases of kinases and phosphatases, phosphorylation sites, kinase inhibitors, and sequence variants affecting kinase function, and bioinformatics tools that can predict phosphorylation sites in addition to the kinase that phosphorylates them, infer kinase activity, and predict the effect of mutations on kinase signaling. However, these resources exist in silos and it is challenging to select among multiple resources with similar functions. Therefore, we put together a comprehensive collection of resources related to phosphoproteomics data interpretation, compared the use of tools with similar functions, and assessed the usability from the standpoint of typical biologists or clinicians. Overall, tools could be improved by standardization of enzyme names, flexibility of data input and output format, consistent maintenance, and detailed manuals.

- Masson et al. (2019) — Community recommendations that also explain the principles of HDX-MS, how the data are analysed and how differences between states are judged statistically. A good entry point to structural mass spectrometry. *(perspective; CC BY 4.0)*

  Recommendations for performing, interpreting and reporting hydrogen deuterium exchange mass spectrometry (HDX-MS) experiments. Masson et al. (2019). *Nature Methods*. doi:10.1038/s41592-019-0459-y

  > Hydrogen deuterium exchange mass spectrometry (HDX-MS) is a powerful biophysical technique being increasingly applied to a wide variety of problems. As the HDX-MS community continues to grow, adoption of best practices in data collection, analysis, presentation and interpretation will greatly enhance the accessibility of this technique to nonspecialists. Here we provide recommendations arising from community discussions emerging out of the first International Conference on Hydrogen-Exchange Mass

Spectrometry (IC-HDX; 2017). It is meant to represent both a consensus viewpoint and an opportunity to stimulate further additions and refinements as the field advances.

D.8.5 Proteomics without mass spectrometry

- Edfors et al. (2018) — Applies the 'pillars' of antibody validation (genetic, orthogonal, independent antibodies, tagged proteins, capture MS) to thousands of Human Protein Atlas antibodies. Explains why antibody-based proteomics needs systematic validation; it is a primary study rather than a review. *(review; CC BY 4.0)*

  Enhanced validation of antibodies for research applications. Edfors et al. (2018). *Nature Communications*. doi:10.1038/s41467-018-06642-y

  > There is a need for standardized validation methods for antibody specificity and selectivity. Recently, five alternative validation pillars were proposed to explore the specificity of research antibodies using methods with no need for prior knowledge about the protein target. Here, we show that these principles can be used in a streamlined manner for enhanced validation of research antibodies in Western blot applications. More than 6,000 antibodies were validated with at least one of these strategies involving orthogonal methods, genetic knockdown, recombinant expression, independent antibodies, and capture mass spectrometry analysis. The results show a path forward for efforts to validate antibodies in an application-specific manner suitable for both providers and users.

- Eldjarn et al. (2023) — Compares the two main affinity platforms for plasma proteomics, SomaScan (aptamers) and Olink (proximity extension assay), in the same individuals using precision, correlation and genetic associations. A primary study, but the most direct explanation of how the two platforms differ. *(review; CC BY 4.0)*

  Large-scale plasma proteomics comparisons through genetics and disease associations. Eldjarn et al. (2023). *Nature*. doi:10.1038/s41586-023-06563-x

  > High-throughput proteomics platforms measuring thousands of proteins in plasma combined with genomic and phenotypic information have the power to bridge the gap between the genome and diseases. Here we performed association studies of Olink Explore 3072 data generated by the UK Biobank Pharma Proteomics Project 1 on plasma samples from more than 50,000 UK Biobank participants with phenotypic and genotypic data, stratifying on British or Irish, African and South Asian ancestries. We compared the results with those of a SomaScan v4 study on plasma from 36,000 Icelandic people 2 , for 1,514 of whom Olink data were also available. We found modest correlation between the two platforms. Although cis protein quantitative trait loci were detected for a similar absolute number of assays on the two platforms (2,101 on Olink versus 2,120 on SomaScan), the proportion of assays with such supporting evidence for assay performance was higher on the Olink platform (72% versus 43%). A considerable number of proteins had genomic associations that differed between the platforms. We provide examples where differences between platforms may influence conclusions drawn from the integration of protein levels with the study of diseases. We demonstrate how leveraging the diverse ancestries of participants in the UK Biobank helps to detect novel associations and refine genomic location. Our results show the value of the information provided by the two most commonly used high-throughput proteomics platforms and demonstrate the differences between them that at times provides useful complementarity.

- Timp and Timp (2020) — Surveys alternatives to mass spectrometry for identifying and sequencing single protein molecules, such as nanopores and fluorescence-based methods, and their prospects. Background for the subsection on protein sequencing. *(review; CC BY 4.0)*

  Beyond mass spectrometry, the next step in proteomics. Timp & Timp (2020). *Science Advances*. doi:10.1126/sciadv.aax8978

  > Proteins can be the root cause of a disease, and they can be used to cure it. The need to identify these critical actors was recognized early (1951) by Sanger; the first biopolymer sequenced was a peptide, insulin. With the advent of scalable, single-molecule DNA sequencing, genomics and transcriptomics have since propelled medicine through improved sensitivity and lower costs, but proteomics has lagged behind. Currently, proteomics relies mainly on mass spectrometry (MS), but instead of truly sequencing, it classifies a protein and typically requires about a billion copies of a protein to do it. Here, we offer a

survey that illuminates a few alternatives with the brightest prospects for identifying whole proteins and displacing MS for sequencing them. These alternatives all boast sensitivity superior to MS and promise to be scalable and seem to be adaptable to bioinformatics tools for calling the sequence of amino acids that constitute a protein.

D.8.6 Repositories and standards

- Perez-Riverol et al. (2015) — Survey of proteomics repositories and knowledge bases, including PRIDE, PeptideAtlas and ProteomeXchange, and of how their data can be reused. Somewhat dated in details but a good map of the landscape. *(review; CC BY 4.0)*

  Making proteomics data accessible and reusable: Current state of proteomics databases and repositories. Perez-Riverol et al. (2015). *PROTEOMICS*. doi:10.1002/pmic.201400302

  > Compared to other data-intensive disciplines such as genomics, public deposition and storage of MS-based proteomics, data are still less developed due to, among other reasons, the inherent complexity of the data and the variety of data types and experimental workflows. In order to address this need, several public repositories for MS proteomics experiments have been developed, each with different purposes in mind. The most established resources are the Global Proteome Machine Database (GPMDB), PeptideAtlas, and the PRIDE database. Additionally, there are other useful (in many cases recently developed) resources such as ProteomicsDB, Mass Spectrometry Interactive Virtual Environment (MassIVE), Chorus, MaxQB, PeptideAtlas SRM Experiment Library (PASSEL), Model Organism Protein Expression Database (MOPED), and the Human Proteinpedia. In addition, the ProteomeXchange consortium has been recently developed to enable better integration of public repositories and the coordinated sharing of proteomics information, maximizing its benefit to the scientific community. Here, we will review each of the major proteomics resources independently and some tools that enable the integration, mining and reuse of the data. We will also discuss some of the major challenges and current pitfalls in the integration and sharing of the data.

- Deutsch et al. (2023) — Describes the HUPO-PSI standards (mzML, mzIdentML, mzTab, Universal Spectrum Identifier, SDRF-Proteomics and others) and why they exist. Directly covers the standards part of the section. *(review; CC BY 4.0)*

  Proteomics Standards Initiative at Twenty Years: Current Activities and Future Work. Deutsch et al. (2023). *Journal of Proteome Research*. doi:10.1021/acs.jproteome.2c00637

  > The Human Proteome Organization (HUPO) Proteomics Standards Initiative (PSI) has been successfully developing guidelines, data formats, and controlled vocabularies (CVs) for the proteomics community and other fields supported by mass spectrometry since its inception 20 years ago. Here we describe the general operation of the PSI, including its leadership, working groups, yearly workshops, and the document process by which proposals are thoroughly and publicly reviewed in order to be ratified as PSI standards. We briefly describe the current state of the many existing PSI standards, some of which remain the same as when originally developed, some of which have undergone subsequent revisions, and some of which have become obsolete. Then the set of proposals currently being developed are described, with an open call to the community for participation in the forging of the next generation of standards. Finally, we describe some synergies and collaborations with other organizations and look to the future in how the PSI will continue to promote the open sharing of data and thus accelerate the progress of the field of proteomics.

- Perez-Riverol et al. (2019) — Analyses how public proteomics and other omics data sets are downloaded and reused. Illustrates why deposition in repositories such as PRIDE matters. *(perspective; CC BY 4.0)*

  Quantifying the impact of public omics data. Perez-Riverol et al. (2019). *Nature Communications*. doi:10.1038/s41467-019-11461-w

  > The amount of omics data in the public domain is increasing every year. Modern science has become a data-intensive discipline. Innovative solutions for data management, data sharing, and for discovering novel datasets are therefore increasingly required. In 2016, we released the first version of the Omics Discovery Index (OmicsDI) as a light-weight system to aggregate datasets across multiple public omics data resources. OmicsDI aggregates genomics, transcriptomics, proteomics, metabolomics and multiomics

datasets, as well as computational models of biological processes. Here, we propose a set of novel metrics to quantify the attention and impact of biomedical datasets. A complete framework (now integrated into OmicsDI) has been implemented in order to provide and evaluate those metrics. Finally, we propose a set of recommendations for authors, journals and data resources to promote an optimal quantification of the impact of datasets.

Abstract: Proteomics is the field of study that includes the analysis of proteins, from either a basic science prospective or a clinical one. Proteins can be investigated for their abundance, variety of proteoforms due to post-translational modifications (PTMs), and their stable or transient protein–protein interactions. This can be especially beneficial in the clinical setting when studying proteins involved in different diseases and conditions. Here, we aim to describe a bottom-up proteomics workflow from sample preparation to data analysis, including all of its benefits and pitfalls. We also describe potential improvements in this type of proteomics workflow for the future.

Keywords: mass spectrometry; proteomics; protein identification; protein characterization

1. Proteomics

The term proteome refers to all proteins that are produced or modified by an organism (e.g., human [1], animal [2], plant [3], bacteria [4]) or living system (e.g., organ, cell culture, complex community from an environmental sample)). The term "proteome" and the first dedicated proteomics laboratory were introduced in 1994 by Wilkins et al. to describe proteins as a complement to genomic data [5]. However, the "whole" proteome of a particular cell, tissue, organ, or organism is yet to be identified. This is particularly difficult due to the vast variety of proteins and their isoproteins/proteoforms/protein species, which are expressed at different levels—from very abundant proteins, such as actin, to less abundant ones, such as transcription factors—in different cells, tissues, or organs. The variety of post-translational modifications (PTMs) in proteins, which may be stable or transient, is responsible for the vast number of proteoforms, which is an obstacle in most proteomics experiments. This, corroborated with the multiple limitations of proteomics methods, makes the quest to identify the proteome of any given organism a difficult one [6].

The proteomics field consists of a wide range of methodology, which has been largely driven by the modern development of involved technology. The concept of global protein analysis as a complete atlas of human proteins was proposed over 50 years ago [7]; however, proteomics research did not start until the mid-1990s. The beginning of proteomics research was sparked due to parallel

developments in four areas: (i) two-dimensional gel electrophoresis (2D-PAGE) evolving into a robust method to rapidly separate proteins contained in biological complex mixtures [8]; (ii) the continuous development of mass spectrometry methods for accurate mass and chemical structure analysis [9,10]; (iii) the constant production of large-scale genome research and enormous number of peptide/protein sequences catalogued in several databases [11]; and (iv) the development of novel bioinformatics tools to simplify the analysis of large volumes of MS data aiming towards identifying intact proteins and their functional or pathological PTMs [12,13].

The field of proteomics comprises a bioanalytical discipline that performs large-scale studies on proteins [14] that may be rooted from a basic science perspective or a clinical one, i.e., proteins that are associated with a broad range of diseases and conditions by means of their altered expression levels and/or PTMs. In addition to fundamental protein research or development of proteomics-related instrumentation, the detailed analysis of the proteome for a specific type of cell (e.g., tumor, blood, or tissue) has the potential to permit the discovery of new protein biomarkers aimed towards diagnostic purposes and novel drug discovery [15,16]. Currently, the knowledge provided by proteomic research adds greatly to the genetic information generated from all genomics studies. The combination of proteomics and genomics research has the potential to play a major role in future biomedical studies and to impact the development of next generation diagnostic and therapeutic approaches.

Mass spectrometry (MS)-based proteomics has led to the possibility of characterizing and quantifying the protein profile of biological specimens, as well as the possibility to discover their complex interactions involved in various specific pathologies. For example, various proteomic approaches combined with genomic analysis have been used in cancer research for obtaining more information about the molecular basis of tumor genesis and the development of more effective anticancer therapies [17–19].

A typical bottom-up proteomics workflow (Figure 1) consists of several major steps: (i) isolation of the protein mixture from the studied biological sample, followed by (ii) quantification of isolated proteins concentrations (e.g., Bradford assay), then (iii) fractionation of proteins by gel electrophoresis or liquid chromatography methods. After fractionation, (iv) the proteins are proteolytically cleaved by enzymes (usually trypsin); followed by (v) a mass spectrometric measurement of the resulting peptides and (vi) a database search for protein identification.

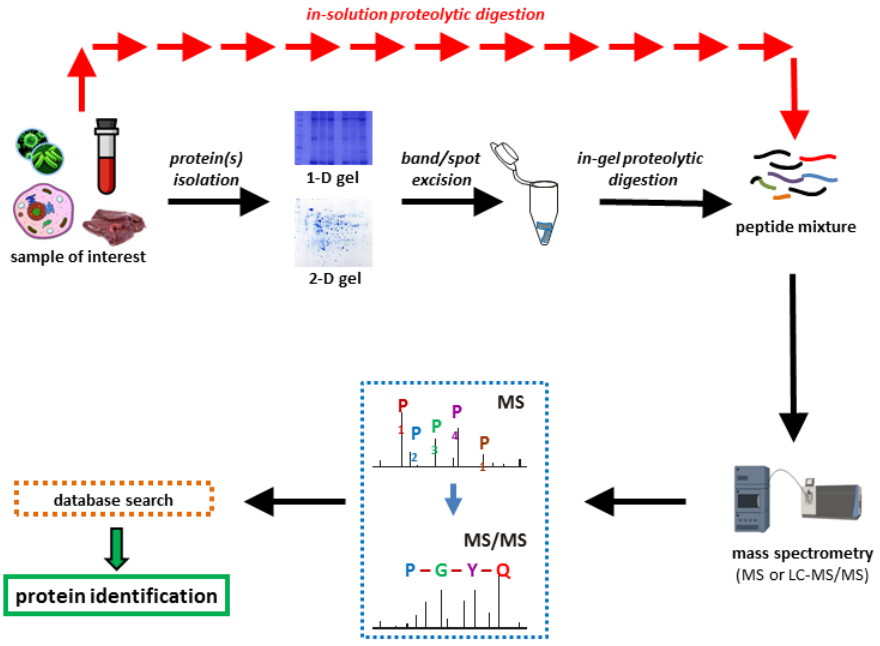

Figure 1. Workflow in a bottom-up proteomics experiment.

The purpose of this review is to briefly introduce the bottom-up proteomic approach from a liquid chromatography–mass spectrometry perspective, to discuss its multidisciplinary development, its strengths and weaknesses, and to identify potential areas of improvement in the current methodology. These potential improvements will be relevant to the current problems in society, including biomedical, clinical, or environmental concerns.

2. Bottom-Up Proteomics

Most proteomic analyses use proteases to digest proteins into peptides with a predictable terminus. Peptides are then analyzed in an MS/MS instrument and their mass to charge ratio and predicted sequence is used to infer information about the proteins in the sample. All experimental set-ups starting from the analysis of peptides from complete protein digests and using a protein database to characterize the open-reading frame this peptide originated from, are grouped under the term "bottom-up" proteomics.

Bottom-up proteomics utilizes the advantages that peptides have over proteins: peptides are more easily separated by reversed-phase liquid chromatography (RPLC), ionize well [20], and fragment in a more predictable manner. This translates into a robust methodology that enables high-throughput analysis, allowing for identification and quantification of thousands of proteins from complex lysates [21]. Today, bottom-up approaches using data-dependent acquisition (DDA) workflows are the core technologies in proteomics. Also termed shot-gun proteomics, these straightforward workflows generate large lists of protein identifications and were used for solving most of the available, complex, full proteomes available today, including the first drafts of the human proteome [22,23]. New data acquisition strategies such as selected reaction monitoring (SRM) further increase the quantification accuracy and reproducibility of bottom-up proteomics studies [24]. Data independent acquisition (DIA) is evolving to become a major driving methodology of the future. It attempts to combine a high number of protein identifications with consistency and accuracy in quantification of protein levels [25].

The hallmark of bottom-up proteomics is the extensive use of protease digestions, which has its drawbacks. Trypsin is the golden standard when it comes to shot-gun approaches and is being used for approximatively 96% of the deposited data sets in the Global Proteome Machine Database [26]. Trypsin is a very efficient protease with high catalytic activity that generates peptides with a basic arginine or lysine at the C-termini, which is ideal for collision-induced dissociation (CID) tandem mass spectrometry analysis [27]. Although efficient, when using trypsin, 56% of all generated peptides are ≤ 6 residues and thus too small to be identified by MS [28]. Moreover, only a fraction of these peptides yields useful fragmentation ladders [29]. The extensive usage of trypsin also leads to analytical tools that are optimized based on tryptic peptide properties. Furthermore, protein identifications are usually inferred by a limited number of typtic peptides. Hence, current bottom-up proteomics offers a rather biased and restricted coverage of the full proteome in a given sample, almost like "tunnel vision" of the proteome [28].

The limited sequence information inferred from small peptides is more often suffice to assign proteins clusters, and not always enough to identify proteoforms. Although possible through the measurement of mass shifts, protein isoform and PTM identification without prior knowledge is extremely limited in bottom-up proteomics.

3. Sample Preparation

As the proteomics field attempts to perform a comprehensive analysis of all the proteins in a given sample [30], sample preparation is the first and most important step in any experimental endeavor. If this step fails to perform, the sensitivity and throughput of the downstream steps are rendered pointless.

Genomics and transcriptomics, the other two major high-throughput -omics fields, benefit from the fact that nucleic acids are relatively uniform in terms of physiochemical properties. As such,

"universal" standard methods and buffers are available that can be used to isolate nucleic acids of any size from almost any sample. No such thing exists in proteomics. The functional groups of the amino acid sidechains allow for such a great diversity in terms of protein charge and hydrophobicity, that a universal buffer will most probably never be available [31].

Nucleic acid-based technologies also benefit from the power of the PCR reaction, which allows the production of large quantities of target DNA in a single, reliable, and easy to do step; however, the proteomics field has nothing of the sort. Biological protein mixtures are characterized by a great diversity of proteins in chemistry, shape, and size, and, most importantly, by their range in abundance. Some proteins can be found in quantities as low as one protein per cell, while others up to several million per cell [32]. Despite the great selectivity and sensitivity of mass-spectrometers, no instrument available today can solve such complexity of range in a single measurement. Thereby, various fractionation strategies must be used in order to improve the depth and coverage of proteomic analysis [33].

3.1. The Good

Usually, methodologies for bottom-up proteomic sample preparation include the extraction of proteins from the biological matrix, removal of the nonprotein contaminants such as DNA, sugars, and lipids, removal of the residual salts that may form adducts during ionization, and protein fractionation to reduce sample complexity.

Bottom-up proteomics utilizes unfolded proteins that allow for easy access for proteases since amino acids are more readily available, thus, generating more peptides for MS analysis. In this case, tissue or cell lysis is performed directly in a buffer containing strong denaturants (such as urea or guanidine) and ionic detergents (sodium dodecyl sulfate, SDS, or deoxycholate-SDC). In addition, nonionic zwitterionic detergents (such Triton X-100, NP-40, digitonin, or CHAPS) further help solubilize membrane proteins and can be used when less denaturing conditions are required [34]. Depending on the sample, sometimes protein depletion or enrichment is a crucial step—usually mandatory for serum or plasma samples where albumin represents more than 50% of the proteins. Several methodologies are available for removing high-abundance proteins [35,36] or for enriching cell surface proteins [37], phosphoproteins [38], or various enzyme subclasses [39–41]. The techniques that provide the highest selectivity and sensitivity for the low abundant proteins are affinity chromatography [42] and immunoprecipitation [43], but their applicability depends on the availability of affinity supports or antibodies, as well as the quality of said antibody for the target protein.

For the removal of small molecules that may have originated from the biological sample or were added in the extraction/depletion/enrichment, many methods are available, including dialysis, buffer exchange, size exclusion, protein precipitation, chromatography, or electrophoresis [44,45]. Of all the desalting methods, precipitation with organic solvents (acetone or methanol/chloroform) is the least expensive, simplest, and most scalable option for desalting proteins prior to MS analysis [20].

Two forms of gel electrophoresis, SDS-PAGE and 2D-PAGE, have been extensively used in proteomics analysis as they solve two problems simultaneously—they remove salts, detergent, and other small molecules from the sample and they fractionate the proteins based on apparent molecular mass (SDS-PAGE) or charge and apparent molecular mass (2D-PAGE). SDS-PAGE has the advantage that it is inexpensive, straightforward, and highly reliable. Its separating resolution is higher than size exclusion chromatography, but not as high as 2D-PAGE. 2D-PAGE has a high resolution and, with the introduction of immobilized pH gradient (IPG) strips, its reproducibility has improved considerably, becoming the method of choice for most proteoform studies [46,47]. The development of PTM-specific stains for phosphoproteins (e.g., Pro-Q Diamond) and glycoproteins (e.g., Pro-Q Emerald, Dansylhydrazine) further increased the applicability of 2D-PAGE [48]. 2D gels are very useful for de novo sequencing of proteins from organisms with no genome sequences available and can complement the identification of protein isoforms and modified proteins [49].

3.2. The Bad

When preparing a sample for bottom-up proteomics analysis, many factors can cause the experiment to fail. Some examples include incomplete lysis, incomplete solubilization of the proteins, and contamination during sample handling with compounds that interfere with the downstream analysis steps, including MS. Some of the most troublesome compounds are detergents—both the detergents used for sample solubilization and those used for cleaning laboratory glassware. Detergent-contaminated samples and foul autosampler needles and LC piping reduce column capacity and performance and have poor ionization in both ESI and MALDI [20]. Triton X-100, Tween, or NP-40 contain polyethylene glycol (PEG) chains that elute throughout the LC and overwhelm the MS detector. SDS can cause complete signal suppression at levels as low as 0.01% [50]. Not all detergents are the same—some are considered safer for mass spectrometry, such as N-octyl-beta-glucoside and octylthioglucoside [51]. Moreover, several mass-spectrometry-compatible detergents are available, such as ProteaseMax (Promega), Rapigest (Waters), PPS Silent Surfactant (Expedeon), or Progenta (Protea), which degrade with heat and in the low pH of the acid containing LC-MS buffers [20]. Compounds leaching from poor quality plastics and fittings are also common contaminants. Phthalates, for example, are known to ionize well and overwhelm the mass spectrometer. An extensive list of contaminates in mass spectrometry is provided by Keller, 2008 [52].

In many proteomic experiments, the immunoaffinity methods are used to deplete the most abundant proteins. For example, there are many methods available that deplete albumin from human serum. Although these methods allow for the identification of a larger number of proteins due to the decrease in signal suppression, there may be problems with the nonselective loss of other proteins [53].

Keratins from skin and dust are another common contaminant, which takes up detector time, clutters the raw data, and reduces the number of useful spectra recorded. Keratins are commonly introduced when casting and handling gels and gel pieces [54]. It is thereby imperative to wear gloves and scrupulously wipe down surfaces to minimize this contamination. Other frequent proteinaceous contaminants are lysozyme, DNase, and RNase introduced in the cell lysis step, bovine serum albumin and other weight marker components from electrophoresis, as well as trypsin and other proteases from the digestion step [52]. A significant amount of MS instrument time is spent sequencing peptides from these abundant contaminant proteins and not peptides from the actual sample of interest [55]. Exclusion lists have been put together in an attempt to cleverly remove the burden of these contaminants [55]; however, these lists are useless in certain instances when, for example, keratins are expected to be present in the sample to be analyzed. In this case, it is difficult to distinguish between endogenous and contaminating keratins [56].

SDS-PAGE is an easy, inexpensive method to separate proteins prior to mass spectrometry analysis; however, its separating power is not very high. Although 2D PAGE has better separating power, it is still not uncommon to have multiple proteins in the same spot [57]. Along with this, proteins with a low copy number and hydrophobic proteins are difficult to detect in 2-D electrophoresis [58].

Ultimately, difficulties in sample preparation for bottom-up proteomics analysis are a result of the huge variability of protein properties. There is an overwhelming number of methods and technologies available, each tailored for specific samples and protein groups. With such variety to choose from, one will have a hard time deciding which method to pick and how they should adapt it to fit the specific sample. Moreover, most of the methodologies are long, multistep preparations that are prone to losses, biases, and contaminations, while being extremely time-consuming and labor-intensive. In the end, all of this ultimately contributes to poor reproducibility of the current sample preparation and fractionation methods [59].

3.3. The Future

Ideally, what is needed is a reliable and universal method to extract and fractionate proteins; one that is fast, does not require detergents, requires minimal steps and sample handling, and can be automated. This may be achievable with the development of new approaches that rethink sample

preparation in bottom-up proteomics. Sample Preparation by Easy Extraction and Digestion (SPEED) is a new approach that does what its name suggests—reduces sample preparation to three easy steps: (1) acidification with pure trifluoroacetic acid (TFA) to lyse cells and extract proteins, (2) neutralization with TRIS base, and (3) digestion with proteases to generate peptides [59]. All steps and buffers required for sample preparation can be integrated for a straightforward and possibly automated sample preparation. Depending on the protein digestion mechanism, three types of integrated sample preparation methods are emerging: (1) in solution digestion, (2) immobilized-enzyme-reactor, and (3) on bed digestion methods [60]. Integrated in-solution digestion methods include filter-aided sample preparation (FASP) that repurposes centrifugal ultrafiltration concentrators in order to remove detergents, perform protein cleavage and isolate peptide fractions [61,62]. Derived from FASP, an encapsulated in-StageTip (iST) device has an enclosed tip chamber with an inserted membrane where lysis, denaturation, and alkylation take place [63]. The membrane serves both as a filter and as separation support. NanoPOTS are microfluidic chip devices that use nanodroplet-based processing methods. They allow in-solution digestion and processing of single cells and are reproducible [64]. Immobilized enzymatic reactor (IMER) methods make use of special columns that contain immobilized trypsin and can be directly coupled to LC-MS system for automated protein digestion and online LC-MS/MS analysis [65]. On-bead digestion methods perform reduction, alkylation, and digestion steps on functionalized beads by trapping proteins into a very limited void volume. Suspension trapping (STrap) is a method that uses tips packed with a quartz or glass filter and a hydrophobic C18 layer to perform sample clean-up and protein digestion in one step [66]. Single-Pot Solid-Phase-enhanced Sample Preparation (SP3) uses paramagnetic beads for the same purpose [67] and can be easily automated using a liquid handling robot [68]. These methods can be easily automated and integrated.

4. Conventional HPLC/Modern UHPLC Fractionation

Currently, liquid chromatography coupled with mass spectrometry (LC-MS) is a common and indispensable analytical technique for proteomic investigation. This coupling initiated the development of novel ionization methods and led to a broad range of interfaces aimed at separating various biological complex mixtures [69]. Atmospheric pressure ionization (API) was the first method to directly interface a solution stream with a mass analyzer [70]. Several thermospray units were also introduced as a breakthrough for modern LC-MS [71,72].

4.1. The Good

The main applications of HPLC in proteomics are rooted in the concept that peptides can be separated over a time and buffer gradient. This allows for maximum identification by the mass spectrometer, helps with the problem of ion suppression from coeluting peptides, and helps in the identification of the individual protein sequence. Significant research has been aimed towards developing HPLC methods to enable the resolution and identification of all generated peptides from digested proteins in a given proteome. This is a difficult task for many reasons. For example, a serum proteome may contain up to 20,000 proteins with a concentration dynamic range of 10^{11}, which, by proteolytical digestion, may result in more than 600,000 peptides [73] excluding PTMs. Fractionation of such complex peptide mixtures is a critical aspect of their mass spectrometric identification. The general principle of HPLC fractionation of complex peptides mixtures is based on their interaction with a stationary phase (column) and a mobile phase (solvent gradient elution). The three major HPLC modes developed for peptide fractionation or sequential separation utilize differences in peptide size (Size-Exclusion Chromatography (SEC)), net charge (Ion-Exchange Chromatography (IEX)), or hydrophobicity (Reverse-Phase Chromatography (RP-HPLC)) [74,75].

The well-established proteomic methods approaching structural characterization of proteins (top-down and bottom-up approaches), have led to the use of HPLC methods in a particular mode [76]. For example, SEC [77] was used in top-down approaches to study intact proteins as a favored method for size-based separation. SEC has been mostly selected to analyze antibody–drug conjugates

to determine their purity [78] and to purify recombinantly expressed proteins [79]. Since SEC is considered a low-resolution chromatographic method that requires diluted samples, the SEC technique was employed in a combination of columns with different pore sizes to achieve sufficiently high resolution in the separation of a complex protein mixture with a broad molecular weight range (10–223 kDa) [80].

Moreover, the combination of SEC with RP-HPLC, in a two dimensional (2D) separating platform exceeded a one-dimensional (1D) RP-HPLC experimental run with 4044 more unique proteoforms identified in a sarcomeric protein mixture [80]. This multidimensional HPLC was introduced as a shotgun approach to analyze very complex protein or peptide mixtures without performing gel electrophoresis, but achieving the same separating resolution as bidimensional gel electrophoresis (2D-PAGE) [81]. In the so-called multidimensional protein identification technology (MudPIT) [82,83], a protein mixture was subject to specific enzymatic digestion, usually using trypsin and endoproteinase LysC, and the resulting peptide mixture was separated by strong cation exchange (SCX) and reversed-phase high performance liquid chromatography (RP-HPLC) [84,85]. A combination of HPLC, liquid phase isoelectric focusing, and capillary electrophoresis was reported as a multimodular approach for obtaining a better separation of complex protein mixtures [86]. Recently, the large dynamic range and complexity of human cancer cells was overcome by employing a 2D separation using a high pH and low pH reversed-phase liquid chromatography technique, and 2778 proteoforms from 628 intact proteins were detected [87].

RP-HPLC is used in most bottom-up proteomic experiments for separating proteolytically generated peptides due to its high peak capacity, reproducibility, and robustness [88,89]. Both bottom-up and top-down proteomics approaches are fully dependent on employed separation technologies to: (i) provide large-scale proteome coverage in a given time; (ii) accomplish higher analytical throughput; and (iii) cover a broad dynamic protein concentration range, including trace amounts of distinct proteins. Many proteomic approaches use a IEX/RPLC [90,91] combination where octadecylsilanes (C18) remains the preferred RP ligand and the choice of ionic ligands experimentally depends on the class of peptides to be enriched and/or fractionated.

The development of an HPLC column with an "ideal and perfect" peptide/protein separation capability is an important, continuous research objective. The main types of analytical columns currently used in proteomics research present different characteristics with regard to the material composition and particle size packed into it, and the length and diameter [92]. Remarkable separation of complex peptide mixtures in proteomic studies was achieved using nano-LC/UPLC and capillary columns containing packed alkyl bonded C8 or C18 [93] and silica-based monolithic capillaries [94,95]. In proteomic analysis, the ability to handle very small amounts of biological material is crucial. Miniaturized HPLC separation systems have been developed by using fused silica capillary columns [96,97] or chip-based devices [98–100]. Monolithic capillary columns (and other columns, such as C8 or C18 columns) can be produced in the laboratory without the need of expensive media, packing solvents, and high-pressure packing instrumentation with the proper training [101]. Even if reproducibility issues of published protocols to produce such columns were reported, they remain cost-efficient and depend on the researcher's capability to pack it perfectly.

Separation time is an important factor in nanoflow LC/tandem MS technologies, which has been shown by Mann et al. [102] where the results on the yeast proteome were compared using different mobile-phase gradient running times, identifying 5806 peptides in 140 min and 13,682 peptides in 480 min. Furthermore, improved fractionation in chromatography was shown as a straightforward approach to separate coeluting peptides and the pH of the mobile phase was shown to have an important impact on the retention, selectivity, and sensitivity of the separation [103].

In 1997, MacNair introduced a hybrid stationary phase for ultrahigh-pressure reversed-phase liquid chromatography (UHPLC) for rapid separation [104]. The difference between UHPLC and traditional HPLC is that UHPLC uses smaller diameter packing material in the column and higher pump pressures than HPLC. In UHPLC separation, the size of the particles is usually approximately

1.7 µm in diameter, versus the 3–5 µm diameter of HPLC column particles and requires a pressure of up to 1000 bar, versus the 50–600 bar range that is typical in HPLC instruments [105]. UHPLC has raised the level of performance of the separation with significant gain in resolution, speed, and sensitivity. The use of UHPLC doubled the peak capacity and increased the separation speed over nine-fold and the sensitivity by three- to five-fold, as compared with an HPLC run [106]. The problematic thermal effect occurring in the column by using high pressure in UHPLC system was overcome by their narrower diameters. However, as column diameters decrease, technical problems such as (i) sealing the LC system to resist leakage, (ii) very high backpressures at high flow rates, and (iii) contamination were reported. In terms of primordial advantages of UHPLC over HPLC, there is the faster speed and less solvent consumption, but its evident disadvantage is the price [107].

4.2. The Bad

A problem that remains in part unresolved by liquid chromatography is membrane protein solubility, which requires the use of special solubilization agents such as acidic solvents, detergents, and/or chaotropes that need to be diluted or even removed prior to proteolytical digestion or mass spectrometric analysis [108].

To optimize fractionation protocols using multidimensional separation, several factors need to be considered, including the impact of ionic strength, buffer capacity, pH response on the retention time behavior, and peak shape of proteins or peptides [109]. Moreover, when using multiple SCX /HPLC separation, the elution of the peptides from the SCX column is not precise and the same peptide will appear in several of the subsequent HPLC runs, reducing the amount of that peptide and thus decreasing the sensitivity. In samples that are too complex/concentrated, the first few buffer injections will contain the majority of singly charged peptides and di/triprotonated peptides are usually not trapped [110]. The major obstacle for liquid chromatography in using multiple parallel columns is adjusting the hardware and/or software to work in a synchronic manner. The price of the columns and their stability is not to be neglected. Future contributions in column technology require important developments so that LC is not restricted to the conventional single-column fractionation methods.

Broadly, pharmaceutical and clinical laboratories seem to be willing to sacrifice resolution to gain analysis speed. This sacrifice may not be acceptable in fundamental research when analyzing complex peptide/protein mixtures to provide data for developing novel drugs or when identifying new biomarkers with diagnostic purposes. HPLC/UHPLC will continue to be a pivotal analytical technique that, in combination with high resolution mass spectrometry, will further raise the level of performance with significant increases in resolution, speed, and sensitivity required for elucidation of complex biological of proteomes [111].

4.3. The Future

HPLC/UHPLC-MS will remain very useful in "omics" sciences and reference methods will be developed, but the transition to various clinical applications is more desired. In recent years, immunoassays have been progressively replaced by HPLC-MS due to higher sensitivity, significantly less false positives, and the reduced costs of used reagents because multiple analytes can be measured simultaneously [112]. On the other hand, some drawbacks of HPLC-MS analysis include the high cost of instrumentation and the necessity for the initial method development and rigorous validation. As of today, universal chromatographic methods are not available, and each laboratory has to develop their own methods critically depending on their available infrastructure. The improvement of proteome coverage by first reducing sample complexity via chromatography will be a great challenge to researchers. One important requirement that gets increasingly supported by the literature is the fact that the current column hardware is no longer adequate to maintain the very high efficiencies and small peak volumes produced by the high-quality particles (continually smaller) and high-quality packing procedures. The proteomics field has also been utilizing very slow microflow rates in order to increase sensitivity, which cuts down on buffer costs, but also increases analysis time [113].

As several method parameters, such as pH, temperature, buffer concentration, and gradient time are varied simultaneously, a revolutionary software that predicts chromatograms based on HPLC method development is desired to determine the behavior of the separation. This is necessary in order to optimize complex sample separation and to economize resources spent developing and running wet lab activities. With the help of bioinformatics developments, in silico chromatography will be of great help in the near future to predict LC experimental flows for avoiding time, solvent, and sample consumption normally used in optimizing protocols for complex biological peptide/protein mixtures. Recently, a predictive algorithm of peptide and protein retention times in reversed-phase chromatography [114] was reported as a complementary experimental tool for proteomics.

5. MS Analysis: Instrumentation

MS-based proteomics is one of the chosen methods for complex protein sample analysis. It has established itself as a superior technology for complete characterization of proteins [29]. It is widely used for sequence analysis, protein–protein interactions, and identifying PTMs [29]. In general, a mass spectrometer consists of an ion source to ionize the analytes, a mass analyzer to measure the mass to charge ratio (m/z) of the analytes, and a detector that detects the number of ions at each m/z value. Electrospray ionization (ESI) is a commonly used technique to ionize peptides or proteins for MS analysis [115]. It ionizes a liquid solution of sample and hence can be coupled to liquid chromatography for separation [29,115]. There are four different type of mass analyzers used in proteomics: ion trap, quadrupole, time of flight (TOF), and Fourier transform ion cyclotron (FT-MS). These analyzers are the key to maintain sensitivity, mass accuracy, resolution, and to generate information rich ion mass spectra (MS/MS spectra) from peptide fragments [116]. They can be used individually in instruments or combined with each other to take advantage of the strengths of each [29,116].

It is also necessary for peptides be broken up further before being analyzed by the mass spectrometer, by a process known as dissociation. Different dissociation techniques exist for mass spectrometers, including (1) collision-induced dissociation (CID), (2) electron-capture dissociation (ECD), (3) electron-transfer dissociation (ETD), and (4) higher-energy collisional dissociation (HCD).

5.1. The Good

There is a diverse range of MS instruments that cover many possible applications in proteomics. Recent developments in the instrument design have led to new ion activation techniques as well as allowing for lower limits of detection. It has also increased the ability of tandem mass spectrometry for peptide and protein structure elucidation by improving the understanding of gas-phase ion chemistry [117]. In addition, the dynamic range of instruments allows one to optimize LC-MS and LC-MS/MS methods such as Data Dependent Analysis (DDA), Data Independent Analysis (DIA), Selected Reaction Monitoring (SRM), and Parallel Reaction Monitoring (PRM).

DDA is a common data acquisition strategy that selects the most abundant precursor ions for MS/MS analysis [118]. It takes the selection of peptide signals forward for fragmentation and matches them to a predefined database. The method allows for minimal selection of redundant peptide precursors [119]. The semirandom peptide sampling phenomenon in a DDA method has shown to increase the rates at which new peptides are identified, especially during replicate analysis. However, the reproducibility of the low abundant peptides between the runs, remain a challenge in the random sampling situation [118,120].

DIA is a method in which all the peptides within a defined m/z frame are subjected to fragmentation [121]. This method allows for accurate peptide quantification without being restricted to profiling only the predefined peptides of interest. In addition, DIA has the potential to overcome the random sampling problem and to reproduce and quantify low abundant peptides [121]. DIA offers several advantages over DDA for characterizing complex proteins. Unlike DDA, which sequentially detects, selects, and analyzes the individual ions, DIA systematically parallelizes the fragmentation of detectable ions within an m/z window, regardless of their intensity, thus providing a broader dynamic

range of detected signals, improved reproducibility for identification, better accuracy and sensitivity for quantification, and enhanced protein coverage [122].

SRM is an MS-based technique for quantitative analyses. It is a nonscanning technique where selectivity is increased through fragmentation [123]. This method has the benefit of being able to control error rates in discovery proteomic experiments and can efficiently generate specific and quantitative assays for a large number of proteins and their PTMs by being both cost and time efficient [124]. It serves as a benchmark to all time segment methods [125]. PRM is another targeted method of quantitation performed using high-resolution mass spectrometers such as quadrupole-Orbitrap (q-OT). The development and application of higher-energy collisional dissociation (HCD) fragmentation enables MS/MS spectra to be acquired in the Orbitrap analyzer with high mass accuracy and high resolution. HCD is a beam-type collisional dissociation similar to the dissociation achieved in QQQ as well as QTOF mass spectrometers. An advantage of using q-OT is that both the discovery and targeted experiments can be performed on the same instrument, and it is convenient to transfer instrumental parameters such as collision energy, retention time, quadrupole isolation window, etc. [126]. This approach enables the acquisition of full MS/MS spectra of a targeted peptide with high mass accuracy and resolution, thus quantifying highly specific proteins. Similar to SRM, PRM can also validate the abundance of proteins and their PTMs [126]. While SRM and PRM are comparable, PRM is the most suitable for an attomole-level detection and quantification of multiple proteins in a complex sample [127]. Its simple and straight forward acquisition method in addition to its high selectivity and specificity of data acquired from high resolution and high mass accuracy makes it a powerful quantitation method [128]. Thus, one can choose from one of the previously mentioned methods based on their specific needs and optimize these methods in the instrument in order to acquire data in a short period of time with accurate peptide quantitation.

Recently, the combination of the linear ion trap with the Orbitrap analyzer has benefitted the advances in high resolution MS greatly [129]. It can achieve high mass resolutions within a fraction of a second, which is important in both qualitative and quantitative applications. Moreover, it allows for the identification and quantification of a compound even in the presence of a background ion that has a nominally identical mass [129]. Complementing the ion trap and Orbitrap combination, the quadrupole mass filter was coupled to an Orbitrap analyzer known as the "Q Exactive" instrument, which features fast collision-induced dissociation peptide fragmentation with high energy because of parallel filling and detection modes, and features high ion currents because of an S-lens. This combination aids multiplexed operation at the MS and tandem MS levels, enabling joint analysis of HCD fragment ions in the Orbitrap analyzer and fragmentation of different precursor masses by the quadrupole analyzer, overall making Q Exactive an exciting instrument for proteomics [129]. SWATH-MS is a DIA–LC-MS technique that has become prominent for quantitative proteomics mainly due to its high quantitation accuracy, increased peptide coverage, generation of a digital map, and excellent reproducibility. In addition to that, it also permits qualitative analyses and allows for small molecule applications such as forensic analysis and the identification of metabolites and metabolomics [130]. MS instruments are usually compared to Nuclear Magnetic Resonance (NMR) instruments because they are expensive and require regular maintenance and troubleshooting. However, the robustness, the relative simplicity of sample preparation steps, high-throughput analysis, and sensitivity of MS remains unmatched [131,132].

Ion mobility mass spectrometry (IM-MS) uses electric fields to drag analytes through a buffer gas, separating the analytes whilst providing structural information, and has had many improvements in recent years [133]. The extra dimension that ion mobility provides increases the peak capacity in LC-MS workflows [134]. It is most common to couple a TOF mass analyzer with ion mobility; however, other analyzers can be used.

5.2. The Bad

Mass spectrometers are very expensive, delicate, and require a significant amount troubleshooting and maintenance. Although they are known to produce extensive information on proteins, the abundance of data can give rise to negatives, false positives, and unassigned spectra. There is a dynamic range of instruments to cover all possible applications; however, there is not one specific instrument that can perform all kinds of experiments [132]. MS detection oscillates with the concentration range of 10^4 and 10^5 and sometimes even 10^7. Overall, the complexity, dynamic range of biological samples, and low abundance of disease-specific biomarkers remains a major challenge for proteomic biomarker discovery, and there is no MS instrument that can simultaneously address these challenges efficiently [135]. In addition, complete characterization of the proteome both quantitatively and qualitatively remains a challenge [136]. These problems can be remedied by reducing the sample complexity before introduction into the MS. Another major challenge is the analysis of a large number of samples in clinical studies or discovery proteomics where there is often experimental variability among the clinical samples. Additionally, the impact of single nucleotide polymorphisms (SNPs) on proteome analysis has still not been fully investigated [136]. Proteomics experiments for hundreds of samples are expensive and time consuming [132]. Very few proteomics techniques allow for high throughput analysis while simultaneously maintaining the sensitivity and robustness. DIA/SWATH, as mentioned above, is an alternative for proteomic analysis of clinical samples on a large scale [132,137].

5.3. The Future

Although mass spectrometers have the upper hand concerning their high throughput analysis and robustness, there is a need for MS with better sensitivity, resolution, and accuracy for analyzing samples such as proteins in the blood plasma. This will further allow the instrument to detect low-abundance proteins and their PTMs or interacting partners [132]. In addition, conventional MS has trouble resolving multiple charge states for species such as protein complexes of several hundred kilodaltons, especially for heterogenous samples such as heavily glycosylated proteins. Instruments such as charge detection mass spectrometry (CDMS), a variant of MS can help overcome such complexities by allowing the detection of m/z and charge states, making it easy to determine the mass of ions in a sample [138]. Advances in MS methods will aid in improving the chances of biomarker discovery for MS-based proteomics. Bottom-up proteomics is the workhorse for proteomic analysis. The middle and top-down approaches must advance in order to completely characterize the protein isoforms as well as the PTMs [136]. Overall, continued improvements are needed in both MS methods and technology in order to overcome the aforementioned challenges.

6. Analysis of Mass Spectrometry Data

Analysis of MS data proves to be a limiting factor in many proteomics experiments. Although direct analysis of the raw data can be very useful, this practice can be tedious and time-consuming. There are many different software pipelines available for a more high-throughput and time-efficient approach; however, these programs have a great number of limitations. Although there are still many obstacles to overcome, in recent years, the limitations in proteomic data analysis have lessened, and high-throughput data analysis continues to improve tremendously.

It is important to understand the basics of peptide fragmentation before one can grasp a firm understanding of the current problems in proteomic data analysis, since most problems arise from lacking complete sequence information for many proteins. Peptides produced by enzymatic (i.e., trypsin) digestion will have between 5 and 20 amino acids. During collision-induced dissociation (CID) MS/MS fragmentation, the peptide is fragmented into many smaller fragment ions. In CID, these fragments are called y ions and are numbered from y1 (the C-terminal amino acid) to y(n), where (n) is the maximum number of amino acids in the peptide. A second type of ion in CID is the b ion. These ions start from the N-terminus, and end at the C terminus of the peptide. Both y

and b ions are produced through fragmentation at the peptidic bond—the weakest bond in peptides (Figure 2). Additional ions are also produced in CID and observed in MS/MS: a and c (and b) ions from the N-terminus of the peptide and x and z (and y) ions from the C-terminus of the peptide (Figure 2). Predictability of peptide fragmentation (and production of the y, b, and a ions) allows for identification of peptide sequences using the de novo sequencing and in almost any database search algorithm. Different dissociation techniques produce different types of fragment ions. For example, ECD is complementary to CID as it provides more extensive sequence coverage. Disulfide bonds are preferentially cleaved in this method, and PTMs tend to stay intact; however, this method is specific to FTICR MS instruments [139]. Similarly, ETD fragments in the same type of way, creating longer c and z-type ions and preserving PTMs, but instead uses an RF quadrupole ion trapping device [140]. If used together, these dissociation techniques can give complementary information.

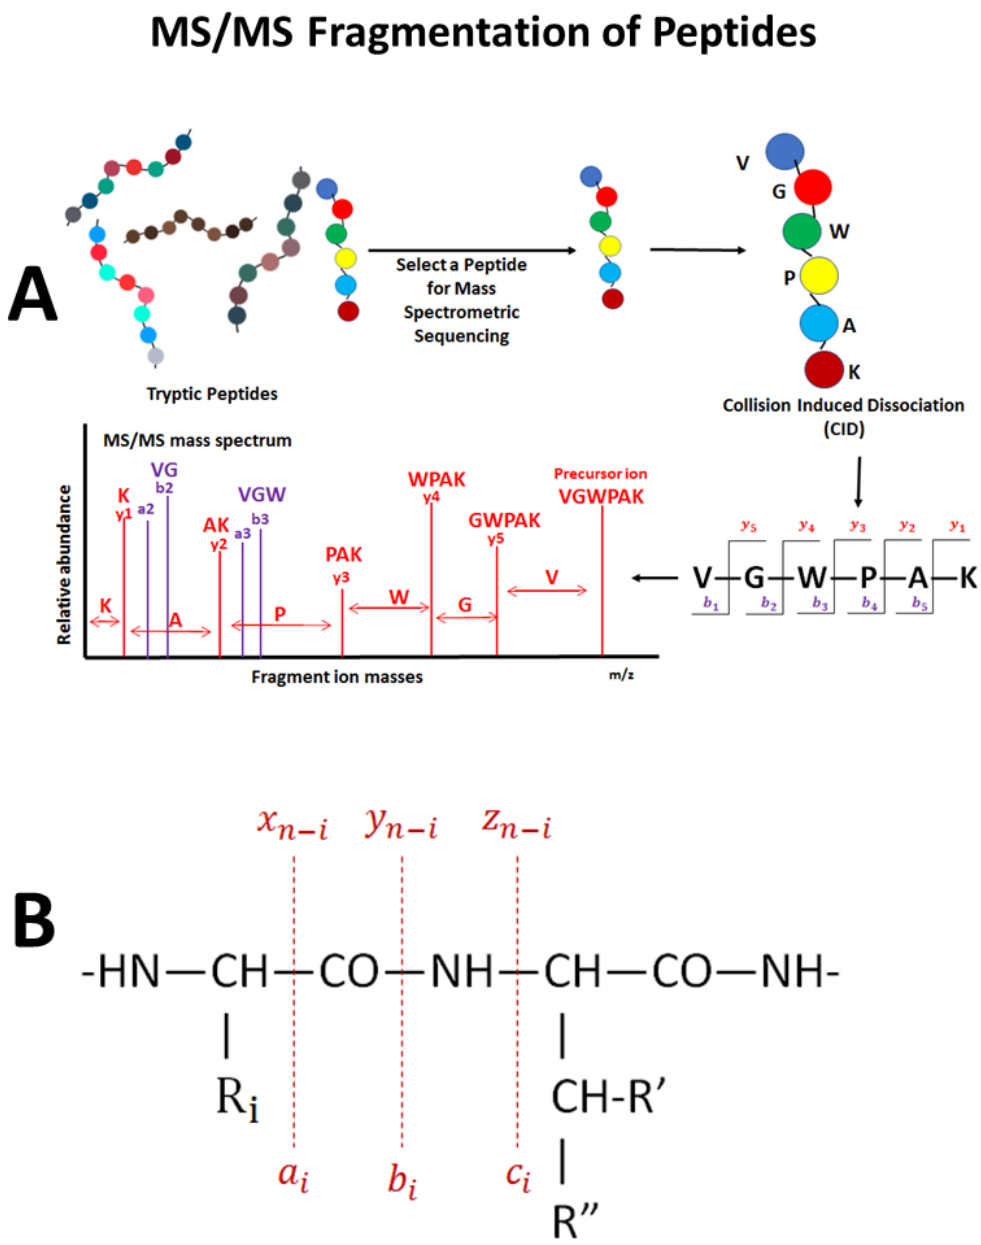

Figure 2. Correspondence between the peptide's amino acid sequence and the fragment ion peaks that are produced in MS/MS (**A**) and the major theoretical fragment ions that are produced from fragmentation of a peptide (**B**).

A particular advantage in proteomics-based analysis is that one protein upon enzymatic digestion can produce many peptides that can be useful in both identification and characterization of that protein. For example, if a protein can theoretically produce 50 peptides that can be analyzed by MS, only a few of those peptides are needed to identify that protein. These peptides can be native peptides and modified peptides (i.e., with Methionine oxidized), or can be native peptides with a different charge state. In addition, identification of these additional charge states for one peptide or unmodified and modified peptides can be particularly useful in characterization of that protein. For example, most therapeutic proteins have at least one or two methionines within their sequences. Knowing whether they are oxidized or not may be useful for long-term storage of those proteins since a methionine does not oxidize if it is buried inside the protein because it is not exposed to solvent. Having two or three charges may be useful in de novo sequencing, when the number of charges indicate the number of amino acids that can be protonated (i.e., only Arg, Lys, and His are/can be protonated).

6.1. The Good

In a typical proteomics experiment, the raw data file is usually dependent on the MS instrument used and it should be first converted into a universal, readable file. More often, this file is a peak list and will concisely show the mass to charge ratio of precursor ions with their relative intensity and charge, as well as the mass to charge ratio of its fragment ions and their relative intensities. OmicX is an online a resource that lists different -omics software. Once the readable file is obtained, it can be submitted for a search against a target database containing theoretical peptide sequences. These sequences are generated by computationally performing theoretical digestions and MS/MS analysis of all the possible proteins/resulting peptides from a given genomic dataset. The search output is a list of peptide-spectrum matches (PSMs) that are used to identify individual peptides. The PSMs are then further used to infer the identity of proteins present in the sample [141]. Such searches can be performed through PLGS or through other programs such as Mascot (Matrix Science, London, UK), which has a subset of programs like the free Mascot Server, Mascot Daemon, Mascot Distiller, and Mascot Parser. This program can be used for protein identification and scoring. In this software, it is also possible to set the parameters to search for certain PTMs based on the mass shift. It is also possible to customize PTM searches to match specific experiments. In 1993, the Yates lab proposed a method that could be used to correlate mass spectral data with a predicted amino acid sequences in a protein database [142]. Following, a program known as Sequest came into the works [143]. PEAKS (Bioinformatics Solutions Inc, Waterloo, ON) is another protein identification software that also has a de novo sequencing function. Comet [144], is another search program which became publicly available in 2012. For experiments requiring relative quantification and statistical analysis, programs such as Scaffold (Proteome Software Inc., Portland, OR, USA) can be utilized. MaxQuant is an important quantitative software that is freely available [145].

Although typical database and spectral library searching are the main tools used for proteomic data analysis, in some instances, de novo sequencing of the raw MS/MS spectrum data is used to identify peptides in instances of novel proteins, mutations, and PTMs. This approach involves acquiring the data and determining mass and composition of peptides directly from the MS/MS spectrum and predicted fragmentation [146]. Current de novo sequencing algorithms include PEAKS [147], Lutefisk [148], PepNovo [149]. Mascot Distiller [150], Protein Prospector [151], Novor [152], UniNovo [153], and PeptideProphet [154].

Proteogenomics, first seen in 2004, in an approach that uses genomic and transcriptomic sequence information as a reference for MS/MS spectra to identify novel peptides [155]. Some examples of proteogenomic approaches include six-frame translation, ab initio gene prediction, and expressed sequence tags. The ability to pair genomic, transcriptomic, and proteomic methods has been the key factor in many discoveries [156–159].

The alignment of amino acids in proteins from different species can be a beneficial characteristic in proteomic analysis. If a well-developed protein database does not exist for a certain species, protein

databases of similar species can be used. The protein hits that are obtained from these other databases can be used as a reference to determine what proteins are present in the species of interest; therefore, databases can be utilized that may not be specifically for the species of interest [160,161]. PEAKS software has a SPIDER algorithm that allows for cross-species homology search and detection of peptide mutations [147].

Many different approaches exist for quantitative proteomics experiments. In a simple, label-free method, a known concentration of an internal standard peptide can be spiked into samples prior to mass spectrometry analysis [148]. Likewise, an external standard peptide sample can be run in between samples on the mass spectrometer, and if the spectral count intensities of the standard runs are the same, the spectral counts/intensities of peptides in the actual samples can be compared as a relative quantitation [162–165]. In this case, the standard acts as proof that running conditions are identical enough that relative quantitation using spectral intensities can be used. There are also many available software for label-free quantitative proteomics, including MapQuant, MZmine, MsInspect, OpenMS, MSight, SuperHirn, and MaxLFQ [166–172]. The advantage of these types of analysis is that they are affordable and time-efficient. This type of quantitation works well enough for pilot and preliminary studies, but findings should be confirmed later using a more precise, reliable method. Labeling methods for quantification are also abundant, including methods such as isotope-coded affinity tag (ICAT), stable isotope labeling by amino acids in cell culture (SILAC), $^{15}N/^{14}N$ metabolic labeling, $^{18}O/^{16}O$ enzymatic labeling, isotope coded protein labeling (ICPL), tandem mass tags (TMT), and isobaric tags for relative and absolute quantification (iTRAQ) [173]. The absolute quantification (AQUA) method allows for the precise determination of protein expression and even post-translational modification levels by mimicking the exact peptide of interest, with the exception of stable isotope enrichment [174].

6.2. The Bad

The aforementioned type of proteomic data analysis is based off the premise that peptides are identified by matching their m/z information to a library of known proteins and their theoretical fragmentation. Similarly, peptides can be identified by matching MS/MS spectra against a library of theoretical spectra for that cell, tissue, organism, etc. which is a slowly growing practice. Therefore, it is assumed that all protein-coding gene sequences are known and well-annotated, and that all proteins encoded by these sequences exist in a database. Such databases include NCBI RefSeq or UniProtKB [175]. Unfortunately, this assumption is far from reality. The PTMs are not easily identifiable from genetic data; therefore, most modified peptides for the proteome of most organisms do not exist in a protein database, which makes proteomic data analysis a tricky task to tackle. As previously stated, de novo sequencing is a method that can be used in this instance. Although de novo sequencing is a very thorough type of analysis, problems with this technique include incomplete peptide fragmentation and low mass accuracy. These problems have been improved slightly in the most current software, but not totally. The downfall of proteogenomic approaches like six-frame translation, ab initio gene prediction, and expressed sequence tags is that they make very large reference databases that can sometimes be hard to work with [175].

Although the alignment of amino acids between different species can be beneficial, it can also be a complication in data analysis because most peptides are not unique to one specific protein or proteome. The NCBI Basic Local Alignment Search Tool (BLAST) shows regions of similarity between protein sequences [176]. Proteins of two different species can have more than 99% alignment of amino acids if they are closely related and can still have much more than 80% alignment if they are distantly related. The quality of alignment and conservation of sequences between proteins is interesting because it can hint towards species homology; however, it can be a complication when analyzing proteomics data.

When trying to perform quantitative proteomics experiments, the tools needed for a reliable analysis can be expensive. The cheapest way to quantify peptides is a label-free approach; however, variable running conditions for the mass spectrometer can lead to errors [177]. The amount of

instrument time required for technical replicates is also a downfall when it comes to label-free approaches. In addition, it is not possible to accurately quantify the relative abundance of different peptides since these molecules have different physicochemical properties and thus will behave differently under mass spectrometry conditions [178]. The different labeling methods for quantitative proteomics also have their flaws. For example, ^{15}N labeling relies on the number of nitrogen atoms present in the proteins, which is variable and can complicate analysis. A disadvantage of the SILAC method is that its cell culture origin limits its capabilities [178]. A universal problem with most labeling approaches is that there may be incomplete labeling of the peptides, which would cause errors in the quantitative analysis.

6.3. The Future

One of the major problems that needs to be addressed in proteomic data analysis is the lack of well-annotated protein databases. It is necessary for researchers to help develop these databases so that they can be used in future proteomics studies. When using a reference database for proteomic analyses, strict, relevant search parameters should be followed to decrease the likelihood of false positives. Whenever possible, smaller protein databases should be used instead of larger ones to minimize the false positives, peptide thresholds should be set to a reasonable tolerance, and relevant PTMs should be taken into consideration. In addition, if peptide identifications are particularly important, it is wise to verify them using the raw data spectrums.

7. False Positives, False Negatives, and Unassigned Spectra

The final and most biologically relevant result of a proteomics experiment is the identification of the proteins present in the sample. This is a two-step process that includes finding PSMs and inferring protein identity based on sequence alignments. Each step is dependent on a database, and, in each step, as the database grows larger, the probability to find peptides and hence proteins due to chance alone increases. Hits that are not actually present in the sample are called false positive identifications and used to be the most challenging problem in proteomics.

7.1. The Good

In order to assess the quality of the PSMs and hence peptide identity, the false discovery rate (FDR) was introduced as the ratio between false PSMs and total number of PSMs. The lower the FDR, the more meaningful the results. Two major strategies for calculating FDR are available: target-decoy search strategy (TDS) [179] and mixture model-based methods [180].

In TDS, fictious decoy peptides are fabricated by reversing or shuffling the protein sequence from the target database. This decoy database is also used for searches, and the FDR level is controlled based on the amount of decoy peptides found in the search output [181]. This approach is the most widely used, although it has several disadvantages. First, as the target database grows larger, so does the decoy database, which increases search time and complexity. Some strategies for reducing [182] or eliminating the decoy database altogether [183] are available and have yet to find their way into the mainstream. Secondly, decoy database searches are more often biased by different peptide features or score functions [181], but some work has been done to overcome this issue [182].

When it comes to protein inference, many effective protein inference algorithms have been developed, such as ProteinProphet, ComByne, and MSBayesPro. For quality assessment of protein identification, two methodologies are available: *p*-value-based approaches that calculate a probability parameter for each identified protein, and FDR approaches that apply a single threshold to all proteins identified [141]. Previously, one of the major sources of false positive protein identification was identification of peptides based on a reduced number of fragment ions. However, this is no longer a problem, since identification of a protein based on one peptide alone is no longer acceptable within the scientific community. This strategy clearly eliminates true identification of some proteins, but it also eliminates any doubts in the proteomics dataset.

The most commonly used computational strategy is to use database search algorithms based on searching acquired MS/MS spectra against a protein sequence database [184]. However, a large fraction of spectra remains unexplained despite a substantial improvement in the quality of MS/MS data acquired on modern mass spectrometers [184]. Novel sequences and the vast diversity of PTMSs remain unidentified in traditional database searches [185]. To develop a fast computational strategy that could be broadly applicable for searches using wide precursor mass tolerance of hundreds of Daltons (open database search), a novel fragment-ion indexing method was designed that provides orders of magnitude improvement in speed over existing tools [186]. This method implements a new database search tool called MS Fragger, which can perform open searches with variable modifications, thus identifying peptides with unknown alterations. It further allows open searches for data sets containing millions of MS/MS spectra and is applicable to data obtained from labeling-based qualitative proteomics experiments [186,187]. Open database searching offers a potential solution to the problem of inaccurate FDR estimates due to unaccounted peptide modifications in traditional narrow mass-window searches [186]. Using an independent platform tool like MS Fragger that is not limited to data from a particular MS instrument can be easily incorporated into most of the existing data analysis pipelines [186].

7.2. The Bad

A problem that will always persist in the proteomics community is false-negative identification of peptides, i.e., not detecting a peptide and a protein that contains it, for a variety of reasons. One such reason is physiological/pathological. For example, if a peptide should be identified in a sample, but it is physiologically/pathologically post-translationally modified (PTMs, i.e., phosphorylation, acetylation etc.), then the peptide is not found in any database search. While most researchers do search for common PTMs in peptides such as phosphorylation, they do not necessarily search for rare PTMs such as farnesylation, and are unable to search for unknown PTMs.

While this problem could be solved (i.e., by expanding the database search using even more powerful software), the price is relatively high and each search will require a considerable amount of time. Another factor for false-negative identification of peptides is experimental. For example, if a peptide that should be identified is modified during the sample preparation process by artificial modifications/PTMs such as methionine oxidation, tryptophan oxidation, cysteine oxidation (to cysteic acid), iodoacetamide-based modification of cysteine (to carbamydomethyl cysteine) or cysteineless peptides, or acrylamide-based modification of cysteine-containing peptides (to propionamide), then these peptides will no longer be identified in a database search, unless all these artificial PTMs are selected in a database search.

Physicochemical properties of proteins and peptides are also important and are not always considered. Hydrophobic proteins and natural PTMs in proteins are two examples of this. For example, hydrophobic peptides do not ionize well and, therefore, are not even found in the MS data. PTMs such as glycosylation and disulfide bridges can prevent trypsin cleavage and thus lead to false negative identification of peptides. An example of a peptide with a series of disulfide bridges, in which analysis of the precursor ions works well, but the disulfide bridges prevent a good fragmentation of these precursor ions, and thus leads to poor quality MS/MS spectra, was recently published from our lab [188].

Incomplete enzymatic digestions (usually trypsin) can lead to erroneous proteomics results and false negative identifications of some peptides. One such case is when one or more trypsin cleavage sites are missed. While 1–3 missed cleavages can easily be fixed (i.e., by database search with missed cleavages), peptides larger than 4–5 kDa that are produced by incomplete trypsin digestion are usually not identified, unless a specialized database is used. Furthermore, fragmentation of such large precursor ions does not produce good MS/MS spectra and therefore does not lead to the positive identification of any proteins [132].

Perhaps one of the biggest problems in a proteomics experiment is the unassigned MS/MS spectra (unpublished observations and [132]). Indeed, in a proteomics experiment, about 60–70% of the spectra are not assigned with confidence to any peptide (unpublished observations). This is true for experiments analyzing just one protein as well as analysis of a large set of proteins (unpublished observations). Again, multiple database searches that are sometimes customized can reduce the number of unassigned peptides to perhaps 50% or as low as 40% in the best-case scenarios, but there is still a lot of work that needs to be done in the area of bioinformatics and database searches.

7.3. The Future

False positive results, false negative results, and unassigned spectra can be solved only by advances in database search and superior bioinformatics analysis of proteomes, i.e., additional software that allows identification of additional peptides that correspond to previously unassigned MS/MS spectra.

8. Conclusions

MS and proteomic methods have greatly advanced the field of protein analysis for both fundamental and clinical research. There are well-established methods for sample preparation and great instrumentation (both UPLC and MS) for MS analysis. There is also a diverse variety of database search engines. However, under the assumption that a proteomics experiment is done properly, the greatest challenge that we still face is a full, comprehensive database search of a proteomics dataset. It is clear that what proteomics needs most is a better, more powerful bioinformatics support for database searching.

Funding: This research received no external funding.

Acknowledgments: We thank the past and current members of the Biochemistry & Proteomics Group for the pleasant working environment.

Conflicts of Interest: The authors declare no conflict of interest.

Computational and Statistical Analysis of Protein Mass Spectrometry Data

William Stafford Noble[1,2]*, Michael J. MacCoss[1]

1 Department of Genome Sciences, University of Washington, Seattle, Washington, United States of America, **2** Department of Computer Science and Engineering, University of Washington, Seattle, Washington, United States of America

Abstract: High-throughput proteomics experiments involving tandem mass spectrometry produce large volumes of complex data that require sophisticated computational analyses. As such, the field offers many challenges for computational biologists. In this article, we briefly introduce some of the core computational and statistical problems in the field and then describe a variety of outstanding problems that readers of *PLoS Computational Biology* might be able to help solve.

This is an "Editors' Outlook" article for *PLoS Computational Biology*

Introduction

DNA gets a lot of attention these days, in whole genome sequencing projects, genome-wide association studies, and experiments measuring transcription factor binding, chromatin accessibility, DNA methylation, and histone modification profiles. But proteins are the molecular workhorses of the cell, and proteomics—the systematic study of the complete set of proteins expressed in a given cell, tissue, or organism—is poised to become the next hot topic.

Just as next-generation sequencing tehcnology is driving the current genomics boom, so improvements in tandem mass spectrometry technology are leading to more comprehensive and precise proteomics assays. Like a short-read sequencing machine, a mass spectrometer runs 24 hours a day, producing a huge quantity of data. And like short-read sequencing data, mass spectral data sets exhibit complex dependencies and patterns of missing data. In both fields, the underlying technologies, along with the characteristics of the resulting data sets, change rapidly, requiring constant development of new analytical methods.

Strikingly, however, relatively few bioinformatics researchers work on methods for analyzing mass spectrometry data. *PLoS Computational Biology* published only two papers on the topic in 2010 [1,2]. At the Intelligent Systems for Molecular Biology (ISMB) conference, none of the designated subject areas for submitted manuscripts is relevant to mass spectrometry analysis, and over the last three years, a total of four mass spectometry papers were published at ISMB, each appearing in the "Other bioinformatics applications" category. Meanwhile, the annual American Society for Mass Spectrometry conference draws more than 6,000 attendees, and the society boasts 7,000 current members.

Some of the forces preventing people from entering the mass spectrometry research arena are social. As a field, mass spectrometry is older than genomics, and as such, the norms around the sharing of mass spectrometry data are less open. In addition, intellectual property issues, such as the SEQUEST patents held by the University of Washington, may have discouraged some researchers from entering the field.

An equally important impediment, however, is the "energy barrier" associated with starting out in mass spectrometry. In the late 1990s, microarray analysis took off with surprising rapidity, in part because the data could be fairly accurately summarized in matrix format, and manipulating matrices is familiar to computer scientistics, electrical engineers, and physicists. This is not the case with mass spectrometry data. If you show someone with no relevant background knowledge a DNA sequence or a microarray image, explaining what they are looking at will take less time than explaining to that same person what a peptide fragmentation spectrum is.

The goal of this article is to lower that energy barrier by explaining in simple terms how a tandem mass spectrometry experiment works and what are the key research problems associated with this type of data.

A Typical Shotgun Proteomics Experiment

A typical shotgun proteomics experiment proceeds in three steps, as illustrated in Figure 1A. The input to the experiment is a collection of proteins, which have been isolated from a complex mixture. A typical complex mixture may contain a few thousand proteins, ranging in abundance from tens of copies to hundreds of thousands of copies.

In the first experimental step, the proteins are digested into peptides using a protease. This digestion is necessary because whole proteins are too massive to be subject to direct mass spectometry analysis without using very expensive equipment. Second, the peptides are subjected to liquid chromatography, in which the peptides pass through a thin glass column that separates the peptides based on a particular chemical property (e.g., the hydrophobicity). This separation step reduces the complexity of the mixtures of peptides going into the mass spectrometer. The

third step, which occurs inside the mass spectrometer, involves two rounds of mass spectrometry. Approximately every second, the device analyzes the population of $\sim$20,000 intact peptides that most recently exited from the liquid chromatography column. Then, based on this initial analysis, the machine selects approximately five distinct peptide species for fragmentation. Each of these fragmented species is isolated and subjected to a second round of mass spectrometry analysis. The resulting "fragmentation spectra" are the primary output of the experiment.

A sample fragmentation spectrum is shown in Figure 1B. During the fragmentation process, each amino acid sequence is typically cleaved once, so cleavage of the population results in a variety of observed prefix and suffix sequences. Each of these subpeptides is characterized by its mass-to-charge ratio (m/z, shown on the horizontal axis) and a corresponding intensity (unitless, shown on the vertical axis). The primary analysis challenge is to infer, for each observed fragmentation spectrum, the peptide sequence that was responsible for generating the spectrum.

Peptide and Protein Identification

The Spectrum Identification Problem

The spectrum identification problem is difficult to solve primarily because of noise in the observed spectrum. In general, the x-axis of the observed spectrum is known with relatively high precision. However, in any given spectrum, many expected fragment ions will fail to be observed, and the spectrum is also likely to contain a variety of additional, unexplained peaks. These unexplained peaks may result from unusual fragmentation events, in which small molecular groups are shed from the peptide during fragmentation, or from contaminating molecules (peptides or other small molecules) that are present in the mass spectrometer along with the target peptide species.

In practice, solutions to the spectrum identification problem fall into four general categories. By far the most commonly used approach is database search. The first computer program to use a database search procedure to identify fragmentation spectra was SEQUEST [3], and SEQUEST's basic algorithm (not including the function used to score individual peptide-spectrum matches) is still used by essentially all database search tools available today. The approach is as follows. We are given a spectrum S, a peptide database P, a precursor mass m (i.e., the observed mass of the intact peptide), and a user-specified precursor mass tolerance δ. The algorithm extracts from the database all peptides whose mass lies within the range $[m-\delta, m+\delta]$. These comprise the set of *candidate peptides*

$$C(m,P,\delta)=\{p : p \in P; |m(p)-m| < \delta\}$$

where $m(p)$ is the calculated mass of peptide p. In practice, depending on the size of the peptide database and the precursor mass tolerance, the number of candidate peptides ranges from hundreds to hundreds of thousands. Each candidate peptide p is compared to the observed spectrum using a score function $\Xi(\cdot,\cdot)$. Frequently, the score function generates a theoretical spectrum for the given peptide and then compares the observed and theoretical spectra to one another. The program reports the candidate peptide that scores highest with respect to the observed spectrum:

$$\arg \max_{p \in C(m,P,\delta)} \Xi(S,p).$$

Database search methods differ primarily in their choice of score function.

An alternative to database search is de novo spectrum identification, in which the "database" of candidate peptides consists of the entire universe of possible amino acid sequences. A variety of graph-based dynamic programming methods can efficiently solve this problem, but in practice many spectra do not contain sufficient information to uniquely identify the correct peptide. Consequently, de novo identification methods generally fail to provide as many correct identifications as database search methods. Conversely, of course, de novo approaches are necessary when a peptide database is unavailable—i.e., for analysis of organims whose genomes have not yet been sequenced—or when the user is interested in identifying novel protein isoforms or polymporphisms.

Tag-based methods occupy an appealing middle ground between database search and de novo methods. Here, the basic idea is to use de novo analysis to identify a collection of subpeptides ("tags") that are hypothesized to occur in the sequence, and then extract candidates from a database that contain the tags. Tag-based methods can be quite fast, and retain the ability to partially identify spectra for which the corresponding peptide is not in the database.

Finally, so-called library search methods identify spectra by comparing them to a library of previously identified spectra. These methods suffer a bit from a chicken-and-egg problem, in the sense that you must first somehow identify the spectra that go into the library. However, once you have successfully built such a library, searching an observed spectrum against real spectra is likely to give better results than searching against theoretical spectra. The caveat is that you have to be sure that your library does not contain false positives or chimeric spectra, i.e., spectra that were generated by a heterogeneous population of two or more co-eluting peptides.

Machine learning methods have been applied extensively to the spectrum identification problem, primarily as post-processors that discriminate between correct and incorrect identifications. Using methods such as support vector machines [4], linear discriminant analysis [5], or decision trees [6], these methods can dramatically increase the percentage of spectra from a given experiment that are confidently identified. Particularly powerful are semi-supervised learning methods [7,8] that dynamically adjust their ranking scheme on the basis of characteristics of a given data set.

Protein Identification

Once the peptide responsible for generating each observed spectrum has been identified, the downstream task of deciding which proteins are present in the sample seems like it should involve a straightforward process of aggregating evidence over all the spectra associated with a given protein. Unfortunately, this task is made much more difficult by the presence of so-called degenerate peptides, i.e., peptides that occur in multiple proteins.

Protein identification algorithms have improved significantly over the last decade. Early methods used simple heuristics to identify high-confidence proteins that contain a specified number of high-confidence peptide assignments [9]. A more sophisticated version of this approach employs a parsimony argument and attempts to find a minimal set of proteins that explain the observed identified spectra [10]. The most widely used method is pseudo-probabilistic, employing an expectation-maximization-like procedure to apportion evidence from each degenerate peptide among its corresponding parent proteins [11]. Other, related approaches either handle peptide degeneracy in a similar, heuristic fashion [12–14] or ignore the degeneracy entirely [15,16]. Only recently have several groups proposed algorithms that directly solve the full protein identification problem within a rigorous probabilistic framework [17,18].

Computational and Statistical Challenges

Despite the almost dizzying array of existing methods for identifying peptides and proteins from shotgun proteomics data (reviewed in [19]), many significant analytical challenges remain. Perhaps most obvious is the need for algorithms that successfully identify proteins that are not in the database, either because they are polymorphic or because they contain post-translational modifications. The difficulty here is two-fold: how to make the search efficient, and how to successfully control the rate of false positive identifications, especially in the case when a wide variety of polymorphisms or modifications are allowed.

More fundamentally, the spectrum identification problem could likely benefit from the application of a rich, generative model of the peptide fragmentation process. Several such models have been described in the spectrum identification literature [20,21], but none take into account the relatively rich literature on peptide fragmentation (reviewed in [22]).

A source of ongoing confusion and controversy in the field is the assignment of statistical confidence estimates to spectrum, peptide, or protein identifications. Varying protocols have been proposed, based upon empirical null distributions created by searching the spectra against a "decoy" database of shuffled or reversed peptide sequences [23,24], upon procedures that involve fitting a parametric distribution to the empirical score distribution [25–27], or upon score functions for which exact p-values can be calculated under a simple zero-order Markov null model of peptides [28]. Critical assessment and comparison of many of these methods, especially with respect to potential biases incurred during evaluation of new algorithsm, is lacking in the literature. Furthermore, extending a statistic that is calculated with respect to individual spectra up to the peptide and protein levels is a non-trivial and relatively unexplored subject.

Historically, the development of tools for analyzing shotgun proteomics data has occurred in a stepwise fashion. The result is that small subtasks—assigning charge states to spectra, mapping peptides to spectra, re-ranking and assigning statistical confidence to spectrum identifications, and computing protein-level posteriors—have been solved separately. Clearly, in the long run, this piecemeal approach should be replaced by a joint model in which all relevant aspects of the experiment are taken into account. Such a joint model has the potential to model dependencies among variables at the spectrum, peptide, and protein level that are currently decoupled.

A perhaps equally challenging task is to convey the results of such a rich model to the user in a useful fashion. With current probabilistic protein identification tools, the standard approach of reporting a ranked list of proteins is insufficient. Even when we allow the list to contain groups of redundant proteins (i.e., protein isoforms that are indistinguishable on the basis of the observed spectra), crucial information about dependencies among the protein identifications is lost. For example, it is difficult to convey the information that, e.g., either protein A or protein B was present in the sample, but probably not both.

Authors' Biographies

William Stafford Noble (formerly William Noble Grundy) received the PhD in computer science and cognitive science from University of California (UC) San Diego in 1998. After a one-year postdoc with David Haussler at UC Santa Cruz, he became an Assistant Professor in the Department of Computer Science at Columbia University. In 2002, he joined the faculty of the Department of Genome Sciences at the University of Washington. He is now a Professor of Genome Sciences, with adjunct appointments in the Department of Computer Science and Engineering and the Department of Medicine. His research group develops and applies statistical and machine learning techniques for modeling and understanding biological processes at the molecular level. Dr. Noble is a member of three editorial boards, is the recipient of National Science Foundation CAREER award, and is a Sloan Research Fellow.

Michael J. MacCoss has been working with mass spectrometry instrumentation since 1994 when he was an undergraduate in a stable isotope geochemistry lab at the University of Vermont. He became interested in biomedical applications working in Dr. Patrick Griffin's protein mass spectrometry lab at Merck Research Laboratories during two summer internships in 1995 and 1996. In 2001, he completed a PhD in analytical chemistry with Professor Dwight Matthews in the development of stable isotope and mass spectrometry methodologies for the measurement of human amino acid and protein metabolism. After completing his degree, Dr. MacCoss moved to The Scripps Research Institute to work with Professor John R. Yates III as a postdoctoral fellow. Dr. MacCoss moved to the University of Washington in 2004 as an Assistant Professor of Genome Sciences, where his lab has focused on the development and application of mass spectrometry–based technologies for the high-throughput characterization of complex protein mixtures. In 2009 he was promoted to Associate Professor.

Another area where proteomics is in great need of guidance is experimental design. Proteomics experiments can be expensive and time consuming, yet most are being pursued without proper care in minimizing batch or systematic effects. Furthermore, most proteomics experiments are not powered correctly. Like gene expression analyses previouly, proteomics practices could benefit greatly from lessons learned in experimental design from classical statistics.

Protein Quantification

The next logical step, after developing methods to *identify* the proteins in a complex mixture, is to develop methods to *quantify* the proteins. Quantification provides a more complete picture of the molecular contents of the cell, and allows us to generate or test specific hypotheses regarding the relationship between protein abundance and fundamental cellular processes or disease states.

Existing methods for protein quantification fall into three categories. *Stable isotope labeling* methods [29] perform relative protein quantification by incorporating a distinct heavy isotope tag to a sample to use as an internal standard. This labeled internal standard is then mixed into one or more other samples, and the relative signal intensity of the peptide measured by the mass spectrometer is compared to the measured intensity of the same peptide containing the heavy stable isotope label. This type of approach is quite powerful but the isotopic labeling step imposes significant overhead and limits the general applicability of these methods. *Spectral counting* methods [30–33] rely on counting the number of spectra that map to a given protein across multiple experiments. Spectral counting methods are not very accurate, because these methods fail to take into account the data-dependent acquisition that leads to the selection of peptides for fragmentation. However, spectral counting is appealing because the required counts are relatively easy to compute. Finally, *peptide chromatographic peak intensity* methods [34–37] use the area under the precursor ion peak as a proxy for peptide abundance. In contrast to spectral counting, methods based on peak areas are potentially much more accurate, but these methods require highly reproducible liquid chromatography as well as accurate methods for chromatographic alignment and identification of relevant spectral features.

Most of the mass spectrometry quantification literature focuses on measuring the relative abundance of the same protein across different samples. This allows, for example, comparing protein expression across different patients, tissues, or developmental stages. More difficult is estimating the relative abundance of two proteins within the same sample. For this task, the most commonly used, low-throughput approach is to calibrate the response of an individual peptide in a targeted selective reaction monitoring method (described in the next section). For large-scale quantification of many proteins, a few methods use a standard shotgun proteomics experiment, and either use a simple learning procedure [30] or rely on the observation that the three most intense peptides ionize similarly between proteins [38,39].

Targeted Proteomics

Many high-throughput proteomics experiments aim to identify or quantify all proteins in a complex sample. In contrast, selected reaction monitoring (SRM) experiments [40,41] seek to quantify a smaller, specified set of proteins, e.g., a panel of biomarkers or members of a pathway of interest.

In an SRM experiment, the mass spectrometer is set to monitor the m/z values for a small number of peptides, as well as a specific fragment ion for each peptide. Each m/z pair, corresponding to the intact peptide and its fragment ion, is called a *transition*. Monitoring a small number of transitions, rather than scanning the entire m/z range, yields dramatically increased sensitivity relative to conventional "full scan" techniques. The goal of SRM is to select transitions that best detect the proteins of interest, subject to the constraint that such experiments can monitor only $\sim$1,000 transitions per run in an automated fashion [42]. Thus, two complementary criteria must be optimized: (1) detect as many proteins of interest as possible and (2) accurately estimate the abundance of the monitored proteins.

Existing SRM pipelines typically focus on so-called proteotypic peptides [43] that can be easily observed in a mass spectometry experiment and that uniquely identify a specific protein. A variety of methods exist for identifying proteotypic peptides, either based on empirical rules [44,45] or machine learning methods [43,46,47]. After identifying these peptides, SRM protocols typically use them as independent protein identifiers [48], with each peptide contributing equally to the evidence for that protein. What is missing is a method to search for a panel of peptides that jointly provide high quality quantification information about all of the target proteins.

Outlook

Traditionally, most proteomics analysis has been carried out using relatively inexpensive ion trap instruments, which offer fairly

low precision and accuracy on the m/z axis. Higher resolution instruments, which achieve precision of <10 ppm, were expensive and hence more rare. However, with the introduction of *Orbitrap* and improved quadrupole time-of-flight mass spectrometers [49], high-resolution instruments have become much more commonplace. Corresponding analytical methods that fully exploit the information available from high-resolution spectra have not used these data to their full potential.

In a mass spectrometer, intact peptides are characterized in an initial scan, followed by a series of secondary scans that characterize fragmented versions of the same peptides. The most common means of fragmenting peptides between the two scans is collision-induced dissociation, in which the charged peptides collide with neutral molecules such as helium, nitrogen, or argon. However, a variety of other fragmentation methods have been developed, including electron-capture dissociation, electron-transfer dissociation, and infrared multiphoton dissociation [50], and these can provide fragmentation spectra with quite different properties. More recently, some protocols have been developed to alternate between different types of fragmentation methods, with the aim of observing two complementary spectra representing each peptide [51]. Most existing analysis pipelines are tuned to handle one or two of the resulting types of spectra. Although some search engines allow users to select which types of fragmentation ions are included in the search, and some progress has been made recently toward developing score functions that can be adapted to various types of spectra [52], the field is still missing a generic analysis platform that can be adapted automatically and in a principled fashion to handle spectra produced by any given fragmentation protocol.

An interesting consideration is that as the scan speeds of tandem mass spectrometers increase, the difference between targeted and discovery proteomics will become more and more blurred. As an instrument becomes capable of collecting MS/MS spectra continuously across the chromatographic time-scale on an increasingly larger number of peptide precursors, the "m/z space" that remains unsampled will become less significant. Approaches that improve sampling by multiplexing the collection of fragmentation data are promising, but require methods to deconvolve the resulting mixed spectra. Such approaches fall under a general category known as *data-independent acquisition* because they collect their fragmentation data independently of whether a signal is observed within a particular precursor m/z window. Some initial attempts to interpret these data have shoe-horned traditional proteomics analysis pipelines to handle these data [53,54]. Other workflows that have been developed specifically for these unique data have remained proprietary and, thus, not attracted much effort from the academic community to build and improve on these analyses.

One challenge that remains is enabling computational and experimental scientists pursuing proteomics to interact effectively. Frequently, experimentalists design new experiments using suboptimal analysis tools because they do not have the skills or knowledge to pursue alternatives. Likewise, computational scientists can expend a large amount of energy developing solutions to problems that are not interesting to experimentalists. The challenge remains how to get scientists from different disciplines that are based on different cultures and who speak different scientific languages to communicate and collaborate effectively. The RECOMB Satellite Conference on Computational Proteomics is one attempt to solve this problem. Speakers are brought from both the computational and experimental backgrounds. This meeting provides a forum for experimentalists to present problems that they are facing and for computational scientists to present algorithmic and statistical approaches that they have been developing. Ultimately, we need more meetings that foster collaboration between disciplines.

D.9 Protein structure

Further explanations for Chapter 9.

D.9.1 CASP: a blind test of structure prediction

- Elofsson (2023) — A short review of what CASP15 showed after AlphaFold2: where monomer prediction stands, the progress for multimers and the categories that remain difficult. Useful as a compact account of how CASP results are read. *(review; CC BY 4.0)*

  Progress at protein structure prediction, as seen in CASP15. Elofsson (2023). *Current Opinion in Structural Biology*. doi:10.1016/j.sbi.2023.102594

  > In Dec 2020, the results of AlphaFold version 2 were presented at CASP14, sparking a revolution in the field of protein structure predictions. For the first time, a purely computational method could challenge experimental accuracy for structure prediction of single protein domains. The code of AlphaFold v2 was released in the summer of 2021, and since then, it has been shown that it can be used to accurately predict the structure of most ordered proteins and many protein-protein interactions. It has also sparked an explosion of development in the field, improving AI-based methods to predict protein complexes, disordered regions, and protein design. Here I will review some of the inventions sparked by the release of AlphaFold.

- Abriata and Dal Peraro (2025) — Summarises the CASP16 results from the point of view of a user: which kinds of targets (monomers, complexes, ligands, nucleic acids) can be modelled reliably and which cannot. Helps to translate CASP metrics into practical expectations. *(review; CC BY 4.0)*

  Practical Outcomes From CASP16 for Users in Need of Biomolecular Structure Prediction. Abriata & Dal Peraro (2025). *Proteins: Structure, Function, and Bioinformatics*. doi:10.1002/prot.70078

  > The 16th Critical Assessment of Structure Prediction benchmarked advancements in biomolecular modeling, particularly in the context of AlphaFold 2 and 3 systems. Protein monomer and domain prediction is largely solved, with barely any space for further improvements at the backbone level except for very specific details, irregular secondary structures, and mutational effects that remain challenging to predict. For protein assemblies, AF-based methods, especially when expertly guided or enhanced by servers like those from the Yang, Zheng/Zhang, and Cheng lab, show progress, though complex topologies and in particular antibody-antigen interactions are still difficult. Notably, a priori knowledge of stoichiometry significantly aids assembly prediction. Protein-ligand co-folding with AF3 demonstrated strong potential for pose prediction, outperforming many participants and some dedicated docking tools in baseline tests, but several caveats hold as discussed. Ligand affinity prediction is totally unreliable. Nucleic acid structure prediction lags considerably, heavily relying on 3D templates and expert human intervention, even AF3 showing substantial limitations. Overall, on all fronts, AF3's modeling capabilities are at or close to the state of the art; additionally, it shows slight improvements over AF2 and more detailed confidence metrics than it. We guide users on tool selection, realistic accuracy expectations, and persistent challenges, emphasizing the critical role of confidence metrics in interpreting AI-generated models.

D.9.2 Background: amino acids, energetics and enzymes

- Jakubowski & Flatt (2024) — Open textbook chapter on the chemistry of the amino acids, side-chain properties and the peptide bond; the neighbouring chapters of the same book cover protein structure and enzyme activity. Good for revising the biochemistry this section assumes. *(book chapter; CC BY-NC-SA 4.0)*

  Amino Acids, Peptides, and Proteins (Chapter 3 of Fundamentals of Biochemistry). Jakubowski & Flatt (2024). *LibreTexts Biology (open textbook)*. https://bio.libretexts.org/Bookshelves/Biochemistry/Fundamentals_of_Biochemistry_(Jakubowski_and_Flatt)/01%3A_Unit_I-_Structure_and_Catalysis/03%3A_Amino_Acids_Peptides_and_Proteins

- Jarmoskaite et al. (2020) — Explains what a dissociation constant means and the controls needed to measure it correctly, with many examples of common errors. Gives a concrete feel for the thermodynamics of binding discussed in the section. *(tutorial; CC BY 4.0)*

  How to measure and evaluate binding affinities. Jarmoskaite et al. (2020). *eLife*. doi:10.7554/elife.57264

  > Quantitative measurements of biomolecule associations are central to biological understanding and are needed to build and test predictive and mechanistic models. Given the advances in high-throughput technologies and the projected increase in the availability of binding data, we found it especially timely to evaluate the current standards for performing and reporting binding measurements. A review of 100 studies revealed that in most cases essential controls for establishing the appropriate incubation time and concentration regime were not documented, making it impossible to determine measurement reliability. Moreover, several reported affinities could be concluded to be incorrect, thereby impacting biological interpretations. Given these challenges, we provide a framework for a broad range of researchers to evaluate, teach about, perform, and clearly document high-quality equilibrium binding measurements. We apply this framework and explain underlying fundamental concepts through experimental examples with the RNA-binding protein Puf4.

- Cornish-Bowden (2015) — A short historical and conceptual account of the Michaelis–Menten equation, what kcat and Km mean and how they are often misinterpreted. Useful background for the enzyme part of the section. *(perspective; CC BY 4.0)*

  One hundred years of Michaelis–Menten kinetics. Cornish-Bowden (2015). *Perspectives in Science*. doi:10.1016/j.pisc.2014.12.002

  > The year 2013 marked the centenary of the paper of Leonor Michaelis and Maud Menten (Michaelis and Menten, 1913), and the 110th anniversary of the doctoral thesis of Victor Henri (Henri, 1903). These publications have had an enormous influence on the progress of biochemistry, and are more often cited in the 21st century than they were in the 20th. Henri laid the groundwork for the understanding of enzyme mechanisms, but his experimental design was open to criticism. He reached essentially correct conclusions about the action of invertase, but he took no steps to control the hydrogen-ion concentration, and he took no account of the spontaneous mutarotation of the glucose produced in the reaction. Michaelis and Menten corrected these shortcomings, and in addition they introduced the initial-rate method of analysis, which has proved much simpler to apply than the methods based on time courses that it replaced. In this way they defined the methodology for steady-state experiments that has remained standard for 100 years.

D.9.3 Protein structure and how it is determined

- Vénien-Bryan et al. (2017) — Compares the principles, strengths and limitations of X-ray crystallography and single-particle cryo-EM, written for readers who are not specialists in either. Helps to understand why resolution and sample requirements differ between the methods. *(review; CC BY 2.0 UK)*

  Cryo-electron microscopy and X-ray crystallography: complementary approaches to structural biology and drug discovery. Vénien-Bryan et al. (2017). *Acta Crystallographica Section F Structural Biology Communications*. doi:10.1107/s2053230x17003740

  > The invention of the electron microscope has greatly enhanced the view scientists have of small structural details. Since its implementation, this technology has undergone considerable evolution and the resolution that can be obtained for biological objects has been extended. In addition, the latest generation of cryo-electron microscopes equipped with direct electron detectors and software for the automated collection of images, in combination with the use of advanced image-analysis methods, has dramatically improved the performance of this technique in terms of resolution. While calculating a sub-10 Å resolution structure was an accomplishment less than a decade ago, it is now common to generate structures at sub-5 Å resolution and even better. It is becoming possible to relatively quickly obtain high-resolution structures of biological molecules, in particular large ones (>500 kDa) which, in some cases, have resisted more conventional methods such as X-ray crystallography or nuclear magnetic resonance (NMR). Such newly resolved structures may, for the first time, shed light on the precise mechanisms that are essential for cellular physiological processes. The ability to attain atomic resolution may support the development

> of new drugs that target these proteins, allowing medicinal chemists to understand the intimacy of the relationship between their molecules and targets. In addition, recent developments in cryo-electron microscopy combined with image analysis can provide unique information on the conformational variability of macromolecular complexes. Conformational flexibility of macromolecular complexes can be investigated using cryo-electron microscopy and multiconformation reconstruction methods. However, the biochemical quality of the sample remains the major bottleneck to routine cryo-electron microscopy-based determination of structures at very high resolution.

- Laurents (2022) — Reviews what NMR spectroscopy measures (structure, dynamics, disorder) and how it complements AlphaFold2 models. Useful for the NMR subsection and for seeing what a static prediction does not capture. *(review; CC BY 4.0)*

  AlphaFold 2 and NMR Spectroscopy: Partners to Understand Protein Structure, Dynamics and Function. Laurents (2022). *Frontiers in Molecular Biosciences*. doi:10.3389/fmolb.2022.906437

  > The artificial intelligence program AlphaFold 2 is revolutionizing the field of protein structure determination as it accurately predicts the 3D structure of two thirds of the human proteome. Its predictions can be used directly as structural models or indirectly as aids for experimental structure determination using X-ray crystallography, CryoEM or NMR spectroscopy. Nevertheless, AlphaFold 2 can neither afford insight into how proteins fold, nor can it determine protein stability or dynamics. Rare folds or minor alternative conformations are also not predicted by AlphaFold 2 and the program does not forecast the impact of post translational modifications, mutations or ligand binding. The remaining third of human proteome which is poorly predicted largely corresponds to intrinsically disordered regions of proteins. Key to regulation and signaling networks, these disordered regions often form biomolecular condensates or amyloids. Fortunately, the limitations of AlphaFold 2 are largely complemented by NMR spectroscopy. This experimental approach provides information on protein folding and dynamics as well as biomolecular condensates and amyloids and their modulation by experimental conditions, small molecules, post translational modifications, mutations, flanking sequence, interactions with other proteins, RNA and virus. Together, NMR spectroscopy and AlphaFold 2 can collaborate to advance our comprehension of proteins.

- Terwilliger et al. (2023) — Compares AlphaFold models directly with experimental electron-density maps and shows where even high-confidence predictions differ from the data. Directly relevant to the subsection on experimental structures versus predicted models. *(perspective; CC BY 4.0)*

  AlphaFold predictions are valuable hypotheses and accelerate but do not replace experimental structure determination. Terwilliger et al. (2023). *Nature Methods*. doi:10.1038/s41592-023-02087-4

  > Artificial intelligence-based protein structure prediction methods such as AlphaFold have revolutionized structural biology. The accuracies of these predictions vary, however, and they do not take into account ligands, covalent modifications or other environmental factors. Here, we evaluate how well AlphaFold predictions can be expected to describe the structure of a protein by comparing predictions directly with experimental crystallographic maps. In many cases, AlphaFold predictions matched experimental maps remarkably closely. In other cases, even very high-confidence predictions differed from experimental maps on a global scale through distortion and domain orientation, and on a local scale in backbone and side-chain conformation. We suggest considering AlphaFold predictions as exceptionally useful hypotheses. We further suggest that it is important to consider the confidence in prediction when interpreting AlphaFold predictions and to carry out experimental structure determination to verify structural details, particularly those that involve interactions not included in the prediction.

D.9.4 Protein folding

- Gianni et al. (2021) — Introduces the energy-landscape view of folding, the principle of minimal frustration and how residual frustration relates to function and disorder. A readable route from folding funnels to current ideas. *(review; CC BY 4.0)*

  Fuzziness and Frustration in the Energy Landscape of Protein Folding, Function, and Assembly. Gianni et al. (2021). *Accounts of Chemical Research*. doi:10.1021/acs.accounts.0c00813

> Are all protein interactions fully optimized? Do suboptimal interactions compromise specificity? What is the functional impact of frustration? Why does evolution not optimize some contacts? Proteins and their complexes are best described as ensembles of states populating an energy landscape. These ensembles vary in breadth from narrow ensembles clustered around a single average X-ray structure to broader ensembles encompassing a few different functional "taxonomic" states on to near continua of rapidly interconverting conformations, which are called "fuzzy" or even "intrinsically disordered". Here we aim to provide a comprehensive framework for confronting the structural and dynamical continuum of protein assemblies by combining the concepts of energetic frustration and interaction fuzziness. The diversity of the protein structural ensemble arises from the frustrated conflicts between the interactions that create the energy landscape. When frustration is minimal after folding, it results in a narrow ensemble, but residual frustrated interactions result in fuzzy ensembles, and this fuzziness allows a versatile repertoire of biological interactions. Here we discuss how fuzziness and frustration play off each other as proteins fold and assemble, viewing their significance from energetic, functional, and evolutionary perspectives.We demonstrate, in particular, that the common physical origin of both concepts is related to the ruggedness of the energy landscapes, intramolecular in the case of frustration and intermolecular in the case of fuzziness. Within this framework, we show that alternative sets of suboptimal contacts may encode specificity without achieving a single structural optimum. Thus, we demonstrate that structured complexes may not be optimized, and energetic frustration is realized via different sets of contacts leading to multiplicity of specific complexes. Furthermore, we propose that these suboptimal, frustrated, or fuzzy interactions are under evolutionary selection and expand the biological repertoire by providing a multiplicity of biological activities. In accord, we show that non-native interactions in folding or interaction landscapes can cooperate to generate diverse functional states, which are essential to facilitate adaptation to different cellular conditions. Thus, we propose that not fully optimized structures may actually be beneficial for biological activities of proteins via an alternative set of suboptimal interactions. The importance of such variability has not been recognized across different areas of biology.This account provides a modern view on folding, function, and assembly across the protein universe. The physical framework presented here is applicable to the structure and dynamics continuum of proteins and opens up new perspectives for drug design involving not fully structured, highly dynamic protein assemblies.

- Bowman (2024) — A short review arguing that predicting a single structure does not solve the folding problem, and that folding pathways and conformational ensembles remain open questions. Fits the subsection on folding and prediction. *(review; CC BY 4.0)*

  AlphaFold and Protein Folding: Not Dead Yet! The Frontier Is Conformational Ensembles. Bowman (2024). *Annual Review of Biomedical Data Science*. doi:10.1146/annurev-biodatasci-102423-011435

  > Like the black knight in the classic Monty Python movie, grand scientific challenges such as protein folding are hard to finish off. Notably, AlphaFold is revolutionizing structural biology by bringing highly accurate structure prediction to the masses and opening up innumerable new avenues of research. Despite this enormous success, calling structure prediction, much less protein folding and related problems, "solved" is dangerous, as doing so could stymie further progress. Imagine what the world would be like if we had declared flight solved after the first commercial airlines opened and stopped investing in further research and development. Likewise, there are still important limitations to structure prediction that we would benefit from addressing. Moreover, we are limited in our understanding of the enormous diversity of different structures a single protein can adopt (called a conformational ensemble) and the dynamics by which a protein explores this space. What is clear is that conformational ensembles are critical to protein function, and understanding this aspect of protein dynamics will advance our ability to design new proteins and drugs.

D.9.5 Structure comparison and evolution

- Sahakyan et al. (2025) — A brief review of methods for detecting distant relationships between proteins, from sequence profiles to structure comparison with large predicted-structure databases. Shows why structure comparison reaches further back in evolution than sequence comparison. *(review; CC BY 4.0)*

  Exploring the protein universe with distant similarity detection methods. Sahakyan et al. (2025). *Protein Science*. doi:10.1002/pro.70397

> During the last few years, the body of data on proteins is expanding almost exponentially with the development of advanced methods for gene sequencing, protein structure determination, particularly by cryoelectron microscopy, and structure prediction using artificial intelligence-based approaches. These developments create the potential for a comprehensive exploration of the protein universe, the entirety of the proteins existing in the biosphere. Elucidation of the relationships among proteins including the most distant ones, where only the core fold is shared, is crucial for understanding protein functions, folding mechanisms, and evolution, as well as the evolution of cellular life forms and viruses. In this brief review, we discuss methods that shaped the field of protein bioinformatics, first, through comparative sequence analysis, and the recent developments in protein structure prediction that transformed the state of the art in the comparative analysis of distantly related proteins. The combination of the rapidly growing databases of genome and metagenome sequences with sensitive methods for sequence comparison and the new generation of structure analysis tools can make charting the protein universe at the structural level a realistic goal.

- Kulkarni et al. (2025) — A perspective on how views of the protein structure universe have changed, including fold switching, disorder and amyloid. Useful as background for what structure comparison can and cannot reveal about evolution. *(perspective; CC BY 4.0)*

  Evolving concepts of the protein universe. Kulkarni et al. (2025). *iScience*. doi:10.1016/j.isci.2025.112012

  > The protein universe is the collection of all proteins on earth from all organisms both extant and extinct. Classical studies on protein folding suggested that proteins exist as a unique three-dimensional conformation that is dictated by the genetic code and is critical for function. In this perspective, we discuss ideas and developments that emerged over the past three decades regarding the protein structure-function paradigm. It is now clear that ordered (active/functional) and disordered/denatured (and hence inactive/non-functional) represent a continuum of states rather than binary states. Some proteins can switch folds without sequence change. Others exist as conformational ensembles lacking defined structure yet play critical roles in many biological processes, including forming membrane-less organelles driven by liquid-liquid phase separation. Numerous diverse proteins harbor segments with the potential to form amyloid fibrils, many of which are functional, and some possess prion-like properties enabling conformation-based transfer of heritable information. Taken together, these developments reveal the remarkable complexity of the protein universe.

D.9.6 Protein structure databases

- Burley et al. (2022) — Describes what the PDB contains, how entries are deposited and validated, and how the archive is used. A good overview of the central structure database. *(review; CC BY 4.0)*

  Protein Data Bank: A Comprehensive Review of 3D Structure Holdings and Worldwide Utilization by Researchers, Educators, and Students. Burley et al. (2022). *Biomolecules*. doi:10.3390/biom12101425

  > The Research Collaboratory for Structural Bioinformatics Protein Data Bank (RCSB PDB), funded by the United States National Science Foundation, National Institutes of Health, and Department of Energy, supports structural biologists and Protein Data Bank (PDB) data users around the world. The RCSB PDB, a founding member of the Worldwide Protein Data Bank (wwPDB) partnership, serves as the US data center for the global PDB archive housing experimentally-determined three-dimensional (3D) structure data for biological macromolecules. As the wwPDB-designated Archive Keeper, RCSB PDB is also responsible for the security of PDB data and weekly update of the archive. RCSB PDB serves tens of thousands of data depositors (using macromolecular crystallography, nuclear magnetic resonance spectroscopy, electron microscopy, and micro-electron diffraction) annually working on all permanently inhabited continents. RCSB PDB makes PDB data available from its research-focused web portal at no charge and without usage restrictions to many millions of PDB data consumers around the globe. It also provides educators, students, and the general public with an introduction to the PDB and related training materials through its outreach and education-focused web portal. This review article describes growth of the PDB, examines evolution of experimental methods for structure determination viewed through the lens of the PDB archive, and provides a detailed accounting of PDB archival holdings and their utilization by researchers, educators, and students worldwide.

- Fleming et al. (2025) — Describes the contents and use of the AlphaFold Protein Structure Database and the 3D-Beacons network that links predicted and experimental models. Useful for understanding how predicted structures are distributed and accessed. *(review; CC BY 4.0)*

  AlphaFold Protein Structure Database and 3D-Beacons: New Data and Capabilities. Fleming et al. (2025). *Journal of Molecular Biology*. doi:10.1016/j.jmb.2025.168967

  > The AlphaFold Protein Structure Database (https://alphafold.ebi.ac.uk/) has made significant strides in enhancing its utility and accessibility for the life science research community. The recent integration of AlphaMissense predictions enables access to the pathogenicity of human protein missense variants, with an innovative and interactive heatmap and 3D visualisation that display variant data at the residue level. Users can now toggle between structure model quality (pLDDT) and average pathogenicity scores, providing insights into the implications of specific residue changes. The Foldseek integration offers a rapid and accurate method for protein structure searches and comparisons. Bulk data download options further facilitate comprehensive data analysis and integration with other computational tools. The 3D-Beacons framework (https://www.ebi.ac.uk/pdbe/pdbe-kb/3dbeacons/) has also been enhanced with detailed annotation endpoints (such as AlphaMissense data) and integrates LevyLab's dataset of homomeric AlphaFold 2 models. These advancements significantly improve the functionality and accessibility of these resources, enabling discoveries using structure data.

- Waman et al. (2024) — Explains the CATH hierarchy (class, architecture, topology, homologous superfamily) and how it has been extended with predicted models. Illustrates how structure classification works in practice. *(review; CC BY 4.0)*

  CATH 2024: CATH-AlphaFlow Doubles the Number of Structures in CATH and Reveals Nearly 200 New Folds. Waman et al. (2024). *Journal of Molecular Biology*. doi:10.1016/j.jmb.2024.168551

  > CATH (https://www.cathdb.info) classifies domain structures from experimental protein structures in the PDB and predicted structures in the AlphaFold Database (AFDB). To cope with the scale of the predicted data a new NextFlow workflow (CATH-AlphaFlow), has been developed to classify high-quality domains into CATH superfamilies and identify novel fold groups and superfamilies. CATH-AlphaFlow uses a novel state-of-the-art structure-based domain boundary prediction method (ChainSaw) for identifying domains in multi-domain proteins. We applied CATH-AlphaFlow to process PDB structures not classified in CATH and AFDB structures from 21 model organisms, expanding CATH by over 100%. Domains not classified in existing CATH superfamilies or fold groups were used to seed novel folds, giving 253 new folds from PDB structures (September 2023 release) and 96 from AFDB structures of proteomes of 21 model organisms. Where possible, functional annotations were obtained using (i) predictions from publicly available methods (ii) annotations from structural relatives in AFDB/UniProt50. We also predicted functional sites and highly conserved residues. Some folds are associated with important functions such as photosynthetic acclimation (in flowering plants), iron permease activity (in fungi) and post-natal spermatogenesis (in mice). CATH-AlphaFlow will allow us to identify many more CATH relatives in the AFDB, further characterising the protein structure landscape.

D.9.7 Protein structure prediction

- Bertoline et al. (2023) — Covers the history of structure prediction from homology modelling, threading and fragment assembly through coevolution to AlphaFold2. Follows the same order as the section and is a good overview for revision. *(review; CC BY 4.0)*

  Before and after AlphaFold2: An overview of protein structure prediction. Bertoline et al. (2023). *Frontiers in Bioinformatics*. doi:10.3389/fbinf.2023.1120370

  > Three-dimensional protein structure is directly correlated with its function and its determination is critical to understanding biological processes and addressing human health and life science problems in general. Although new protein structures are experimentally obtained over time, there is still a large difference between the number of protein sequences placed in Uniprot and those with resolved tertiary structure. In this context, studies have emerged to predict protein structures by methods based on a template or free modeling. In the last years, different methods have been combined to overcome their individual limitations, until the emergence of AlphaFold2, which demonstrated that predicting protein structure with

> high accuracy at unprecedented scale is possible. Despite its current impact in the field, AlphaFold2 has limitations. Recently, new methods based on protein language models have promised to revolutionize the protein structural biology allowing the discovery of protein structure and function only from evolutionary patterns present on protein sequence. Even though these methods do not reach AlphaFold2 accuracy, they already covered some of its limitations, being able to predict with high accuracy more than 200 million proteins from metagenomic databases. In this mini-review, we provide an overview of the breakthroughs in protein structure prediction before and after AlphaFold2 emergence.

- Kovalevskiy et al. (2024) — Reviews how AlphaFold2 predictions have been validated against experiments and how they have been used. Written by DeepMind authors, so it should be read alongside independent assessments; not peer reviewed. *(review; CC BY 4.0)*

  AlphaFold two years on: validation and impact. Kovalevskiy et al. (2024). doi:10.48550/arXiv.2403.02124

  > Two years on from the initial release of AlphaFold2 we have seen its widespread adoption as a structure prediction tool. Here we discuss some of the latest work based on AlphaFold2, with a particular focus on its use within the structural biology community. This encompasses use cases like speeding up structure determination itself, enabling new computational studies, and building new tools and workflows. We also look at the ongoing validation of AlphaFold2, as its predictions continue to be compared against large numbers of experimental structures to further delineate the model's capabilities and limitations.

- Rennie and Oliver (2025) — Discusses how to interpret predicted models and extends to complexes, ligands and other biomolecules, and proposes guidelines for reporting AlphaFold predictions. Relevant to the subsections on co-folding, limitations and checking a model. *(review; CC BY 4.0)*

  Emerging frontiers in protein structure prediction following the AlphaFold revolution. Rennie & Oliver (2025). *Journal of The Royal Society Interface*. doi:10.1098/rsif.2024.0886

  > Models of protein structures enable molecular understanding of biological processes. Current protein structure prediction tools lie at the interface of biology, chemistry and computer science. Millions of protein structure models have been generated in a very short space of time through a revolution in protein structure prediction driven by deep learning, led by AlphaFold. This has provided a wealth of new structural information. Interpreting these predictions is critical to determining where and when this information is useful. But proteins are not static nor do they act alone, and structures of proteins interacting with other proteins and other biomolecules are critical to a complete understanding of their biological function at the molecular level. This review focuses on the application of state-of-the-art protein structure prediction to these advanced applications. We also suggest a set of guidelines for reporting AlphaFold predictions.

D.9.8 Protein language models and structure

- Weissenow and Rost (2025) — Discusses how embeddings from protein language models are replacing multiple sequence alignments as input for many prediction tasks, and the trade-offs in accuracy and cost. Directly relevant to the comparison of language models with alignments. *(review; CC BY-NC-ND 4.0 (link only))*

  Are protein language models the new universal key?. Weissenow & Rost (2025). *Current Opinion in Structural Biology*. doi:10.1016/j.sbi.2025.102997

  > Protein language models (pLMs) capture some aspects of the grammar of the language of life as written in protein sequences. The so-called pLM embeddings implicitly contain this information. Therefore, embeddings can serve as the exclusive input into downstream supervised methods for protein prediction. Over the last 33 years, evolutionary information extracted through simple averaging for specific protein families from multiple sequence alignments (MSAs) has been the most successful universal key to the success of protein prediction. For many applications, MSA-free pLM-based predictions now have become significantly more accurate. The reason for this is often a combination of two aspects. Firstly, embeddings condense the grammar so efficiently that downstream prediction methods succeed with small models, i.e., they need few free parameters in particular in the era of exploding deep neural networks. Secondly, pLM-based methods provide protein-specific solutions. As additional benefit, once the pLM pre-training is complete, pLM-based solutions tend to consume much fewer resources than MSA-based solutions. In

> fact, we appeal to the community to rather optimize foundation models than to retrain new ones and to evolve incentives for solutions that require fewer resources even at some loss in accuracy. Although pLMs have not, yet, succeeded to entirely replace the body of solutions developed over three decades, they clearly are rapidly advancing as the universal key for protein prediction.

- Zhang et al. (2024) — A research article rather than a review: it analyses what ESM-2 has learned and argues that it mainly stores coevolution statistics of interacting motifs. Helps to understand why language-model structure prediction resembles alignment-based methods and where it fails. *(research article; CC BY 4.0)*

  Protein language models learn evolutionary statistics of interacting sequence motifs. Zhang et al. (2024). *Proceedings of the National Academy of Sciences*. doi:10.1073/pnas.2406285121

  > Protein language models (pLMs) have emerged as potent tools for predicting and designing protein structure and function, and the degree to which these models fundamentally understand the inherent biophysics of protein structure stands as an open question. Motivated by a finding that pLM-based structure predictors erroneously predict nonphysical structures for protein isoforms, we investigated the nature of sequence context needed for contact predictions in the pLM Evolutionary Scale Modeling (ESM-2). We demonstrate by use of a "categorical Jacobian" calculation that ESM-2 stores statistics of coevolving residues, analogously to simpler modeling approaches like Markov Random Fields and Multivariate Gaussian models. We further investigated how ESM-2 "stores" information needed to predict contacts by comparing sequence masking strategies, and found that providing local windows of sequence information allowed ESM-2 to best recover predicted contacts. This suggests that pLMs predict contacts by storing motifs of pairwise contacts. Our investigation highlights the limitations of current pLMs and underscores the importance of understanding the underlying mechanisms of these models.

D.9.9 Membrane proteins

- Phillips and Miller (2021) — A short review of how α-helical membrane proteins are inserted and folded in the endoplasmic reticulum and how misfolded ones are recognised. Gives the biological context for topology and insertion. *(review; CC BY 4.0)*

  Membrane protein folding and quality control. Phillips & Miller (2021). *Current Opinion in Structural Biology*. doi:10.1016/j.sbi.2021.03.003

  > Membrane proteins account for a quarter of cellular proteins, and most are synthesised at the endoplasmic reticulum (ER). Insertion and folding of polypeptides in the membrane environment is prone to error, necessitating diverse quality control systems. Recent discoveries have demonstrated how forces act on the nascent chain during insertion, and revealed new translocon components and accessories that facilitate the correct biogenesis of substrates. Our understanding of one of the best studied quality control systems-ER-associated degradation-has been advanced through new structural and functional studies of the core Hrd1 complex, and through the discovery of a new branch of this degradative pathway. New data also reveal how cells resolve clogged translocons, which would otherwise be unable to function. Finally, new work elucidates how mitochondrial tail-anchored proteins that have been mistargeted to the ER are identified and destroyed. Overall, we describe an emerging picture of an increasingly complex quality control network.

- Whitley et al. (2021) — Explains how the translocon recognises transmembrane helices, the hydrophobicity-based insertion scale and the role of charged residues in topology. Underpins the principles behind α-helical topology prediction. *(review; CC BY 4.0)*

  Folding and Insertion of Transmembrane Helices at the ER. Whitley et al. (2021). *International Journal of Molecular Sciences*. doi:10.3390/ijms222312778

  > In eukaryotic cells, the endoplasmic reticulum (ER) is the entry point for newly synthesized proteins that are subsequently distributed to organelles of the endomembrane system. Some of these proteins are completely translocated into the lumen of the ER while others integrate stretches of amino acids into the greasy 30 Å wide interior of the ER membrane bilayer. It is generally accepted that to exist in this non-aqueous environment the majority of membrane integrated amino acids are primarily non-polar/hydrophobic and adopt an α-helical conformation. These stretches are typically around 20 amino acids long

> and are known as transmembrane (TM) helices. In this review, we will consider how transmembrane helices achieve membrane integration. We will address questions such as: Where do the stretches of amino acids fold into a helical conformation? What is/are the route/routes that these stretches take from synthesis at the ribosome to integration through the ER translocon? How do these stretches 'know' to integrate and in which orientation? How do marginally hydrophobic stretches of amino acids integrate and survive as transmembrane helices?

- Horne et al. (2020) — Reviews the structure, folding and membrane insertion of β-barrel outer membrane proteins and the role of the BAM complex and the lipid bilayer. Covers the β-barrel subsection. *(review; CC BY 4.0)*

  Role of the lipid bilayer in outer membrane protein folding in Gram-negative bacteria. Horne et al. (2020). *Journal of Biological Chemistry*. doi:10.1074/jbc.rev120.011473

  > β-Barrel outer membrane proteins (OMPs) represent the major proteinaceous component of the outer membrane (OM) of Gram-negative bacteria. These proteins perform key roles in cell structure and morphology, nutrient acquisition, colonization and invasion, and protection against external toxic threats such as antibiotics. To become functional, OMPs must fold and insert into a crowded and asymmetric OM that lacks much freely accessible lipid. This feat is accomplished in the absence of an external energy source and is thought to be driven by the high thermodynamic stability of folded OMPs in the OM. With such a stable fold, the challenge that bacteria face in assembling OMPs into the OM is how to overcome the initial energy barrier of membrane insertion. In this review, we highlight the roles of the lipid environment and the OM in modulating the OMP-folding landscape and discuss the factors that guide folding in vitro and in vivo We particularly focus on the composition, architecture, and physical properties of the OM and how an understanding of the folding properties of OMPs in vitro can help explain the challenges they encounter during folding in vivo Current models of OMP biogenesis in the cellular environment are still in flux, but the stakes for improving the accuracy of these models are high. OMP folding is an essential process in all Gram-negative bacteria, and considering the looming crisis of widespread microbial drug resistance it is an attractive target. To bring down this vital OMP-supported barrier to antibiotics, we must first understand how bacterial cells build it.

D.9.10 Dynamics and docking

- Braun et al. (2018) — Introduces the foundations of molecular simulation: force fields, integration, ensembles, sampling and statistical uncertainty. Written for beginners and useful for understanding what molecular dynamics can and cannot tell you. *(tutorial; CC BY 4.0)*

  Best Practices for Foundations in Molecular Simulations [Article v1.0]. Braun et al. (2018). *Living Journal of Computational Molecular Science*. doi:10.33011/livecoms.1.1.5957

  > This document provides a starting point for approaching molecular simulations, guiding beginning practitioners to what issues they need to know about before and while starting their first simulations, and why those issues are so critical. This document makes no claims to provide an adequate introduction to the subject on its own. Instead, our goal is to help people know what issues are critical before beginning, and to provide references to good resources on those topics. We also provide a checklist of key issues to consider before and while setting up molecular simulations which may serve as a foundation for other best practices documents.

- Togashi and Flechsig (2018) — Explains elastic network models and normal-mode analysis and how they are used to describe large-scale protein motions. Covers the subsection on normal modes. *(review; CC BY 4.0)*

  Coarse-Grained Protein Dynamics Studies Using Elastic Network Models. Togashi & Flechsig (2018). *International Journal of Molecular Sciences*. doi:10.3390/ijms19123899

  > Elastic networks have been used as simple models of proteins to study their slow structural dynamics. They consist of point-like particles connected by linear Hookean springs and hence are convenient for linear normal mode analysis around a given reference structure. Furthermore, dynamic simulations using these models can provide new insights. As the computational cost associated with these models is considerably lower compared to that of all-atom models, they are also convenient for comparative

studies between multiple protein structures. In this review, we introduce examples of coarse-grained molecular dynamics studies using elastic network models and their derivatives, focusing on the nonlinear phenomena, and discuss their applicability to large-scale macromolecular assemblies.

- Paggi et al. (2024) — A clear review of how docking works (sampling and scoring), why it succeeds or fails, and how deep-learning methods compare with physics-based docking. Directly relevant to the subsection on docking and scoring functions. *(review; CC BY 4.0)*

  The Art and Science of Molecular Docking. Paggi et al. (2024). *Annual Review of Biochemistry*. doi:10.1146/annurev-biochem-030222-120000

  > Molecular docking has become an essential part of a structural biologist's and medicinal chemist's toolkits. Given a chemical compound and the three-dimensional structure of a molecular target-for example, a protein-docking methods fit the compound into the target, predicting the compound's bound structure and binding energy. Docking can be used to discover novel ligands for a target by screening large virtual compound libraries. Docking can also provide a useful starting point for structure-based ligand optimization or for investigating a ligand's mechanism of action. Advances in computational methods, including both physics-based and machine learning approaches, as well as in complementary experimental techniques, are making docking an even more powerful tool. We review how docking works and how it can drive drug discovery and biological research. We also describe its current limitations and ongoing efforts to overcome them.

D.9.11 Protein design

- Pan and Kortemme (2021) — Explains the principles of physics-based de novo design, including energy functions and sequence and backbone design, and the early deep-learning approaches. Good for the physics-based design subsection. *(review; CC BY 4.0)*

  Recent advances in de novo protein design: Principles, methods, and applications. Pan & Kortemme (2021). *Journal of Biological Chemistry*. doi:10.1016/j.jbc.2021.100558

  > The computational de novo protein design is increasingly applied to address a number of key challenges in biomedicine and biological engineering. Successes in expanding applications are driven by advances in design principles and methods over several decades. Here, we review recent innovations in major aspects of the de novo protein design and include how these advances were informed by principles of protein architecture and interactions derived from the wealth of structures in the Protein Data Bank. We describe developments in de novo generation of designable backbone structures, optimization of sequences, design scoring functions, and the design of the function. The advances not only highlight design goals reachable now but also point to the challenges and opportunities for the future of the field.

- Winnifrith et al. (2024) — A short overview of generative models for protein design, including diffusion models for backbones, inverse folding and language models for sequences. Covers the deep-learning design subsection. *(review; CC BY 4.0)*

  Generative artificial intelligence for de novo protein design. Winnifrith et al. (2024). *Current Opinion in Structural Biology*. doi:10.1016/j.sbi.2024.102794

  > Engineering new molecules with desirable functions and properties has the potential to extend our ability to engineer proteins beyond what nature has so far evolved. Advances in the so-called 'de novo' design problem have recently been brought forward by developments in artificial intelligence. Generative architectures, such as language models and diffusion processes, seem adept at generating novel, yet realistic proteins that display desirable properties and perform specified functions. State-of-the-art design protocols now achieve experimental success rates nearing 20%, thus widening the access to de novo designed proteins. Despite extensive progress, there are clear field-wide challenges, for example, in determining the best in silico metrics to prioritise designs for experimental testing, and in designing proteins that can undergo large conformational changes or be regulated by post-translational modifications. With an increase in the number of models being developed, this review provides a framework to understand how these tools fit into the overall process of de novo protein design. Throughout, we highlight the power of incorporating biochemical knowledge to improve performance and interpretability.

- Jänes and Beltrao (2024) — Reviews deep-learning structure prediction beyond single chains (complexes, alternative conformations, evolution) and its use in protein design. Links the design section back to the prediction methods it builds on. *(review; CC BY 4.0)*

  Deep learning for protein structure prediction and design—progress and applications. Jänes & Beltrao (2024). *Molecular Systems Biology*. doi:10.1038/s44320-024-00016-x

  > Proteins are the key molecular machines that orchestrate all biological processes of the cell. Most proteins fold into three-dimensional shapes that are critical for their function. Studying the 3D shape of proteins can inform us of the mechanisms that underlie biological processes in living cells and can have practical applications in the study of disease mutations or the discovery of novel drug treatments. Here, we review the progress made in sequence-based prediction of protein structures with a focus on applications that go beyond the prediction of single monomer structures. This includes the application of deep learning methods for the prediction of structures of protein complexes, different conformations, the evolution of protein structures and the application of these methods to protein design. These developments create new opportunities for research that will have impact across many areas of biomedical research.

Before and after AlphaFold2: An overview of protein structure prediction

Letícia M. F. Bertoline†, Angélica N. Lima†, Jose E. Krieger and Samantha K. Teixeira*†

Laboratory of Genetics and Molecular Cardiology, Heart Institute, University of São Paulo Medical School, São Paulo, Brazil

Three-dimensional protein structure is directly correlated with its function and its determination is critical to understanding biological processes and addressing human health and life science problems in general. Although new protein structures are experimentally obtained over time, there is still a large difference between the number of protein sequences placed in Uniprot and those with resolved tertiary structure. In this context, studies have emerged to predict protein structures by methods based on a template or free modeling. In the last years, different methods have been combined to overcome their individual limitations, until the emergence of AlphaFold2, which demonstrated that predicting protein structure with high accuracy at unprecedented scale is possible. Despite its current impact in the field, AlphaFold2 has limitations. Recently, new methods based on protein language models have promised to revolutionize the protein structural biology allowing the discovery of protein structure and function only from evolutionary patterns present on protein sequence. Even though these methods do not reach AlphaFold2 accuracy, they already covered some of its limitations, being able to predict with high accuracy more than 200 million proteins from metagenomic databases. In this mini-review, we provide an overview of the breakthroughs in protein structure prediction before and after AlphaFold2 emergence.

KEYWORDS

protein structure prediction, AlphaFold, template-based modeling, free modeling, protein language model

1 Introduction

Protein is the term proposed by the Swedish chemist Jacob Berzelius to compounds containing nitrogen and constituted by a combination of amino acids linked by a bond, called peptide bond (Fruton, 1985; Wisniak, 2000; Lehninger et al., 2005; Voet et al., 2014). They are responsible for housekeeping and specific functions essential to life, such as cell structural support, immune protection, enzymatic catalysis, cell signal transduction to transcription and translation regulation (Pearce and Zhang, 2021). The biological function of a protein depends on its tertiary/quaternary structures that derives ultimately from the folding of a polypeptide sequence(s) considering physical chemistry principles and the lowest free energy level, being the understanding of protein folding one of the most important goals in structural biology (Lehninger et al., 2005; Voet et al., 2014).

Experimentally, tertiary protein structures are resolved by X-ray crystallography, nuclear magnetic resonance and electron cryomicroscopy (cryo-EM). Nevertheless, those techniques

are complex, time consuming, expensive, and often the structure is not in its native form. Under these constrains, it is no surprise that the number of proteins with resolved tertiary structures is small (200,988 PDB entries) compared to the large number of proteins sequence known (229,580,745 entries on UniProtKB as of January 2023). This is an open challenge waiting for innovative ways to develop novel protein structure prediction approaches such as the ones using computationally models to predict the three dimensional protein structures starting from a polypeptide sequence (Dill et al., 2007; Nassar et al., 2021).

Several algorithms and web servers have been developed with the aim to improve the protein structure prediction. The relevance of these efforts are underscored by the different application that shall be affected including rational drug design, mutational studies and structural comparison, evolutionary analysis, folding studies. Here, we provide an overview of the methods developed to perform protein structure prediction to compare with AlphaFold2, which combines neural networks and homology modeling to generate models that may have experimental accuracy in a growing number of examples. We also discuss its applicability, limitations and efforts to improve the overall algorithm's performance.

2 Structure prediction methods

The prediction methods are usually divided into template-based modeling (TBM) and free modeling (FM), considering the use or not of templates (Gromiha et al., 2018; Bongirwar and Mokhade, 2022; Paiva et al., 2022), even though, recently, some TBM methods use energy-guided model refinement, and part of FM uses fragment-based sampling approaches, extracting information from Protein Data Bank (PDB) through machine learning. Within these two groups, the algorithms developed are usually classified into three different groups: *ab initio* (a FM methodology), threading/fold recognition (a TBM methodology), and homology (a TBM methodology) (Gromiha et al., 2018; Agnihotry et al., 2022). Despite controversial, this classification corresponds to the categories from the Critical Assessment of Structure Prediction (CASP), a biennial competition with the aim to establish the current state of the art in protein structure prediction, which contains three categories: TBM, FM, and an intermediate category, FM/TBM. In this contest, participants submit their models for proteins whose experimental structure has not been published yet (Kryshtafovych et al., 2019).

The *ab initio* approaches are based on the thermodynamics hypothesis that the native protein structure presents the lowest free energy possible (Hardin et al., 2002; Yuan et al., 2003; Gromiha et al., 2018; Agnihotry et al., 2022). The idea of these methods are to predict new folds considering physicochemical properties from the protein fold process, such as hydrogen bonding, contact potential energy, PDB-derived secondary structure propensities, and folding involving both bonded and non-bonded interactions. The *ab initio* method may or may not take into account motif identification in databases using small fragments. Some reviews even divide this category into two distinct methodologies, one dependent and another independent on database information. In this mini-review, we will use the term *ab initio* for methods that model protein structure without a template and that use the laws of thermodynamics as a basis, even though FM methods commonly exploit the information from known structures.

The main advantage of *ab initio* methods is the capacity to obtain novel and unknown protein folds (Dorn et al., 2014). Nevertheless, the complexity of the problem and the high number of conformational possibilities is computationally demanding, limiting the use for long protein sequences. Methods that use fragments may help to reduce the conformational space, but again avoid the prediction of new protein folds. One example of *ab initio* method that considers fragments is QUARK, a template-free novel program developed by Xu and Zhang (2012) in 2012. Briefly, this program breaks the protein sequence into fragments of 20 amino acids, searches for structure in a database, and then, using replica-exchange Monte Carlo simulations, unites the fragments taking into account the force field and energy terms, constituting a complete model.

The threading/fold recognition methodologies are based on the idea that structure is more conserved than the amino acid sequence and has a limited number of protein structure folds in nature (Rost et al., 1997; Dorn et al., 2014; Gromiha et al., 2018; Agnihotry et al., 2022). They consist in choosing the best 3D template of known foldings that fit well in the target sequence considering a scoring function built on pairwise potential, second structure comparison, as well as solvent properties. Thus, the target sequence is aligned with the structure model with the optimal scoring function, reorganizing the atoms of the target sequence in the aligned backbone. Finally, the affinity of the sequence with three-dimensional fold is verified followed by a manual verification. GenTHREADER is a program that uses threading techniques to evaluate the alignments, made using a sequence profile method, and then generates models that will be evaluated by a neural network to give a confidence measure (Jones, 1999).

The homology models derive from the fact that two amino acid sequences that are highly similar have similar structures (Dorn et al., 2014; Gromiha et al., 2018; Agnihotry et al., 2022; Sanjeevi et al., 2022). For this, the target sequence is aligned to a sequence in which the structure is known and an atomic model for the target protein is generated taking into account its similarities with the template backbone, followed by modeling loop regions and sidechains. The final step is to submit the model to energy minimization and evaluate it using the Ramachandran plot. Usually, homology methods achieve protein structures with higher accuracy than other methodologies. But, as other TBM methods, they are limited due to their inability to predict structures for new proteins, as they are dependent on templates. SWISS-MODEL is an automated system that uses homology modeling to predict a three dimensional structure of a protein (Guex et al., 2009; Kiefer et al., 2009). It was the first web server available to generate a 3D protein structure. This program integrates and automates all the processes involved in a homology modeling method, creating a fully automated workflow using a PERL based framework (Kiefer et al., 2009). The program presents an interface friendly for non-bioinformatician users and information, such as PFAM domain annotation and other tools from SWISS-MODEL (Kiefer et al., 2009).

Recently, new hybrid techniques have been published combining tools or improving known methods with artificial intelligence approaches. This was possible in part due to the

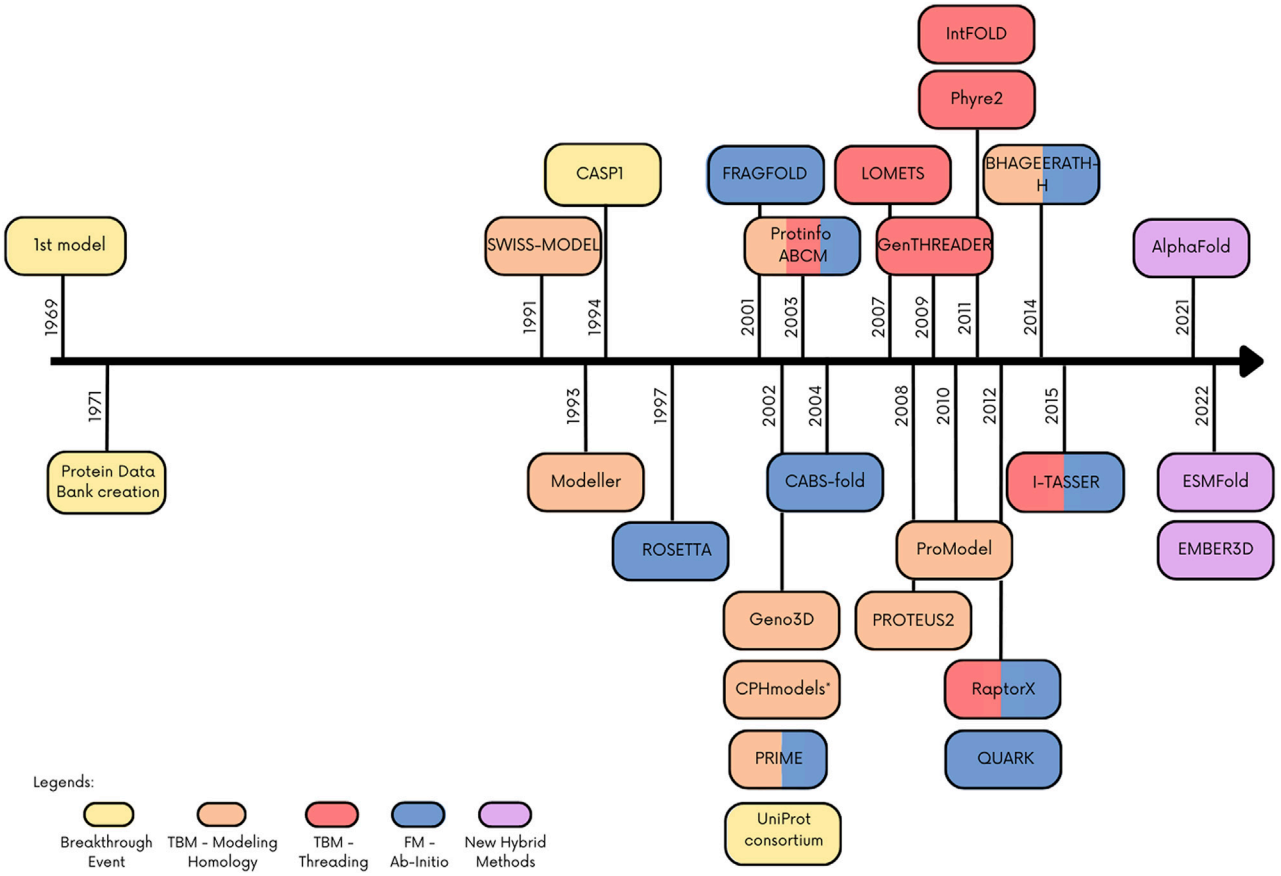

FIGURE 1
Timeline with main events and programs/webserver in the protein structure prediction. Colored boxes indicate the method or important event in the field.

development and improvement of computer processing. One of the breakthrough methods that not only combines methodology but also uses artificial intelligence is AlphaFold, an algorithm that beats the other tools in CASP13 and currently represents the state of art in protein structure prediction. Figure 1 depicts a timeline of the emergence of protein structure prediction programs/web servers and their classification considering the groups of methods adopted in this review, as well as other important dates for this field. More comprehensive and detailed reviews about protein structure prediction methods/tools can be found in Paiva et al. (2022), Bongirwar and Mokhade (2022).

3 AlphaFold

In 2018, DeepMind, a startup of Google, presented a new software that best performed in the 13th edition of CASP, named AlphaFold. In this competition, AlphaFold achieved the best position in the FM (best-of-five), reaching a summed z-score of 52.8 *versus* 36.6 from the second place and, combining FM and FM/TBM categories, achieved 68.3 z-score *versus* 48.2 (Senior et al., 2019). Even without using a template, AlphaFold also scored well in the TBM category (Senior et al., 2019).

The first version of AlphaFold used deep learning to predict the protein structure, demonstrating that it is possible to learn protein specific potential by training a neural network giving only the protein sequence. It contains a convolutional neural network that is trained by PDB structures to predict the distances between residues, creating distograms. From the amino acid sequence of the target protein, the neural network predicts a distogram based on multiple sequence alignment (MSA) features, in which a separate output from prediction network predicts the probability of backbone torsion distribution. The combined potential obtained by both ends is then optimized by gradient descent, predicting the protein structure itself (Senior et al., 2020).

Presented at CASP14 between May and July 2020, AlphaFold2 predicted protein structures with more accuracy than other competing methods, demonstrating a root-mean-square deviation (RMSD) among prediction and experimental backbone structures of 0.8Å *versus* the 2.8Å from the next best performing method. Moreover, AlphaFold2 scored 244.0 in summed z-scores compared with 90.8 for the next closest group (Jumper et al., 2021a; Jumper et al., 2021b). The great performance of AlphaFold2 in all Casp14 categories is depicted in Figure 2.

It is important to emphasize that AlphaFold2 contrasts considerably from the first version of AlphaFold. The authors

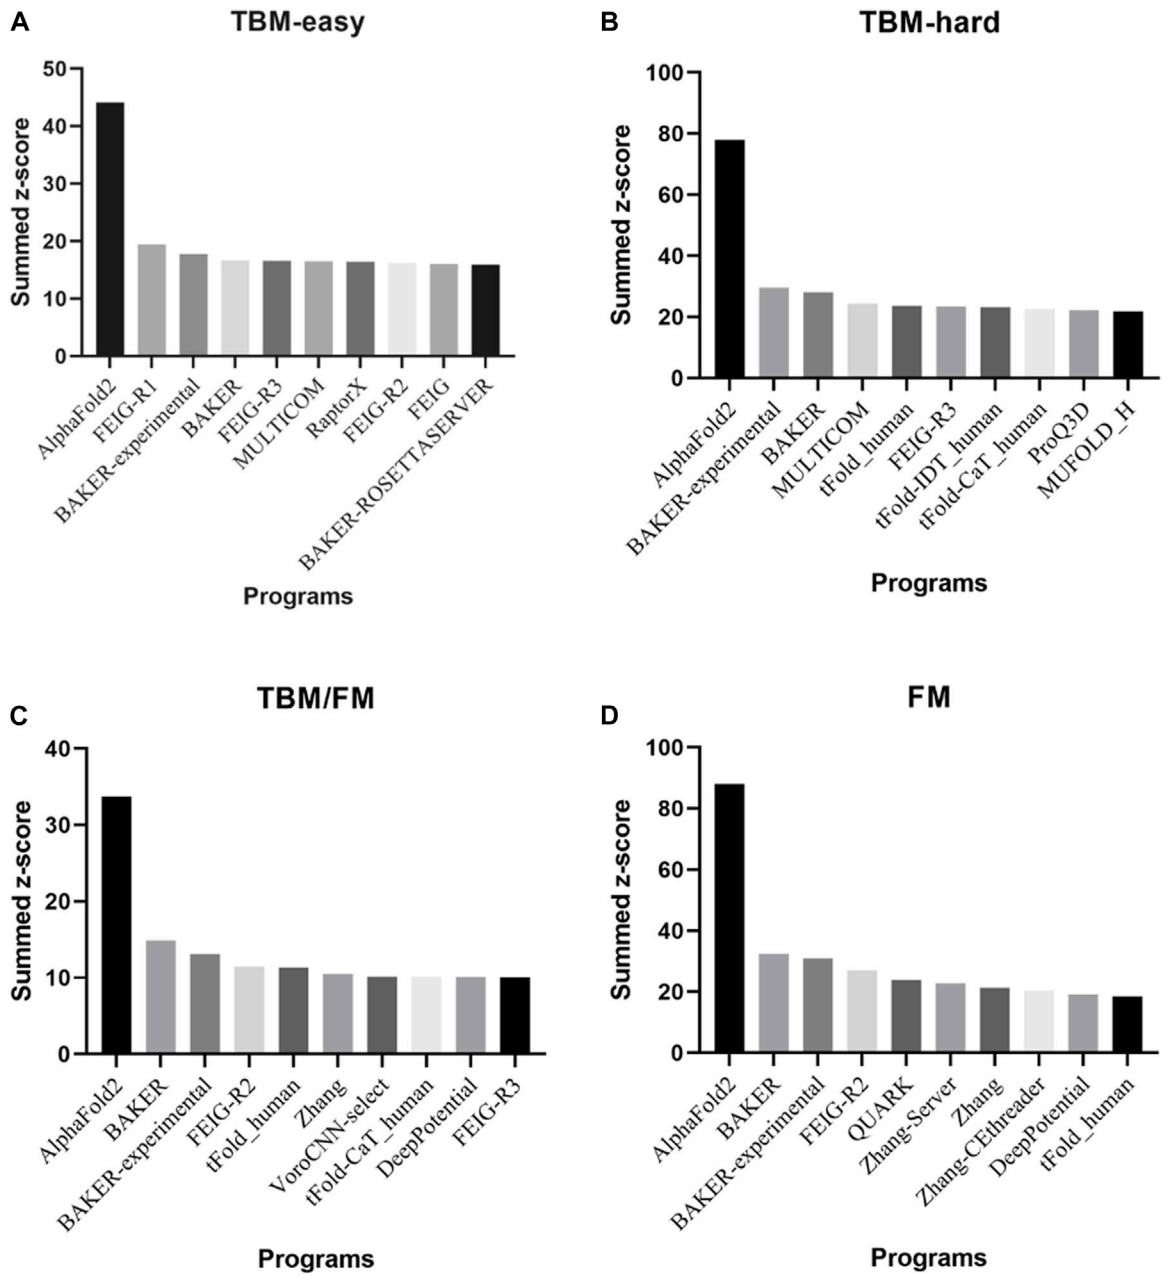

FIGURE 2
The top 10 programs and/or web servers in CASP14 in **(A)** TBM-easy, **(B)** TBM-hard, **(C)** TBM/FM, and **(D)** FM categories considering summed z-score. Data extracted by CASP official website.

attribute the high performance of AlphaFold2 by "incorporating novel neural networks architectures and training procedures based on the evolutionary, physical and geometric constraints of protein structures" (Jumper et al., 2021b; Bouatta et al., 2021; Callaway, 2022). AlphaFold2 uses as an input amino acid sequence to construct a MSA based on several databases of protein sequences to determine which parts of the sequence are mutation prone, detecting correlation between them. It also identifies proteins with similar structure with the input that will be used to build an initial representation of the target sequence (template), named as pair representation. Both strategies are not new and are shared by other algorithms in CASP14. Nevertheless, the breakthrough of AlphaFold2 is due to its neural network architectures, more specifically, the two neural network modules, evoformer and the structure module (Jumper et al., 2021b; Oxford Protein Informatics Group, 2021; Skolnick et al., 2021).

The evoformer extracts information from MSA and templates, exchanging information between them in flows back and forth throughout the network, improving the assessment of the MSA, that in turns modifies the protein structures hypothesized by the templates, allowing the MSA and templates in the correct "embedding space". It consists of two transformers, networks that

use attention to boost the speed with which a model can be trained, each of them specialized for a type of data, MSA or pair representations, with a clear communication channel between them. This allows the MSA transformer attention mechanism to incorporate information from the pair representation, adding a bias term from it, augmenting the attention mechanism and allowing it to pinpoint interacting pairs of residues. The pair representation transformer also works in a similar way, but includes an attention to terms of triangles of residues. The structure module, that also contains an attention architecture, uses both representations to prioritize the orientation of the protein backbone, considering the residue rotations and translations, localizing each side chain of each residue in highly constrained within a frame, followed by local refinement and minimization by gradient descent (Jumper et al., 2021b; Oxford Protein Informatics Group, 2021; Skolnick et al., 2021).

Protein-protein interactions are the basis of the biological process, and high-resolution structural characterization of these interactions give rise to insights of their molecular mechanisms and function, as well as direct the design of new drugs that are able to modulate these molecular pathways. Alphafold2 has been used to predict protein-protein interaction, using flexible linkers or artificial gaps and, in general, it predicted heterodimeric protein complexes accurately, exceeding docking approaches usually used in these analysis (Bryant et al., 2022; Yin et al., 2022). Nevertheless, it was limited to predict complexes, such as antigen-antibody and AlphaFold2 accuracy was also limited to predict complexes with protein from different species (Yin et al., 2022). In October 2021, DeepMind extended Alphafold2 to multiple chains - called AlphaFold-Multimer (Evans et al., 2022). For this, AlphaFold-Multimer was trained with protein complexes, and a series of changes in the code were made. The developers observed that performance was better in homomeric than heteromeric interfaces (Jumper et al., 2021b) and it did not predict binding of antigen to antibodies (Yin et al., 2022). Both, AlphaFold2 and AlphaFold-Multimer, are open-source codes and are available on github (https://github.com/deepmind/alphafold).

In the same year, in a partnership between DeepMind and the EMBL-European Bioinformatics Institute (EMBL-EBI), the AlphaFold Protein Structure Database (AlphaFold DB—Available in https://alphafold.ebi.ac.uk) was created, making available over 360,000 predicted structures from 21 organism proteomes (Varadi et al., 2022). Today, AlphaFold DB has over 200 million entries from the human and 47 other organism proteomes, with the structure predictions and their respective analyses freely available to the scientific community. Porta-Pardo et al. (2022) demonstrated that AlphaFold2 increases the structural coverage from 48% to 76% of all human protein residues, dropping the number of human protein without structural coverage from 5027 to 29. Moreover, they quantified that, among the 5027 of the proteins without structure previously, 4459 had structure prediction for over 50% of the protein's length (88,7%), in which 1408 with high-accuracy (28%). Despite the large amount of data, protein sequences containing non-standard amino acids, like selenocysteine, have been excluded, as well as multiple isoforms codifying by the same gene (Varadi et al., 2022). The database usability is easy, as input, protein name, gene, Uniprot accession number or organism can be used. As output, the AlphaFold DB provides the atomic coordinates in PDB and mmCIF formats and Predicted Aligned Error (PAEs) in JSON format. It is also possible to give feedback about the prediction structure through "Looks great" or "Could be improved" buttons.

Considered as the ground-breaking application of AI in science, AlphaFold has promised to revolutionize structure biology. Its application has been considered to design better protein expression experiment; To solve experimental structures faster, overcoming tedious model building, especially for X-ray crystallography, and to facilitate the interpretation of low-resolution cryo-EM; To protein design and drug development; To examine the effect of mutation in protein function, elucidating their potential impact on human diseases; To provide novel insights in poorly known molecular mechanisms (Perrakis and Sixma, 2021; Porta-Pardo et al., 2022). In this context, Noone et al. (2022) has demonstrated that indeed AlphaFold offers shortcuts to solve protein structures experimentally, predicting the remaining N-terminal region of PTX3 complex, which was, then, validated with cryo-EM class averaging. The hybrid cryoEM/AlphaFold structure allowed the mapping of the putative sites and regions of interaction, giving insights of the functions of PTX3.

However, despite its breakthrough accuracy and performance to predict protein structures, AlphaFold2 models have important limitations. First, AlphaFold2 has difficulty to predict intrinsically disordered proteins/regions (Ruff and Pappu, 2021) and loops (Stevens and He, 2022), especially considering the importance of the latter for drug screening and design, since they are exposed in protein surface and readily available to solvent and other proteins. Ruff and Pappu (2021) demonstrated that residues and regions predicted with low accuracy by AlphaFold2 overlaps intrinsically disordered regions, while Stevens and He (2022) showed that only short loops (<20 amino acids) are predicted with high accuracy by AlphaFold and it has the tendency to over-predict secondary structures in loop regions, usually alpha helix. Both regions are known to be hypervariable and flexible across orthologies, making it difficult to uncover evolutionary constraints from MSA.

Second, AlphaFold2 predicts only a single conformer, not identifying the apo and holo forms. In 67% of a dataset tested, AlphaFold prediction resembled holo form and the proteins were less predictable when the conformational differences between apo and holo forms increased (Saldaño et al., 2022). Moreover, Azzaz et al. (2022) demonstrated that structure prediction of membrane proteins by AlphaFold is not reliable, mainly because it presents inconsistencies in the location of the transmembrane domains. They stress that the protein environment influences the amino acid sequence, imposing folding constraints. These evidences together with the AlphaFold's inability to predict structures with metal ions, cofactors and other ligands, complexes with DNA or RNA, or post-translational modifications, such as glycosylation, methylation and phosphorylation (Perrakis and Sixma, 2021) highlight the steps to be overcome to improve AphaFold models in drug screening and design. Indeed, Scardino et al. (2023) demonstrated that AlphaFold models showed worse performance in high-throughput docking when compared to their corresponding experimental PDB structures, while Wong et al. (2022) showed that AlphaFold2 protein structure prediction exhibits weak performance on reverse docking in a search for binding targets of bacterial compounds, emphasizing that, even though AlphaFold2 provides rich structural information, more accurate

models of protein-ligand interactions are needed to improve use of AlphaFold2 for drug discovery.

Third, AlphaFold fails to predict defects in protein folding due to point mutations. As demonstrated by Buel and Walters (2022), the differences between mutated and wild-type models predicted by AlphaFold are very small, represented by backbones RMSD lower than 1Å. Moreover, Pak et al. (2021) also demonstrated that there is no correlation between AlphaFold accuracy metrics (pLDDT) and the impact of mutations on protein stability change (ΔΔG), neither with the side chain size change.

Finally, of AlphaFold2 cannot predict novel structures, since its algorithm is based on MSA and requires known structures databases. Another important aspect is that the use of evolutionary information from larger MSAs, requiring environmental systems and storage to detect the homology between known and target sequences, demands a powerful computing processors and its structure prediction is time consuming as protein length increases. To overcome this limitation Google offers the Google Colaboratory, which enables access to powerful GPUs. One of these solutions is ColabFold, a fast and easy-to-use software that replaces the AlphaFold2's homology by MMseq2 (Mirdita et al., 2022), making the computational demands less relevant.

4 New methods of protein structure prediction using protein language model

Recently, new free modeling methods have been published to overcome some of the limitations of AlphaFold2, such as the inability to predict novel structures and the necessity of high time and computing processes. These methods are based on protein language models, derived from natural language processing (NLP), which uses the amino acids sequence only and is able to learn evolutionary, structural and functional patterns derived from sequences available in databases, predicting a structural conformation. The idea behind those methods is that the amino acids correspond to words/tokens and proteins to sentences in NLP, assuming that similar semantics come from amino acids that occur in similar contexts.

There are three approaches used in language models: autoregressive, bidirectional, and masked. The first takes into count the previous tokens (amino acids) to predict the probability of a token, the second considers the previous and following tokens independently to estimate the probability of a token, and the last model considers all tokens in a sequence and replaces each token with a mask token. A synthesis of the recent advances in protein language modeling and their applications to protein prediction problems can be found elsewhere (Bepler and Berger, 2021).

Two methods have gained attention this year. ESMfold, developed by Lin et al. (2022) uses a masked transformer protein language model trained in deep information about biological properties, using 15 billion parameters. Compared with AlphaFold2, it did not present the same performance, achieving lower TM-scores (0.68 *versus* 0.85 using AlphaFold2 on CASP14). However, when evaluating AlphaFold2 without MSA, using only the amino acid sequence, ESMFold performed better (0.68 *versus* 0.37 using AlphaFold2 on Casp14). Moreover, it presented an accuracy comparable to AlphaFold2 for structures predicted with high confidence, demonstrating a median all-atom RMSD of 1.91Å and a backbone RMSD of 1.33Å, reaching similar experimental-level accuracy. Finally, this approach also demonstrated a significant improvement in prediction speed, since it does not require the construction of MSA. Using this approach, the authors presented the ESM Metagenomic Atlas, where they predicted more than 617 million structures from metagenomic databases, in which 225 million structures were predicted with high confidence, including those that are novel (Lin et al., 2022).

EMBER2 is a protein language-model developed by Weissenow et al. (2022a), that uses embeddings to predict inter-residue distance (2D structure) introducing attention heads derived from a pre-trained protein language model instead of MSA. Using EMBER2 in *trRosetta* to predict 3D structures is less accurate than AlphaFold2 in predicting a native structure and presents an inferior TM score (0.5 *versus* 0.79 in ColabFold) (Yang et al., 2020). However, it is faster than ColabFold by about 35 fold, similarly to ESMfold. As the comparison made in this work was not fair, since EMBER2 predicts 2D structures and AlphaFold, 3D structures, the authors developed a new approach that uses EMBER2 model, but now applied in three-dimensional structure prediction, named EMBER3D (Weissenow et al., 2022b). Again, Ember3D did not outperform AlphaFold, but is much faster than it and ESMFold. Whereas AlphaFold2 do not perform efficiently in the study of the impact of single amino acids variants into protein structure, Weissenow et al. (2022b) demonstrated that the differences in predicted distances maps generated by EMBER3D correlated well with native and mutant 3D structures from deep mutational scanning, having a better result than ESMfold. Furthermore, they developed a tool that presents the difference between native and mutant predicted structures by all possible amino acid exchanges in each position of a protein sequence. The similarity between de native amino acid and the mutated one helps the identification of exchanges that may cause a high impact on the protein structure.

These new approaches highlight the powerful capacity of language models to identify evolutionary, structural and functional patterns from massive protein sequence databases to solve protein prediction problem, improving prediction speed and requiring less computational power. It is expected that those approaches will develop and gain accuracy with the inclusion of biological knowledge and multi task learning.

5 Conclusion

Three-dimensional protein structure determination is important to elucidate the protein function, being critical to understanding biological processes and addressing human health and life science problems in general. Due to the difficulty of determining protein structures by experimental methods, their predictions have been one of the central problems of the scientific community. The advent of AlphaFold2 and the release of millions of protein structures predicted with high accuracy and available in AlphaFold DB allowed an unprecedented expansion of different research fields in life science, impacting the most biological

sciences, followed by biochemistry and cell biology, genetics, medical and health sciences and chemical sciences (Varadi and Velankar, 2022).

Protein structure prediction can be applied from understanding the interaction between pathogen and host, how pathogens survive and reproduce, and why they are resistant to certain drugs used, to the development of new and more efficient drugs, reducing the cost in drug discovery and development, as well as the development of new and improved vaccines (Duran-Frigola et al., 2013; Hazra and Patra, 2021). The development of a new vaccine strategy used against COVID-19 by Pfizer, Moderna and Johnson & Johnson, in which the prediction of the mutations and its potential effects in spike protein domain allowed the generation of an immunogen, highlights the window of opportunity that AlphaFold2 offers in the structure-guided vaccine design (Higgins, 2021).

The recent advances in protein structure prediction have contributed to improve protein folding issues. The emergence of AlphaFold2 has taken the problem of protein structure prediction to another level, reaching similar experimental-level accuracy in some cases. Nevertheless, improvements are needed to overcome the limitation to predict novel structures, intrinsically disordered regions and loops, the ability to predict only a single conformer without ligands and still present inconsistencies in its models, and the inability to predict the impact of missense mutation on protein structure. These limitations, ultimately, are important drawbacks to expand the use of AlphaFold in life science.

Efforts are in progress to improve AlphaFold performance and models. Johansson-Åkhe and Wallner (2022) demonstrated that randomly perturbing the neural network weights, forcing it to sample more conformational spaces can improve AlphaFold Multimer performance. Terwilliger et al. (2022) suggested that inclusion of new experimental information can improve parts of the models, showing that application of experimental density maps used iteratively allows the rebuilding of models that can be used as templates by AlphaFold new prediction. Finally, Hekkelman et al. (2022) enriched the models in the AlphaFold DB through transplantation of small molecules and ions based on homologous protein structures. They presented a new resource, the AlphaFill databank, to overcome the limitation presented by AlphaFold models that do not present ligands and co-factors, to help life scientists test new hypotheses and design target experiments.

Simultaneously, new strategies using protein language models are arising to compete with AlphaFold2 in terms of performance and accuracy and to overcome some of its limitations. These strategies, more specific ESMfold, offers an opportunity to identify new proteins and novel functions, allowing the identification of new species, including microorganisms and viruses that endanger human health, as well as those that offer solution to mitigate environmental problems, such as the degradation of polluting and the development of transgenic microorganisms for more efficient product production. For this, ESM Metagenomic Atlas is an important 3D protein structures resource to be deeply investigated by the scientific community (Lin et al., 2022). Finally, the efforts to better predict how mutations affect protein structure using these new approaches are essential to gain insights in human genetic disease and further improve disease management and prediction. Today, these methods do not outperform AlphaFold2, but with the improvement of deep language models and the enrichment of these models with biological information through multi-task learning, they promise to revolutionize the protein structural biology.

D.10 Protein function

Further explanations for Chapter 10.

D.10.1 Definitions of function

- Thomas (2016) — Discusses what 'function' means for a gene product and how the GO distinguishes molecular function, biological process and cellular component. Useful background for the section's opening question of how to define function. *(book chapter; CC BY 4.0)*

  The Gene Ontology and the Meaning of Biological Function. Thomas (2016). *The Gene Ontology Handbook*. doi:10.1007/978-1-4939-3743-1_2

  > The Gene Ontology (GO) provides a framework and set of concepts for describing the functions of gene products from all organisms. It is specifically designed for supporting the computational representation of biological systems. A GO annotation is an association between a specific gene product and a GO concept, together making a statement pertinent to the function of that gene. However, the meaning of the term "function" is not as straightforward as it might seem, and has been discussed at length in both philosophical and biological circles. Here, I first review these discussions. I then present an explicit formulation of the biological model that underlies the GO and annotations, and discuss how this model relates to the broader debates on the meaning of biological function.

- Gaudet et al. (2016) — A short introduction to the structure of the GO, its relations, annotations and evidence codes. A practical companion to the subsection on the Gene Ontology. *(primer; CC BY 4.0)*

  Primer on the Gene Ontology. Gaudet et al. (2016). *The Gene Ontology Handbook*. doi:10.1007/978-1-4939-3743-1_3

  > The Gene Ontology (GO) project is the largest resource for cataloguing gene function. The combination of solid conceptual underpinnings and a practical set of features have made the GO a widely adopted resource in the research community and an essential resource for data analysis. In this chapter, we provide a concise primer for all users of the GO. We briefly introduce the structure of the ontology and explain how to interpret annotations associated with the GO.

D.10.2 Function prediction

- Vu and Jung (2021) — Reviews GO-based function prediction from homology, domain and network methods to deep learning, including evaluation. Covers most of the subsections of this section in one place. *(review; CC BY 4.0)*

  Protein function prediction with gene ontology: from traditional to deep learning models. Vu & Jung (2021). *PeerJ*. doi:10.7717/peerj.12019

  > Protein function prediction is a crucial part of genome annotation. Prediction methods have recently witnessed rapid development, owing to the emergence of high-throughput sequencing technologies. Among the available databases for identifying protein function terms, Gene Ontology (GO) is an important resource that describes the functional properties of proteins. Researchers are employing various approaches to efficiently predict the GO terms. Meanwhile, deep learning, a fast-evolving discipline in data-driven approach, exhibits impressive potential with respect to assigning GO terms to amino acid sequences. Herein, we reviewed the currently available computational GO annotation methods for proteins, ranging from conventional to deep learning approach. Further, we selected some suitable predictors from among the reviewed tools and conducted a mini comparison of their performance using a worldwide challenge dataset. Finally, we discussed the remaining major challenges in the field, and emphasized the future directions for protein function prediction with GO.

- Cozzetto and Jones (2016) — Explains annotation transfer by sequence similarity, orthology and domain/family signatures, and the errors this can propagate. Useful for the subsections on homology- and family-based annotation. *(book chapter; CC BY 4.0)*

  Computational Methods for Annotation Transfers from Sequence. Cozzetto & Jones (2016). *The Gene Ontology Handbook*. doi:10.1007/978-1-4939-3743-1_5

  > Surveys of public sequence resources show that experimentally supported functional information is still completely missing for a considerable fraction of known proteins and is clearly incomplete for an even larger portion. Bioinformatics methods have long made use of very diverse data sources alone or in combination to predict protein function, with the understanding that different data types help elucidate complementary biological roles. This chapter focuses on methods accepting amino acid sequences as input and producing GO term assignments directly as outputs; the relevant biological and computational concepts are presented along with the advantages and limitations of individual approaches.

- Lin et al. (2024) — A recent survey grouping function predictors by the information they use (sequence, structure, networks, language models) and comparing them. Gives a more up-to-date view of the machine-learning methods. *(review; CC BY 4.0)*

  A comprehensive review and comparison of existing computational methods for protein function prediction. Lin et al. (2024). *Briefings in Bioinformatics*. doi:10.1093/bib/bbae289

  > Protein function prediction is critical for understanding the cellular physiological and biochemical processes, and it opens up new possibilities for advancements in fields such as disease research and drug discovery. During the past decades, with the exponential growth of protein sequence data, many computational methods for predicting protein function have been proposed. Therefore, a systematic review and comparison of these methods are necessary. In this study, we divide these methods into four different categories, including sequence-based methods, 3D structure-based methods, PPI network-based methods and hybrid information-based methods. Furthermore, their advantages and disadvantages are discussed, and then their performance is comprehensively evaluated and compared. Finally, we discuss the challenges and opportunities present in this field.

D.10.3 Subcellular localisation

- Imai and Nakai (2020) — Describes the main sorting signals (signal peptides, transit peptides, nuclear signals) and the tools that recognise them, written by authors of PSORT. Closely matches the section's structure from signals to prediction. *(review; CC BY 4.0)*

  Tools for the Recognition of Sorting Signals and the Prediction of Subcellular Localization of Proteins From Their Amino Acid Sequences. Imai & Nakai (2020). *Frontiers in Genetics*. doi:10.3389/fgene.2020.607812

  > At the time of translation, nascent proteins are thought to be sorted into their final subcellular localization sites, based on the part of their amino acid sequences (i.e., sorting or targeting signals). Thus, it is interesting to computationally recognize these signals from the amino acid sequences of any given proteins and to predict their final subcellular localization with such information, supplemented with additional information (e.g., k -mer frequency). This field has a long history and many prediction tools have been released. Even in this era of proteomic atlas at the single-cell level, researchers continue to develop new algorithms, aiming at accessing the impact of disease-causing mutations/cell type-specific alternative splicing, for example. In this article, we overview the entire field and discuss its future direction.

- Gillani and Pollastri (2024) — A recent overview of localisation predictors, including deep-learning and language-model-based methods, and the datasets used to train them. *(review; CC BY 4.0)*

  Protein subcellular localization prediction tools <sup/>. Gillani & Pollastri (2024). *Computational and Structural Biotechnology Journal*. doi:10.1016/j.csbj.2024.04.032

> Protein subcellular localization prediction is of great significance in bioinformatics and biological research. Most of the proteins do not have experimentally determined localization information, computational prediction methods and tools have been acting as an active research area for more than two decades now. Knowledge of the subcellular location of a protein provides valuable information about its functionalities, the functioning of the cell, and other possible interactions with proteins. Fast, reliable, and accurate predictors provides platforms to harness the abundance of sequence data to predict subcellular locations accordingly. During the last decade, there has been a considerable amount of research effort aimed at developing subcellular localization predictors. This paper reviews recent subcellular localization prediction tools in the Eukaryotic, Prokaryotic, and Virus-based categories followed by a detailed analysis. Each predictor is discussed based on its main features, strengths, weaknesses, algorithms used, prediction techniques, and analysis. This review is supported by prediction tools taxonomies that highlight their rele- vant area and examples for uncomplicated categorization and ease of understandability. These taxonomies help users find suitable tools according to their needs. Furthermore, recent research gaps and challenges are discussed to cover areas that need the utmost attention. This survey provides an in-depth analysis of the most recent prediction tools to facilitate readers and can be considered a quick guide for researchers to identify and explore the recent literature advancements.

D.10.4 Predicting the effects of mutations

- Riccio et al. (2024) — A short, practical overview of variant effect predictors, how they are built and how to choose and interpret them. Relevant to the subsection on using predictions. *(review; CC BY 4.0)*

  Variant effect predictors: a systematic review and practical guide. Riccio et al. (2024). *Human Genetics*. doi:10.1007/s00439-024-02670-5

  > Large-scale association analyses using whole-genome sequence data have become feasible, but understanding the functional impacts of these associations remains challenging. Although many tools are available to predict the functional impacts of genetic variants, it is unclear which tool should be used in practice. This work provides a practical guide to assist in selecting appropriate tools for variant annotation. We conducted a MEDLINE search up to November 10, 2023, and included tools that are applicable to a broad range of phenotypes, can be used locally, and have been recently updated. Tools were categorized based on the types of variants they accept and the functional impacts they predict. Sequence Ontology terms were used for standardization. We identified 118 databases and software packages, encompassing 36 variant types and 161 functional impacts. Combining only three tools, namely SnpEff, FAVOR, and SparkINFERNO, allows predicting 99 (61%) distinct functional impacts. Thirty-seven tools predict 89 functional impacts that are not supported by any other tool, while 75 tools predict pathogenicity and can be used within the ACMG/AMP guidelines in a clinical context. We launched a website allowing researchers to select tools based on desired variants and impacts. In summary, more than 100 tools are already available to predict approximately 160 functional impacts. About 60% of the functional impacts can be predicted by the combination of three tools. Unexpectedly, recent tools do not predict more impacts than older ones. Future research should allow predicting the functionality of so far unsupported variant types, such as gene fusions.URL: https://cardio-care.shinyapps.io/VEP_Finder/ .Registration: OSF Registries on November 10, 2023, https://osf.io/s2gct .

- Livesey and Marsh (2023) — Benchmarks many predictors, including unsupervised evolutionary models, against deep mutational scanning data. A primary benchmark rather than a tutorial, but it illustrates the experimental-benchmark subsection well. *(review; CC BY 4.0)*

  Updated benchmarking of variant effect predictors using deep mutational scanning. Livesey & Marsh (2023). *Molecular Systems Biology*. doi:10.15252/msb.202211474

  > The assessment of variant effect predictor (VEP) performance is fraught with biases introduced by benchmarking against clinical observations. In this study, building on our previous work, we use independently generated measurements of protein function from deep mutational scanning (DMS) experiments for 26 human proteins to benchmark 55 different VEPs, while introducing minimal data circularity. Many top-performing VEPs are unsupervised methods including EVE, DeepSequence and ESM-1v, a protein language model that ranked first overall. However, the strong performance of recent supervised VEPs, in particular VARITY, shows that developers are taking data circularity and bias issues seriously. We also assess the performance of DMS and unsupervised VEPs for discriminating between known pathogenic and putatively benign missense variants. Our findings are mixed, demonstrating that some DMS datasets

perform exceptionally at variant classification, while others are poor. Notably, we observe a striking correlation between VEP agreement with DMS data and performance in identifying clinically relevant variants, strongly supporting the validity of our rankings and the utility of DMS for independent benchmarking.

- Gerasimavicius et al. (2025) — A brief review of how protein structure, including predicted structures, can be combined with sequence-based predictors to assess missense variants. *(review; CC BY 4.0)*

  Leveraging protein structural information to improve variant effect prediction. Gerasimavicius et al. (2025). *Current Opinion in Structural Biology*. doi:10.1016/j.sbi.2025.103023

  > Despite massive sequencing efforts, understanding the difference between human pathogenic and benign variants remains a challenge. Computational variant effect predictors (VEPs) have emerged as essential tools for assessing the impact of genetic variants, although their performance varies. Initially, sequence-based methods dominated the field, but recent advances, particularly in protein structure prediction technologies like AlphaFold, have led to an increased utilization of structural information by VEPs aimed at scoring human missense variants. This review highlights the progress in integrating structural information into VEPs, showcasing novel models such as AlphaMissense, PrimateAI-3D, and CPT-1 that demonstrate improved variant evaluation. Structural data offers more interpretability, especially for non-loss-of-function variants, and provides insights into complex variant interactions in vivo. As the field advances, utilizing biomolecular complex structures will be pivotal for future VEP development, with recent breakthroughs in protein-ligand and protein-nucleic acid complex prediction offering new avenues.

D.10.5 Benchmarking function prediction

- Friedberg and Radivojac (2016) — Written by CAFA organisers; explains the design of CAFA, its metrics and the difficulties of evaluating function prediction with incomplete annotations. *(book chapter; CC BY 4.0)*

  Community-Wide Evaluation of Computational Function Prediction. Friedberg & Radivojac (2016). *The Gene Ontology Handbook*. doi:10.1007/978-1-4939-3743-1_10

  > A biological experiment is the most reliable way of assigning function to a protein. However, in the era of high-throughput sequencing, scientists are unable to carry out experiments to determine the function of every single gene product. Therefore, to gain insights into the activity of these molecules and guide experiments, we must rely on computational means to functionally annotate the majority of sequence data. To understand how well these algorithms perform, we have established a challenge involving a broad scientific community in which we evaluate different annotation methods according to their ability to predict the associations between previously unannotated protein sequences and Gene Ontology terms. Here we discuss the rationale, benefits, and issues associated with evaluating computational methods in an ongoing community-wide challenge.

- Škunca et al. (2016) — Discusses why assessing GO predictions is hard (open-world annotations, hierarchy, annotation biases) and how evaluation strategies address this. Matches the subsection on why function prediction is hard to evaluate. *(book chapter; CC BY 4.0)*

  Evaluating Computational Gene Ontology Annotations. Škunca et al. (2016). *The Gene Ontology Handbook*. doi:10.1007/978-1-4939-3743-1_8

  > Two avenues to understanding gene function are complementary and often overlapping: experimental work and computational prediction. While experimental annotation generally produces high-quality annotations, it is low throughput. Conversely, computational annotations have broad coverage, but the quality of annotations may be variable, and therefore evaluating the quality of computational annotations is a critical concern.In this chapter, we provide an overview of strategies to evaluate the quality of computational annotations. First, we discuss why evaluating quality in this setting is not trivial. We highlight the various issues that threaten to bias the evaluation of computational annotations, most of which stem from the incompleteness of biological databases. Second, we discuss solutions that address these issues, for example, targeted selection of new experimental annotations and leveraging the existing experimental annotations.

D.10.6 Experimental determination of function

- Bock et al. (2022) — A primer on pooled and arrayed CRISPR screens, their readouts and analysis; linked only. *(primer; not open access)*

  High-content CRISPR screening. Bock et al. (2022). *Nature Reviews Methods Primers*. doi:10.1038/s43586-021-00093-4

Protein function prediction with gene ontology: from traditional to deep learning models

Thi Thuy Duong Vu and Jaehee Jung

Department of Information and Communication Engineering, Myongji University, Yongin-si, Gyeonggi-do, South Korea

ABSTRACT

Protein function prediction is a crucial part of genome annotation. Prediction methods have recently witnessed rapid development, owing to the emergence of high-throughput sequencing technologies. Among the available databases for identifying protein function terms, Gene Ontology (GO) is an important resource that describes the functional properties of proteins. Researchers are employing various approaches to efficiently predict the GO terms. Meanwhile, deep learning, a fast-evolving discipline in data-driven approach, exhibits impressive potential with respect to assigning GO terms to amino acid sequences. Herein, we reviewed the currently available computational GO annotation methods for proteins, ranging from conventional to deep learning approach. Further, we selected some suitable predictors from among the reviewed tools and conducted a mini comparison of their performance using a worldwide challenge dataset. Finally, we discussed the remaining major challenges in the field, and emphasized the future directions for protein function prediction with GO.

INTRODUCTION

Proteins are organic macromolecules that are fundamental determinants of the structure and function of living organisms. They play a role in numerous processes, including biochemical reactions, transmission of signals, nutrient transport, immune system boosting, etc. Therefore, understanding protein properties is essential not only from the biological and evolutionary perspectives, but also from the viewpoint of leveraging their potential in biomedical and pharmaceutical applications, and other areas (*Amiri-Dashatan et al., 2018*).

Generally, protein function identification is accomplished through manual or computational annotation. The former approach is the gold standard for functional annotation, because it is implemented by expert annotators and yields high quality curated results. Nonetheless, this approach is expensive and laborious, and thus, it is difficult to scale. Furthermore, because of the development of high-throughput sequencing technologies, such as next-generation sequencing (NGS), the amount of sequences to be annotated has increased dramatically. Thus, computational annotation methods have been developed as

How to cite this article Vu TTD, Jung J. 2021. Protein function prediction with gene ontology: from traditional to deep learning models. *PeerJ* **9**:e12019 http://doi.org/10.7717/peerj.12019

a must to automatically process the high volume of newly generated sequences, and also to improve the accuracy of the annotated data (*Sleator & Walsh, 2010*).

Because of the variability in the vocabulary used to define protein function, which makes the annotation process confusing to both humans and machines, various databases have been proposed to provide a standardized scheme, such as the Enzyme Commission (EC) (*Webb, 1992*), Functional Catalogue (FunCat) (*Ruepp et al., 2004*), and Kyoto Encyclopedia of Genes and Genomes (KEGG) (*Kanehisa et al., 2004*). Currently, Gene Ontology (GO) (*Ashburner et al., 2000*; *Consortium, 2015*) is the most comprehensive resource, as it possesses all the desirable properties of a functional classification system (*Pandey, Kumar & Steinbach, 2006*). The GO consortium created a database for a controlled vocabulary describing the functional properties of genomic products (*e.g.*, genes, proteins, and RNA). Each ontology (vocabulary) belongs to one of three categories: molecular function (MF), biological process (BP), and cellular component (CC). In terms of structure, the GO follows a hierarchical organization as a directed acyclic graph (DAG), in which each term is a node and each edge connected to two nodes represents a parent–child relationship. It can be used to infer many types of information, such as "is-a" or "part-of". For instance, if term A is denoted as "is-a" of term B, it means that A is a sub-type of B. Further, "part-of" implies that the child node is necessarily part of the parent. This allows the flexible annotation of proteins with respect to the various levels of function—from general to specific terms—depending on the available evidence (*Stein, 2001*).

Automated function prediction (AFP) based on the GO system is a challenging problem in bioinformatics. Many studies have discussed protein functional annotation from different perspectives. Previous reviews focused on AFP (*Rost et al., 2003*) in terms of the data type used (*Watson, Laskowski & Thornton, 2005*; *Pandey, Kumar & Steinbach, 2006*; *Sleator & Walsh, 2010*; *Shehu, Barbará & Molloy, 2016*), drawbacks and corresponding solutions (*Friedberg, 2006*), protein interaction networks (*Sharan, Ulitsky & Shamir, 2007*), types of classified function (*Rentzsch & Orengo, 2009*), and GO assignment based on sequence information (*Cozzetto & Jones, 2017*). The two latest reviews are prepared by *Bonetta & Valentino (2020)* and *Zhao et al. (2020)*. *Bonetta & Valentino (2020)* demonstrate protein function prediction in the machine learning workflow. Meanwhile, *Zhao et al. (2020)* discuss prediction of gene function prediction from the GO modeling perspective. All these researches provided independent perspectives to the issue, but we observed that there has not been any detailed review about deep learning, which is an emerging approach for protein function prediction with GO terms. Therefore, our paper suggests the possibility of predicting protein function using both conventional learning and deep learning, further indicating that better predictive performance can be expected by comparing several methods with each other.

Herein, we reviewed automated protein function prediction using GO terms (ranging from traditional solutions to the most recently developed deep learning-based tools). We presented not only an overview of the literature, but also, a performance comparison of the emerging solutions. Further, we highlighted the challenges and future prospects of the field. We hope that this review will provide bioinformaticians, computer scientists

or any researchers who are interested in this topic, with the latest updates in terms of protein features used, models, and evaluation criteria, hoping to contribute to further improvements in the future.

SURVEY METHODOLOGY

Based on previous studies (*Jung & Thon, 2006*; *Jung et al., 2010*) and the aforementioned surveys, our review is divided in two main parts offering an overview of the field (from its inception to its present state). The first parts covers the conventional approach and includes solutions that do not use deep learning, while the second part describes methods that rely on deep learning to address the problem of protein functional annotation. We used Google Scholar https://scholar.google.com/ as the literature database to retrieve relevant publications, without applying any restrictions as to the publishing data, journal, or publisher.

Below, we review the conventional approach briefly, as some excellent literature reviews are already available on the subject (*Shehu, Barbará & Molloy, 2016*; *Cozzetto & Jones, 2017*). In that part, we summarize three main sub-categories of the traditional approach, and mention prominent or most recent corresponding studies. The second part of the review is our main focus. Search results using combinations of the following keywords: "deep learning", "deep neural network", "Gene Ontology", "GO terms", "protein function prediction", "functional annotation", and "gene function prediction", are selected after screening the titles, abstracts and conclusions. We also referred to references cited in the downloaded papers, to capture significant studies in the field.

CONVENTIONAL APPROACH FOR PREDICTING PROTEIN GO TERMS

In general, several techniques have been proposed to tackle the assignment of GO terms to proteins using different types of data and methods. We review the representative solutions below, focusing on three categories: similarity-based methods, probabilistic methods, and machine learning methods.

Similarity-based methods

Initially, functional annotations were assigned to uncharacterized proteins based on a simple principle: a protein sequence was searched in databases of experimentally curated proteins and if there were any similar proteins retrieved ("similar" in a specifically defined way), GO terms associated with the retrieved sequences were assigned to the query protein.

The very first solution of similarity-based methods was homology-based. These tools relied on local alignment search tools, such as the Basic Local Alignment Search Tool (BLAST) (*Altschul et al., 1997*). In these methods, the unknown sequence is searched in a database that curates well-annotated proteins. Then, a retrieved sequence with the highest alignment score—as per a predetermined threshold—is identified and its annotation is transferred to the query protein. OntoBlast (*Zehetner, 2003*), GOFigure (*Khan et al., 2003*), GOblet (*Hennig, Groth & Lehrach, 2003*), and GOtcha (*Martin, Berriman & Barton, 2004*)

are typical annotation systems adopting sequence similarity determined by BLAST search. Further details regarding these tools are presented in Table 1.

PFP (*Hawkins et al., 2009*) is another method that utilizes functional information associated with remote homologs by employing Position-Specific Iterated BLAST (PSI-BLAST) (*Altschul et al., 1997*). The tool is an improvement in terms of coverage and accuracy, as determined by analyzing a benchmark dataset, compared with GOtcha, top PSI-BLAST, and InterProScan (*Zdobnov & Apweiler, 2001*). Another variant solution based on sequence alignment is INGA (*Piovesan et al., 2015*), in which protein–protein interaction (PPI) network data is combined with domain assignment and sequence similarity from BLAST, to attain a consensus prediction of GO functions using enrichment analysis. Further, GoFDR (*Gong, Ning & Tian, 2016*) takes relevant GO terms from multiple sequence alignment (MSA) querying *via* BLAST or PSI-BLAST search. The probability of assigning a term to the query sequence is determined by the functionally discriminating residues (FDRs), a position-specific scoring matrix (PSSM) for the FDRs, and a score-to-probability table prepared using training sequences.

Although methods based on a local alignment search are straightforward and perform well to some extent, they also have some drawbacks, including database annotation errors or excessive function transfer, threshold relativity, and low sensitivity or specificity (*Sasson, Kaplan & Linial, 2006*). In addition to the alignment-based methods, several other predictors are available that transfer function annotations based on the similarity at the level of protein structure, protein family, or phylogenomics (*Shehu, Barbará & Molloy, 2016*).

Probabilistic methods

A number of probabilistic models have been devised for protein function deduction (*Deng, Chen & Sun, 2004a*; *Deng et al., 2004b*; *Letovsky & Kasif, 2003*; *Nariai, Kolaczyk & Kasif, 2007*). *Letovsky & Kasif (2003)* employed a functional linkage graph (*Marcotte et al., 1999*) constructed based on a PPI network of the yeast *Saccharomyces cerevisiae*. The working assumption was that the probability of sharing functions between (nodes) proteins in close proximity on the graph is higher than that for nodes that are not in close proximity. In this method, the probabilities of GO terms assigned to a protein sequence are derived from a binomial model incorporating the Markov Random Field (MRF) algorithm. Later, *Nariai, Kolaczyk & Kasif (2007)* integrated multiple sources of evidence (PPI, gene expression data, protein motif information, mutant phenotype data, and protein localization data) using a Bayesian framework, to improve the prediction performance, compared with their model that only uses PPI.

Working on the same model organism, *S. cerevisiae*, as used in the methods described above, *Kourmpetis et al. (2010)* suggested applying a Bayesian approach to the MRF model. This suggestion was considered an improvement for the estimation of model parameters and the provision of predictions from network data. Further, *Pinoli, Chicco & Masseroli (2015)* compared different weighting schemes as combined with three algorithms, namely, truncated singular value decomposition (tSVD), semantically improved tSVD (SIM), and probabilistic latent semantic analysis with normalization (pLSAnorm). The first two

Table 1 GO annotation predictors using the traditional approach.

Methods	Program name	Description	Reference
Similarity based	OntoBlast	Web server, which is a part of the "Ontologies TO GenomeMatrix" tool (*Hewelt et al., 2002*). It predicts protein function by a weighted list of GO terms associated with BLAST hit sequences in nine genome databases.	*Zehetner (2003)*
	GOFigure	Produces output as a clickable graph in four steps, including homologous sequence search, minimum cover graph construction, and assigning ontologies after scoring them.	*Khan et al. (2003)*
	GOblet	Software package allowing the user to define the *E*-value sensitivity and databases used for the BLAST search. All ontologies identified after matching the proteins are constructed in a summary DAG structure, where the number of sequences sharing a common GO term is cumulative to present the significance of the term.	*Hennig, Groth & Lehrach (2003)*
	Gotcha	Transfers GO associations retrieved from BLAST to gene products through a novel ranking scheme. The E-values of the derived terms are propagated to their parent terms on DAG, providing normalized confidence scores for an individual GO ontology.	*Martin, Berriman & Barton (2004)*
	PFP	Functional annotation system based on PSI-BLAST hits, exploiting matched sequences up to an unconventionally high threshold, and mining highly relevant GO terms from UniProt to score functions for unknown proteins.	*Hawkins et al. (2009)*
	INGA	Functional annotation server derives GO predictions from combining many data sources.	*Piovesan et al. (2015)*
	GoFDR	Multiple alignment-based method utilizing FDRs and PSSM to rank GO terms for amino acid sequences.	*Gong, Ning & Tian (2016)*
Probabilistic	–	Probabilistic framework based on PPI, predicting GO assignments for 10% unannotated proteins in yeast.	*Letovsky & Kasif (2003)*
	–	Leverages heterogeneous data to increase the probabilistic based model for the functional prediction of *Saccharomyces cerevisiae*.	*Nariai, Kolaczyk & Kasif (2007)*
	BMRF	Variant of the MRF-based approach on PPI that infers novel predictions for unannotated proteins.	*Kourmpetis et al. (2010)*
Machine learning	GOPET	GO term prediction and evaluation tool, supplying molecular function and biological process GO terms for any organism.	*Vinayagam et al. (2006)*
	PoGO	Ensemble model with InterPro sequence similarity, biochemical property, and protein tertiary structure to predict the GO of fungal proteins.	*Jung et al. (2010)*
	FFPred3	SVM-based tool, providing the homology-independent assignment of GO terms for eukaryotic proteins.	
	PANNZER2	Weighted *k*-nearest neighbor classifier, providing functional annotation for uncharacterized proteins with GO terms and free text descriptions.	*Törönen, Medlar & Holm (2018)*
	DeepText2GO	Combination of a text-based method and a sequence-based method to improve large-scale protein function prediction.	*You, Huang & Zhu (2018a)*
	NetGo	Effective LTR-based web server, combining both sequence and massive network information of proteins to annotate gene products.	*You et al. (2019)*

methods are based on linear algebra, while the latter is a modified probabilistic model based on Bayesian inference. These methods were successfully used to generate novel GO annotations for three model organisms, *i.e., Bos taurus*, *Danio rerio*, and *Drosophila melanogaster*.

Machine learning methods

Machine learning-based tools have been developed to identify the hidden relationships between various protein features (sequence, structure, or other related evolutionary evidence) and functional labels, based on a training set (a group of fully characterized macromolecules), and use that information to generate annotations for novel proteins. Various methods that rely on machine learning have been suggested, incorporating different lines of evidence as features to train the classifiers and predict GO terms. Branch (a) of Fig. 1 formulates the common workflow of those solutions, the details of which can vary between methods as described below.

Utilizing multiple support vector machine (SVM) classifiers is a predominant selection in several studies. For instance, GOPET (*Vinayagam et al., 2006*) feeds several features related to GO terms (sequence similarity measures based on BLAST search, frequency, quality of homolog annotation, and annotation level within the GO hierarchy) to 99 SVM classifiers. A specific term will be predicted to be a "correct" or "incorrect" label for an unknown sequence, with voting confidence scores calculated. As another example, FFPred (*Lobley et al., 2007*; *Lobley et al., 2008*) was initially established for the unannotated human proteome, but demonstrated a generalization to other proteomes. The latest version of FFPred is FFPred3 (*Cozzetto et al., 2016*), which is still based on SVM, is expanded to investigate the correlations between feature characteristics retrieved from sequences and structures within the three sub-ontologies (MF, BP, and CC). Another tool, Prediction of Gene Ontology terms (PoGO) (*Jung et al., 2010*), has been developed from Automatic Annotation of Protein Functional Class (AAPFC) (*Jung & Thon, 2006*). Instead of only using InterPro terms as features, PoGO integrates three more sources (sequence similarity, biochemical properties, and protein tertiary structure). Subsequently, SVM and a linear classifier (*Freund & Schapire, 1997*) are used as base-level classifiers before the meta-learning step.

Using the k-nearest neighbor (k-NN) algorithm, PANNZER2 (*Törönen, Medlar & Holm, 2018*) provides a fast functional annotation systems based on sequence homology and other annotation predictors. Meanwhile, MS-k NN (*Lan et al., 2013*) aggregates heterogeneous data to propose a competitive model for protein function prediction. DeepText2GO (*You, Huang & Zhu, 2018a*) is a consensus approach, integrating deep semantic text representation from MEDLINE citations (*ncb, 2018*) as text information, and sequence information obtained *via* BLAST and InterProScan. These features are fed to the k-NN and logistic regression models to produce the functions of no-knowledge proteins on a large scale. NetGO (*You et al., 2019*) is an extension of GoLabeler (*You et al., 2018b*), which employs the learning-to-rank(LTR) model to integrate sequence-based evidence. NetGO improves the performance of a large scale AFP by accessing the enormous protein–protein network of over 2000 species in the STRING database (*Szklarczyk et al., 2016*).

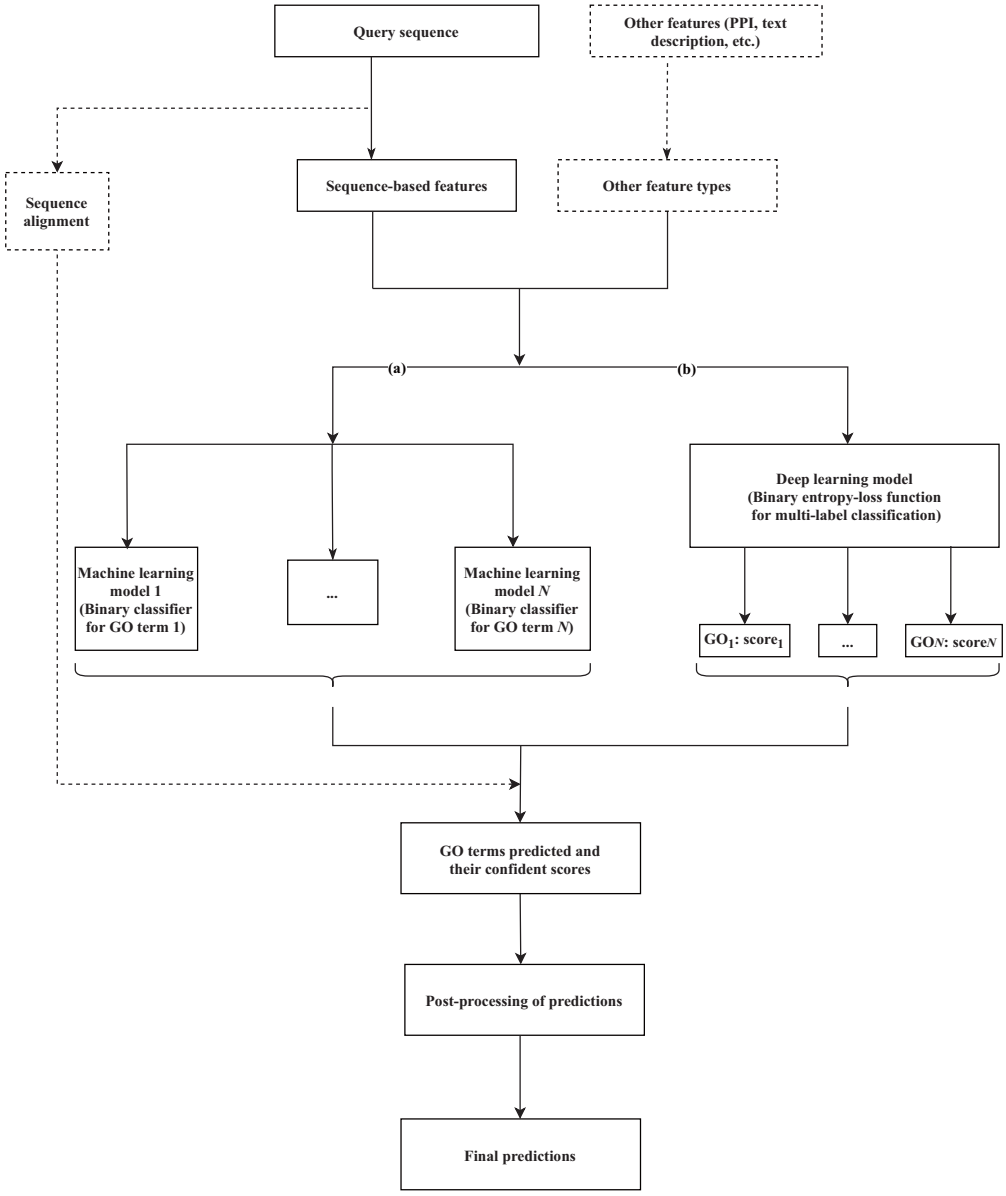

Figure 1 A common workflow of (A) machine learning-based and (B) deep learning-based solutions for predicting the GO terms of proteins. The components presented in the dashed box are optional, depending on each method. *N* is the number of GO terms that are selected for the training dataset to build the model.

Full-size DOI: 10.7717/peerj.12019/fig-1

Machine learning approaches are highly advantageous and considered the future direction for AFP. Some novel proteins either lack identifiable homologous sequences or their detectable homologues have not been assigned any GO labels. Consequently, assigning protein function from scratch using machine learning, *i.e.,* directly inferring the annotation from the amino acid sequence, without access to any additional references or databases,

is an ongoing task. The sophisticated algorithms are being developed, as presented in the next section.

GO TERM ANNOTATION OF PROTEINS USING DEEP LEARNING APPROACH

The excellent potential of deep learning—the latest discipline of machine learning—has been demonstrated in several application fields, including bioinformatics (*Min, Lee & Yoon, 2017*; *Li et al., 2019*). The main characteristic that distinguishes this approach from other methods is the learning process. Deep learning models are inspired by neural networks in the human brain. They automatically extract high-level features from raw data and provide predictions in an end-to-end manner. In contrast to that in conventional machine learning models, accurate classification is achieved *via* handcrafted features.

Currently, the amount of generated genomic data, and the numbers of sophisticated algorithms and computational resources are rapidly growing. These resources support deep learning to tackle the functional annotation problem. Below, we review proposed methods based on two criteria, *i.e.,* the model and the input data used. A summary table of the reviewed methods is presented in Table 2, and a common workflow for deep learning approach is illustrated as Figure 1B.

Model-based approach

Supervised learning

Supervised learning is an essential approach for *in silico* protein function prediction. Supervised models learn to annotate function guided by a training dataset, which is a group of characterized proteins with reliable, experimentally confirmed annotations. After the learning stage, a model that captures the relationship between feature and function is produced, and used to predict the GO terms for novel amino acid sequences.

Deep neural network (DNN) is a feed-forward architecture. It generally comprises an input layer, multiple hidden layers, and an output layer. Input data are processed in a unidirectional manner along the layers, from the first to the final stage. With respect to GO-based functional annotation, DNNs have been employed as multi-task DNNs (MTDNNs) (*Fa et al., 2018*) or a series of MTDNNs (*Rifaioglu et al., 2019*).

Convolutional neural network (CNN) was initially developed to handle two-dimensional images for handwritten digit recognition (*LeCun et al., 1990*). However, it has since become an effective architecture not only for multi-dimensional data, but also for one-dimensional input, such as sentences or genomic sequences. A CNN model starts with convolutional layers, whose units are feature maps. Each unit is obtained by computing convolution operations between local patches of a unit in the preceding layer and a filter (set of weights) (*LeCun, Bengio & Hinton, 2015*). Non-linearity pooling layers are stacked to convolutional layers, enabling the integration of different-scale features in this architecture. CNNs can be applied in AFP either alone (*Kulmanov, Khan & Hoehndorf, 2018*; *Cai, Wang & Deng, 2020*; *Du et al., 2020*) or in combination with other architectures (*Zhang et al., 2020*; *Spalević et al., 2020*).

Table 2 Deep learning-based methods for assigning GO terms to proteins.

Recurrent neural network (RNN) is a deep learning architecture developed especially for sequential data. RNNs have a DNN backbone, and the units of the hidden layer are connected. Therefore, a hidden unit receives information from the input layer at the current time step, and also from the hidden units at the preceding stage (*LeCun, Bengio & Hinton, 2015*). Long short-term memory (LSTM) (*Hochreiter & Schmidhuber, 1997*) is a variant of the RNN model, developed to capture long-term dependencies between input sequences. Bi-directional LSTM (Bi-LSTM) is an LSTM model that processes data in two directions, forwards and backwards. These neural networks are employed to process protein sequences as a natural language (*Cao et al., 2017*) or are combined with the CNN model (*Zhang et al., 2020*) to provide GO annotations.

Another type of neural network, fully connected deep network (FCDN), is a series of fully connected layers. This model was utilized for converting input vectors from InterPro and predicting GO terms (*Zhang et al., 2019*).

Unsupervised learning

Unlike supervised learning, unsupervised learning independently mines hidden patterns in input distribution. It is crucial for exploring unlabeled data and provides important information for supervised architectures. Typically, unsupervised learning models are employed for clustering, reducing dimensions, and transforming data.

Autoencoder (AE) (*Baldi, 2012*) is an unsupervised learning model developed for assigning GO terms to amino acid sequences. AE is a neural network for data transformation. After encoding and decoding, the target output size is the same as that of the input. Using a trained AE model, GO predictions for proteins can be deduced directly from the generated matrix (*Chicco, Sadowski & Baldi, 2014*). Alternatively, low-dimensional feature representations in the hidden layer are extracted and fed into an SVM classifier for final classification (*Gligorijević, Barot & Bonneau, 2018*) or a CNN model (*Peng et al., 2020*) for final classification.

Restricted Boltzmann machine (RBM) (*Salakhutdinov & Hinton, 2009*) has one hidden layer for representing latent features and an input layer encoding the observed data. For GO annotation, units of the input layer are the available GO terms (*Zou, Wang & Yu, 2017*). *Zou, Wang & Yu (2017)* introduced a deep RBM (DRBM), where multi-layer RBMs are trained and unfolded, resulting in protein function prediction.

Finally, generative adversarial network (GAN) (*Goodfellow et al., 2014*) comprises two networks, *i.e.,* a generative model that produces synthetic realistic data and a discriminative model that evaluates whether the data are real or not. In AFP, the GAN model improves the prediction by creating synthetic features for supervised classifiers (*Wan & Jones, 2020*), or by exploiting ontology correlations (*Seyyedsalehi et al., 2021*).

Data-based approach

In terms of the input feature, deep learning-based methods primarily use two approaches to assign GO terms to unknown gene products. One is a sequence-only approach, which is useful for predicting the functions of novel proteins in the absence of homologous information or other references. The second one is structure-based or otherwise exploits big data from several available resources.

Sequence-based models

One of the earliest deep learning-based methods for GO annotation predictions is the one proposed by *Chicco, Sadowski & Baldi (2014)*. The authors compared two annotation solutions, *i.e.,* tSVD, presented in *Pinoli, Chicco & Masseroli (2013)*, and the AE neural network. The output form of the two methods was similar; however, the latter performed better on six different datasets. Later, instead of using the AE architecture, (*Zou, Wang & Yu, 2017*) proposed DRBM for annotating the gene products of four model species, *Homo sapiens, S.cerevisiae, Musmusculus*, and *Drosophila*.

ProLanGo (*Cao et al., 2017*) is the first tool that applies Neural Machine Translation (NMT) developed by Google in AFP. The authors converted amino acid sequences and GO terms into "ProLan" and "GOLan" languages, respectively. The GO annotation of a new protein was then generated after being translated using a model with three RNN layers. In another study, artificial neural networks proposed by *Szalkai & Grolmusz (2018a)* utilized six CNN layers of increasing depth. Based on that work, SECLEF (*Szalkai & Grolmusz, 2018b*) has been designed to train and test the GO function and UniProt protein family using biological sequences as input. The user can implement their self-configured models in a downloadable program or run two pre-trained models (*Szalkai & Grolmusz, 2018a*) on a web server. DeepSeq (*Nauman et al., 2019*) is another method for assigning GO terms to amino acid sequences, based on convolutional layers. However, the authors only predicted the five most frequent MF ontologies for *H. sapiens* proteins.

Using the DNN architecture, DEEPred (*Rifaioglu et al., 2019*) implements a stack of multi-task feed-forward DNNs. Each individual network is built for a specific GO term level on DAG, which allows the hierarchical post-processing of predictions. Protein sequences are experimentally represented by three types of descriptors(subsequence profile map, pseudo-amino acid composition, and conjoint triad feature), with subsequence profile map performing best in the analysis.

DeepGOPlus (*Kulmanov & Hoehndorf, 2020*) has been developed to overcome the existing limitations of DeepGO (*Kulmanov, Khan & Hoehndorf, 2018*), such as sequence length, unavailable PPI features, and the number of GO labels. Functional annotation is predicted by a multi-layer CNN structure in combination with sequence similarity. Lately, TALE (*Cao & Shen, 2021*) has been developed to generate GO predictions by integrating sequence patterns based on transformer encoder and the joint similarity of sequence-term. Similar to DeepGOPlus, TALE is also combined with sequence similarity as TALE+ model to enhance its performance. Meanwhile, PFP-WGAN (*Seyyedsalehi et al., 2021*) is one of two latest ideas that use GAN to infer the functionalities of proteins. While the generator network processes raw sequences, the discriminator takes two inputs; one consists of annotated proteins from the SwissProt database and the other of raw sequences with respective annotations synthesized from the generator.

Integrated data-based/Structure based-models

The functional assignment of amino acid sequences from 3D structures was proposed by (*Tavanaei et al., 2016*). The main analysis involved a CNN model that was trained and

tested on five datasets of human proteins, each of which had been assigned two GO terms. However, the prediction has not been propagated on the DAG tree for inherited GO terms.

DeepGO (*Kulmanov, Khan & Hoehndorf, 2018*) is a functional annotation server based on CNN architecture that had been devised to learn features from amino acid sequences and the PPI network. GO labels are assigned to input proteins through a hierarchical classification structured as a DAG tree. DeepAdd (*Du et al., 2020*) was inspired by DeepGO server and provides a solution for AFP, utilizing a CNN framework to learn vector representations from sequences and additional information. However, sequences are processed into k-mer embedding by Word2Vec, instead of the tri-gram embedding suggested in DeepGO. Further, in DeepAdd, the protein sequence profile (SSP) is added if the PPI network information is not available. Based on a similar concept of combining primary protein structure and PPI, GONET (*Li et al., 2020*), a novel model, was built by employing CNN, RNN, and Attention layer for human and mouse sequences.

Working on a dataset identical to the one collated by FFPred3, *Fa et al. (2018)* tested an MTDNN that treated protein function prediction as a multi-label classification problem. Here, the solution consisted of layers shared by all tasks (GO labels), which are stacked in parallel with task-specific layers. DeepFunc (*Zhang et al., 2019*) is a novel predictor that surpasses DeepGO, FFPred3, and BLAST. First, protein domain, family, and motif information is queried from InterPro and encoded before passing through fully connected layers. Next, topological features of PPI are obtained by the Deepwalk algorithm. Finally, the method concatenates two types of features (sequence- and network-based input) to fit an FCDN. The architecture of DeepGOA (*Zhang et al., 2020*) is more sophisticated than that of DeepFunc. In addition to information generated by InterPro and PPI, global and local semantic features of amino acid sequences are extracted by Bi-LSTM and a convolutional layer, respectively. Using the same types of features, SDN2GO (*Cai, Wang & Deng, 2020*) utilizes three sub-models for each information source, with all outputs integrated in the final weighted model.

In another study, deepNF (*Gligorijević, Barot & Bonneau, 2018*) was constructed by multimodal deep AE to capture hidden information in proteins from different types of interaction networks. In that suggestion, feature representations are extracted to train the final SVM classifier to produce GO terms for human proteins. DeepMNE-CNN (*Peng et al., 2020*) has a superior performance than deepNF in the human data by utilizing CNN layers instead of SVM for the classification model. On the other hand, FFPred-GAN (*Wan & Jones, 2020*) utilizes GAN for feature enrichment to feed conventional machine learning models, especially SVM. Real features are biophysical information extracted from raw amino acid sequences by FFPred, and the generator takes latent variables to augment the synthetic samples.

COMPARISON

In addition to proposing a new approach, accuracy assessment is important for demonstrating the improvements of a novel methodology. This necessitates the establishment of a common framework for the evaluation and comparison of the proposed

Table 3 Statistics of final benchmark CAFA3.

Annotation type	Number of sequences	Number of terms (GO leaf only)		
		MF	CC	BP
NK (no-knowledge)	1177	377	236	1087
LK (limited-knowledge)	2151	368	203	878
All (NK + LK)	3328	631	327	1673

solutions. Accordingly, the critical assessment of functional annotation (CAFA) (*Radivojac et al., 2013*; *Jiang et al., 2016*; *Zhou et al., 2019*) is a community-based experiment that provides a large-scale evaluation of computational protein function prediction methods in a time-delayed manner. Four main competitions (CAFA1–CAFA4) have been held every 3 years since 2010. CAFA-π is an extension of CAFA3, and allows the competitors to improve their computational solutions focusing on the prediction of genes associated with specific GO terms. Generally, each challenge comprises three phases, *i.e.,* predictions for a set of target proteins, experimental verification for a subset of target proteins to obtain a benchmark dataset, and performance analysis of all the competitors based on predefined metrics and the benchmark data. Official reports have just been released for the first three challenges and CAFA-π (*Radivojac et al., 2013*; *Jiang et al., 2016*; *Zhou et al., 2019*).

In the remainder of this section, we present a practical comparison of emerging analysis methods and discuss the retrieved results.

Set up

Data

We used the finalized benchmark set provided in the CAFA3 report (*Zhou et al., 2019*). The statistics are presented in Table 3. There are two sequence types in the benchmark dataset, NK (no-knowledge) and LK (limited-knowledge), which have been coined in CAFA2 (*Jiang et al., 2016*). Based on the timeline of the challenge, t_0 is the deadline for the prediction submission of the target sequences. Then, experimental annotations for a subset of target sequences are accumulated until t_1, to complete a benchmark dataset for the performance evaluation. The NK proteins are those that had not had any experimental annotations in three GO domains at t_0, but had at least one GO term with experimental evidence code between t_0 and t_1. The LK sequences are those that had been experimentally annotated in one or two GO domains at t_0, and gained at least one experimental annotation in the other GO domains between t_0 and t_1.

Methods

The servers of several tools have been updated recently, but we need to control their training data or databases used, in which do not include sequences in the CAFA3 benchmark. Therefore, we chose INGA, which was one of the top models in CAFA3, as a representative conventional tool. DeepGOPlus is a recently developed representative annotation system that is based on deep learning. In addition to these two tools, other studies that performed their analysis on the CAFA3 dataset are also summarized in this part.

For DeepGOPlus, we re-trained the model with the CAFA3 training sequences and generated predictions for the CAFA3 benchmark set based on their source code provided. For INGA, we obtained predictions for the CAFA3 benchmark based on the predictions of CAFA3 targets, which were provided on their website.

Model performances were evaluated based on protein-centric metrics (F_{max}, precision, and recall) provided by the CAFA3 assessment tool. The area under the precision–recall curve (AUPR), which is a measurement of highly imbalanced data, was also considered. Results regarding the performance of other methods, including Naive, BLAST, FFPred3 and DEEPred, were derived from DEEPred paper (*Rifaioglu et al., 2019*).

In terms of evaluation, two modes were designed. In the *partial* mode, the scores of each method were computed on the sequences that have at least one GO term predicted at any threshold. Conversely, scores in the *full* mode were computed on all protein sequences in the benchmark set.

Results

The results of the analysis are shown in terms of GO domains and types of sequences (NK *vs.* All) in *full* mode (Fig. 2) and *partial* mode (Fig. 3). The scores of Naive, BLAST, FFPred3 and DEEPred are only available for the *full* mode. Models using the traditional approach and deep learning approach are depicted in blue and orange tones, respectively.

As is shown in Fig. 2, deep learning-based models (DEEPred and DeepGOPlus) showed a competitive performance compared to conventional models in terms of MF and BP prediction; in particular, DEEPred acquired the highest precision in the three GO categories. Such high precision obtained by DEEPred, which was explained in their paper (*Rifaioglu et al., 2019*), probably resulted from the imbalanced dataset and post-processing step. For example, the negative protein set for each GO term is four times as large as the positive one, this leads to low false positive and high false negative predictions. Additionally, DEEPred filtered some false positives at the post-processing step, thus increasing their precision. For the CC class, two baselines (Naive and BLAST) were at the top for F_{max} and recall, followed by FFPred3. The overall outcome is presented similarly in Fig. 3, in which DeepGOPlus performed better than INGA in most of categories.

The aforementioned results and the CAFA3 report indicate that conventional models, such as INGA and GOLabeler (referred to as "ZhuLab" in CAFA3) perform as well as other high-performing models. ZhuLab was the best performer in terms of F_{max} and NK-*full* evaluation, with the scores of 0.40, 0.61, and 0.62 for BP, CC, and MF, respectively. However, these conventional models integrate several types of information, which is not always available for all sequences. Meanwhile, the deep learning approach had demonstrable advantages in this area and yielded highly competitive predictions. The research direction is currently shifting toward this new approach, with even more efficient solutions being developed.

CONCLUSION

The computational GO annotation of proteins has been an actively pursued and challenging task in bioinformatics since around the 2000s; this is a response to the need to bridge the

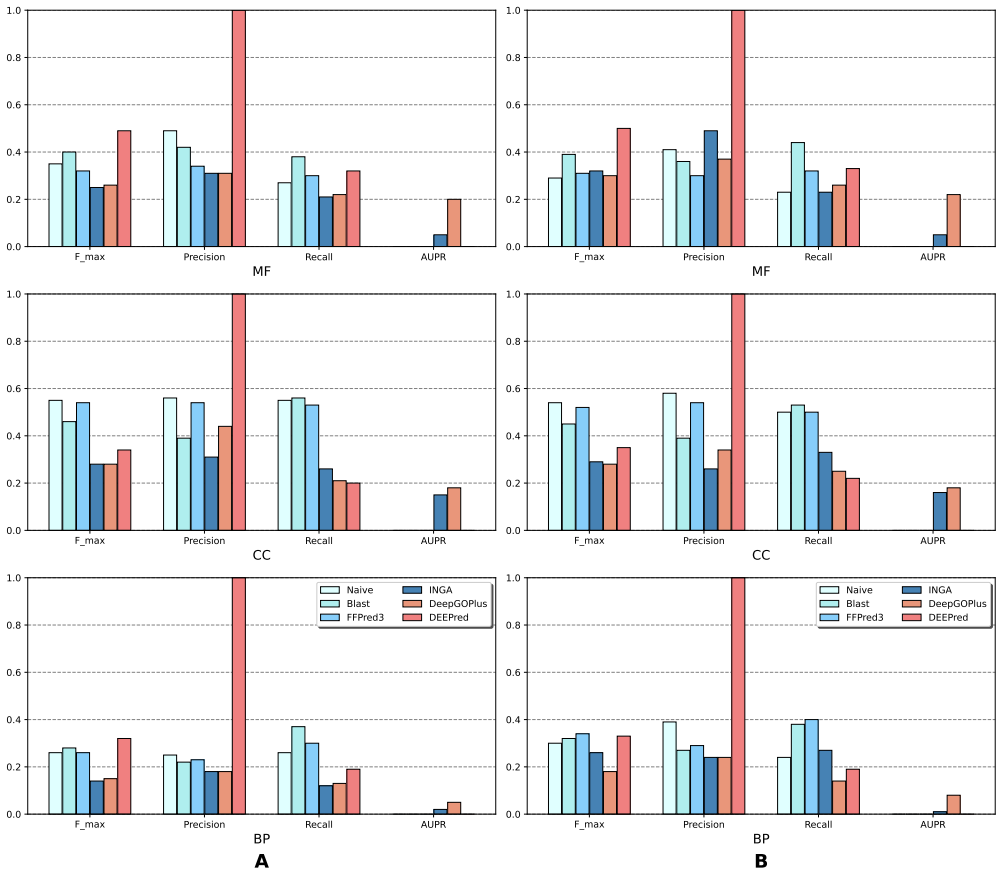

Figure 2 Performance of the selected methods with the CAFA3 benchmark dataset in *full* mode: (A) NK sequences and (B) All sequences (NK + LK). Scores in the *full* mode were computed on all protein sequences in the benchmark set. Scores of Naive, BLAST, FFPred3, DEEPred have been reported directly from *Rifaioglu et al. (2019)*.

Full-size DOI: 10.7717/peerj.12019/fig-2

gap between the known and unknown, newly discovered amino acid sequences. On the one hand, understanding protein function is essential for deciphering biological evolution and for countless applications, such as drug design and disease treatment. The GO database has facilitated a comprehensive vocabulary for functional annotation because it presents structured GO functions in three domains (MF, BP, and CC), thereby effectively supporting *in silico* protein function assignment. Herein, we presented the current state of the field and compared GO-based AFP solutions, classed as conventional and deep learning approaches. As it is difficult to introduce all the available methodologies and comprehensively compare them, we tested the prominent predictors in this study. This was complemented by the analysis of related publications, with the assessment outcomes computed by CAFA, a worldwide venue for comparing computational protein function predictors.

We observed that one of the primary difficulties in the field is the utilization of input features to achieve effective performance. While heterogeneous input data are useful for GO prediction, only sequence information is available for the majority of unannotated

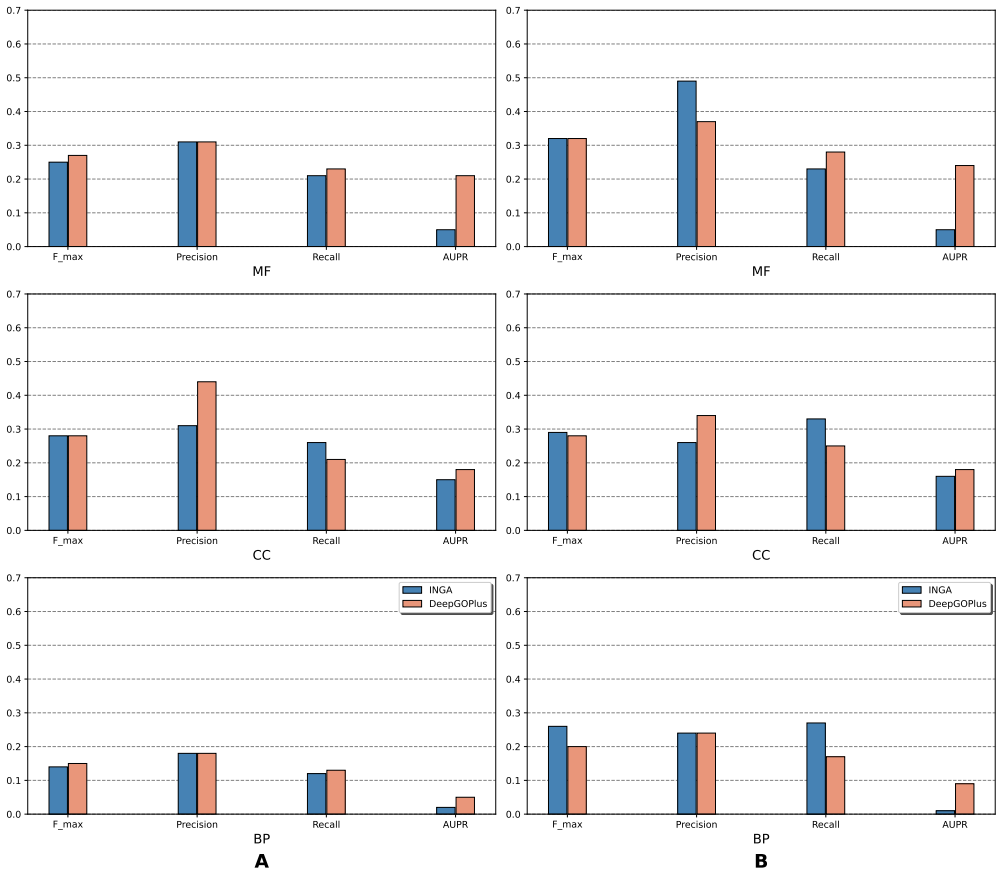

Figure 3 Performance of the selected methods with the CAFA3 benchmark dataset in *partial* mode: (A) NK sequences and (B) all sequences (NK + LK). In the *partial* mode, scores of each method were computed on the sequences that have at least one GO term predicted at any threshold.
Full-size DOI: 10.7717/peerj.12019/fig-3

proteins. With respect to the specific approaches, machine learning models may be limited by the heterogeneity of genomic data when mining different sources of information, while parameter and hyper-parameter tuning is the challenging step of the deep learning approach. In terms of output, the GO database has been updating because GO annotations are still imbalanced and not complete for all species. Its sophisticated structure is ideal for describing the functional roles of proteins, but also makes the prediction task a complex multi-label problem.

Nonetheless, despite the existing challenges, the quest for successful annotation will continue in many directions, driven by the community effort. Together with the constant expansion of -omics databases, data-driven methods have shown excellent applications in various areas, with a promising trend in functional annotation. Depending on the available sources, they can be based on integrated data or sequence information only, considering a hybrid approach. Some approaches have been suggested and developed to cope with imbalanced data; these include working on the subgroups in which the classes are more balanced, data augmentation using GAN, and considering evaluation metrics specified

for imbalanced data, such as AUPR. The multi-label problem can be addressed *via* the advancement of computational resources and well-defined solutions, for example, stacking many individual solutions together. Finally, successful solutions for GO term prediction can be expanded to include other functional resources (EC, pathways, etc.), to comprehend the biological role and life science potential of proteins.

REVIEW

Variant effect predictors: a systematic review and practical guide

Cristian Riccio[1,2] · Max L. Jansen[1,2] · Linlin Guo[3,4] · Andreas Ziegler[1,2,3,4,5]

Abstract

Large-scale association analyses using whole-genome sequence data have become feasible, but understanding the functional impacts of these associations remains challenging. Although many tools are available to predict the functional impacts of genetic variants, it is unclear which tool should be used in practice. This work provides a practical guide to assist in selecting appropriate tools for variant annotation. We conducted a MEDLINE search up to November 10, 2023, and included tools that are applicable to a broad range of phenotypes, can be used locally, and have been recently updated. Tools were categorized based on the types of variants they accept and the functional impacts they predict. Sequence Ontology terms were used for standardization. We identified 118 databases and software packages, encompassing 36 variant types and 161 functional impacts. Combining only three tools, namely SnpEff, FAVOR, and SparkINFERNO, allows predicting 99 (61%) distinct functional impacts. Thirty-seven tools predict 89 functional impacts that are not supported by any other tool, while 75 tools predict pathogenicity and can be used within the ACMG/AMP guidelines in a clinical context. We launched a website allowing researchers to select tools based on desired variants and impacts. In summary, more than 100 tools are already available to predict approximately 160 functional impacts. About 60% of the functional impacts can be predicted by the combination of three tools. Unexpectedly, recent tools do not predict more impacts than older ones. Future research should allow predicting the functionality of so far unsupported variant types, such as gene fusions.

Introduction

Whole-genome sequencing (WGS) has become precise and affordable on a large scale, and several cohorts now involve hundreds of thousands of subjects (Halldorsson et al. 2022; Taub et al. 2022; The All of Us Research Program Investigators 2019). Statistical analyses have associated diseases with common and rare variants (Povysil et al. 2019), and the GWAS Catalog currently contains more than half a million associations (Sollis et al. 2023). However, the causal mechanism behind most genetic associations is unclear and can take a long time to understand. For example, even for the best-replicated locus in cardiovascular disease, it took four years to unravel its function (Harismendy et al. 2011; Wellcome Trust Case Control Consortium 2007). To accelerate the understanding of biological function, a series of computational tools have been proposed in recent years.

In this work, we consider Variant Effect Predictors (VEPs) to be databases or software packages that predict the functional impacts of genetic variants. Each VEP is usually specialized in annotating one or a few categories of variants, such as single nucleotide variations (SNVs), indels, missense variants, or structural variants (SVs) (Geoffroy et al. 2018; Pagel et al. 2019; Rentzsch et al. 2019; Vaser et al. 2016). The variety of VEPs and their functionalities poses the challenge of choosing the appropriate tool for a specific task, a topic that has been addressed in non-systematic reviews

(Katsonis et al. 2022; Tabarini et al. 2022). Some reviews summarize VEPs for one type of variant only (Abramowicz and Gos 2018; Glusman et al. 2017). Other articles focus on variation relevant to the American College of Medical Genetics and Genomics/Association of Molecular Pathology (ACMG/AMP) guidelines (Ghosh et al. 2017; Kassahn et al. 2014). All reviews have in common that their summary tables group functional information into a few categories, usually SNVs, indels, and SVs only. This categorization limits the search for VEPs suitable for other categories of variants, such as missense mutations or copy number variation.

This work aims to provide a systematic overview of the broad range of variant types and their functional impacts across VEPs. To this end, we systematically searched MEDLINE and investigated the possible input and output of each tool. The efficient selection of the most appropriate tool for a specific task can easily be accomplished using an interactive website.

Methods

A systematic review was performed in accordance with the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) guidelines (Page et al. 2021). The protocol was registered in OSF Registries on November 10, 2023 (https://doi.org/10.17605/OSF.IO/S2GCT).

Literature search

The literature search was conducted in the MEDLINE database. The search was restricted to articles published in English after January 1, 2014. This date was chosen to coincide with two milestones in genomics: the launch of the GRCh38 reference genome in December 2013 and the release of higher-throughput sequencing machines (Guo et al. 2017; Sheridan 2014). The search was performed on November 10, 2023, and results up to that date were included. The search query combined groups of terms related to variant, effect, prediction, and tools. Within each group, the terms were combined using the logical operator OR. The complete query is provided in Supplementary Table S1.

Articles containing the term "cancer" in the title were excluded to reduce the number of irrelevant hits and to find VEPs applicable across several diseases. We scanned the reference lists of review and benchmarking articles to retrieve additional eligible articles.

Study selection

Included articles described a VEP, i.e., a tool accepting human genetic variants and predicting functional impacts. The list of exclusion criteria was made to ensure that tools were reliable, broadly applicable, accessible, scalable, and reproducible (Table 1). In cases where a tool appeared to be discontinued, generally indicated by a non-functional URL in the publication, we contacted the corresponding author for confirmation. Some authors supplied a working URL, which allowed us to reassess the publication against the other exclusion criteria. We removed tools not applicable to humans or without any documentation.

Review and benchmarking articles were used to find additional eligible articles. However, only original work describing a VEP was included in this review. Web-only and GUI-only tools were deemed insufficiently reproducible and scalable and were thus excluded. In line with our accessibility requirement, tools requiring a fee were also excluded. Additionally, given the fast pace of progress in the field, we included only tools that support the GRCh38 genome build and were updated at least once since January 1, 2020. Tools that were specific to a small number of genes or a specific disease were excluded, as we were interested in the application of VEPs to a broad range of studies. If several versions of the tool existed, we only included the latest version, regardless of whether the latest version had an associated publication. Nevertheless, significant updates often coincided with a publication, such as dbNSFP v4 (Liu et al. 2020).

One author (CR) selected the studies based on the exclusion criteria (Table 1). First, titles were screened for eligibility. Second, articles were filtered based on the abstract. Third, the full text of the remaining articles was examined. Reasons for exclusion were recorded for each round.

Data extraction

First, one author (CR) extracted the tool name, variant types, functional impacts, and operating system requirements from

Table 1 Exclusion criteria

Not a database, tool, or score
Discontinued tool
Newer version available
Not applicable to humans
Not a VEP
No documentation
Preprint
Review or benchmarking publications
Not easily downloadable, e.g., web-only or GUI-only tool
Not completely free
Not supporting the GRCh38 genome build
Specific to a small number of genes
Specific to a disease
Not updated since January 1, 2020

the included publications and their latest documentation. The URLs of tools with online capabilities were retrieved. Tools that required a high-performance computer were identified. Second, another author (LG) reviewed the extracted data to confirm the accuracy of the information from the publications and documentation. Divergences were resolved through discussion. For each article, the following characteristics were automatically retrieved: PubMed ID, title, authors, citation, first author, journal, year of publication, date of PubMed entry creation, PMCID, NIHMS ID, and digital object identifier.

Sequence Ontology terms were used to describe the variant types and functional impacts wherever applicable (Eilbeck et al. 2005). In case a Sequence Ontology term was unavailable to describe a particular variant type or functional impact, a new term was coined. For terms consistent with the structure of the Sequence Ontology, a request to create the new term was made on the Sequence Ontology GitHub page (https://github.com/The-Sequence-Ontology/SO-Ontologies/issues). Eighteen new terms were requested and are awaiting approval. Examples include "enhancer variant" and "promoter variant". The full list of Sequence Ontology terms is provided in Supplementary Table S2.

Data synthesis

Descriptive statistics were calculated for each tool, including the number of variant and functional impact categories. Linear regression was used to study the relationship between the number of functional impacts predicted by each tool and the date it was uploaded to the MEDLINE database.

Software

All analyses used R version 4.2.2; all R scripts are attached as supplementary files and were uploaded to Zenodo (see section Code availability). A website was created with the shiny package (Chang et al. 2023).

Results

The MEDLINE query yielded 7273 records, of which 6514 were excluded after title screening (Fig. 1). Abstract screening excluded an additional 542 records, leaving 217 full-text articles for eligibility assessment. Detailed reading led to the exclusion of 120 articles. The most frequent reasons for exclusion were the fact that the work did not describe a VEP and the lack of maintenance. Examining references from benchmarking and review articles added 21 relevant publications. In total, this review encompasses 118 original articles, each covering a unique VEP, and references to all 118 articles are provided in Supplementary Table S3

Overview of VEPs

The 118 VEPs differed in both the accepted variant types and the predicted functional impacts (Fig. 2). The number of accepted variant types per VEP ranged from one to seven. Seventy-three VEPs specialized in a single variant type, and two tools, Ensembl VEP and DECIPHER, accepted seven types (Bragin et al. 2014; McLaren et al. 2016). The number of predicted functional impacts per tool ranged from 1 to 58, and approximately two thirds (n = 82) predicted a single functional impact. SnpEff stood out as the VEP with the most predicted functional impacts (Cingolani et al. 2012). Some databases achieved many predicted impacts by aggregating predictions from multiple sources. For example, FAVOR and WGSA aggregated 48 and 40 annotations, respectively (Liu et al. 2016; Zhou et al. 2023).

The implementation of VEPs varied substantially. For example, AbraOM was a simple text file that lists variants and their functional impacts, while SparkINFERNO was a complex software package requiring a high-performance computing environment for execution (Kuksa et al. 2020; Naslavsky et al. 2017).

Variant types

A total of 36 distinct variant types were accepted by VEPs, such as SNVs, indels, CNVs (Supplementary Table S4, Ding et al. 2023). Other acceptable inputs included variants falling in specific regions, such as splice sites, introns, exons, untranslated regions (UTRs), promoters, or enhancers. Despite the diverse range of variants being accepted across tools, some clinically and biologically important variants were missing. Gene fusions were unsupported by VEPs, both as input and predicted functional impacts. Furthermore, variant types were not equally represented across the tools (Fig. 3). While 69 VEPs accepted SNVs as input, 19 other variant types were accepted by only one VEP. For example, DECIPHER was the only database containing inversions and translocations (Bragin et al. 2014).

Functional impacts

VEPs predicted 161 distinct functional impacts (Supplementary Table S5). Pathogenicity was the most common functional impact, predicted by 75 VEPs, because of its clinical relevance and use within ACMG/AMP guidelines (Fig. 3; Richards et al. 2015). Variant frequency, stop gain, and missense variant were the next most commonly predicted functional impacts (Fig. 3). Although variant frequency technically is not a functional impact, it has been reported by some databases and can provide insight into the evolutionary context and potential benignity of certain variants. Functional impacts are generally classified into

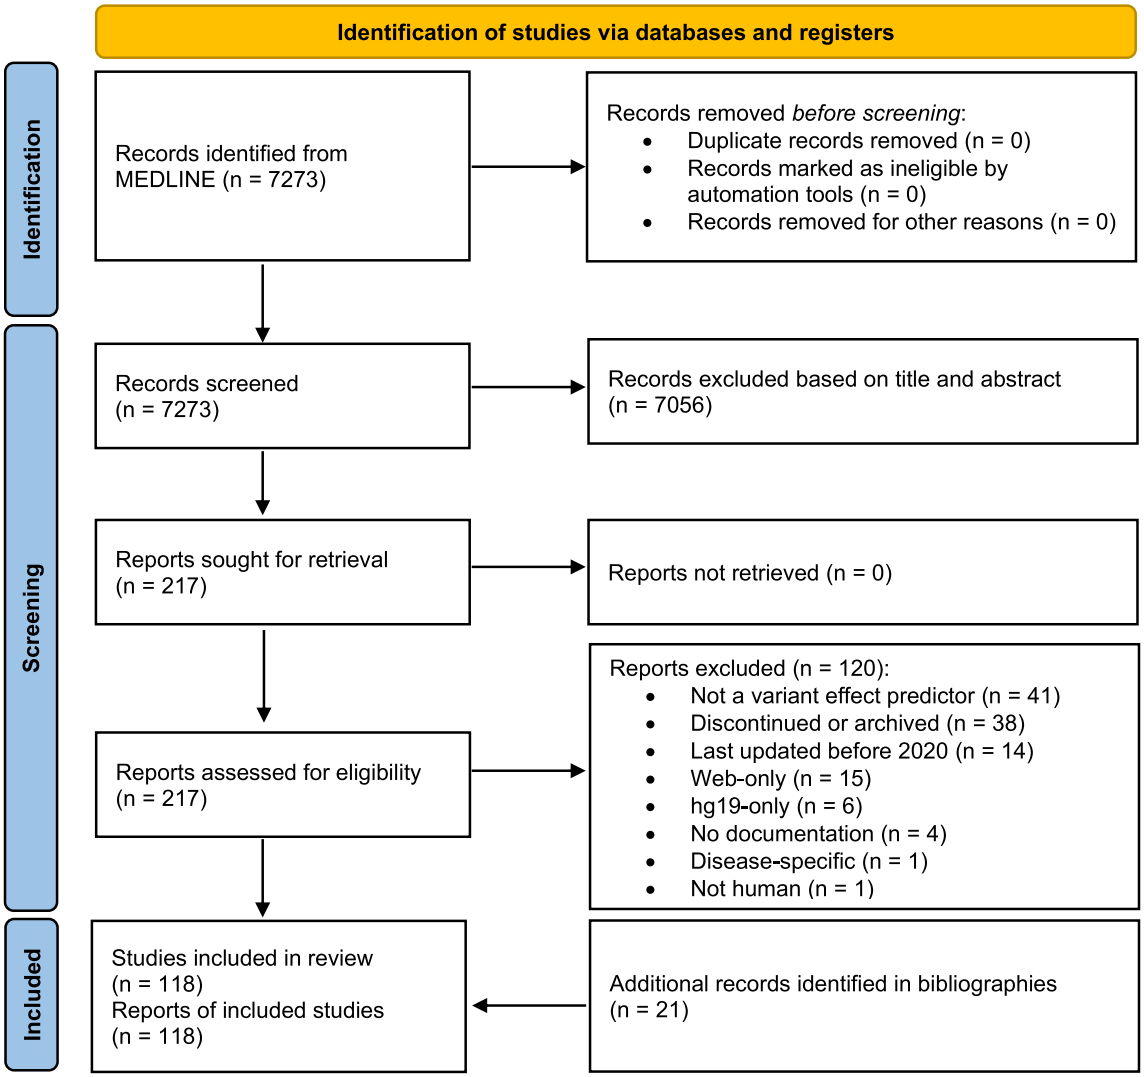

Fig. 1 PRISMA flow diagram of the literature search and selection process

several categories, and effects on the protein sequence, such as missense variants and frameshift indels, formed one well-studied class. Effects on splicing and regulatory elements, e.g., transcription factor-binding sites and enhancers, formed additional categories. Some tools predicted functional impacts not supported by other tools. For example, UTRannotator was the sole predictor of five specific changes in the open reading frames of 5′ UTRs (Zhang et al. 2021). Eighty-nine functional impacts were predicted by only one tool, making these tools indispensable for a study aiming to interpret those impacts.

Only Ensembl VEP, SnpEff, and VAGrENT used a controlled vocabulary, the Sequence Ontology, to describe functional impacts (Cingolani et al. 2012; McLaren et al. 2016; Menzies et al. 2015). However, none of the tools used the Sequence Ontology to describe variant types. Controlled vocabularies may also be used for phenotypes, such as the Experimental Factor Ontology in the GWAS Catalog or Human Phenotype Ontology for DECIPHER.

Figure 4 displays the number of functional impacts by date of publication. While two aggregators (FAVOR and Ensembl VEP) had a publication in the last two years, SnpEff and WGSA were published more than seven years ago. The slope of the linear regression line was –1.03 (95% confidence interval –1.68, –0.37) functional impacts/year, which was significantly different from 0 ($p = 0.002$). As the assumption of linearity in this regression model is questionable, we also ran a quantile regression for the median. The quantile regression revealed a slope of 0 (95% confidence interval 0, 0) and an intercept of 1, indicating no change in the median number of predicted functional impacts over time. This result is due to the 82 VEPs that predict only one functional impact. The number of functional impacts presented in Fig. 4 does not necessarily correspond to the

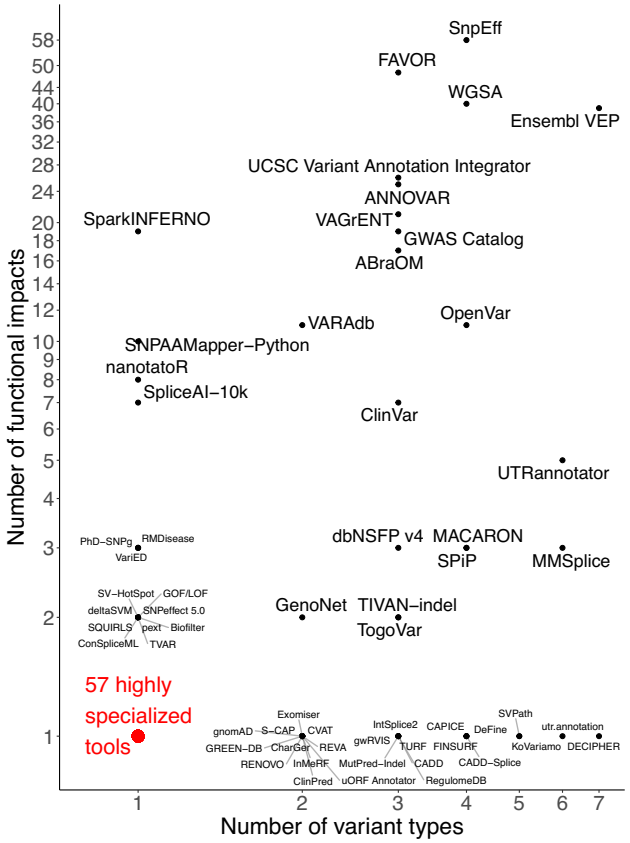

Fig. 2 Scatter plot of the 118 variant effect predictors (VEPs). The number of functional impacts is plotted against the number of accepted variant types. To avoid overplotting, tools that annotate a single variant type and output only one functional impact type are collectively represented by a single red dot

number predicted in that year. This discrepancy can occur because tools are updated, and we extracted data from the most recent documentation.

Supplementary Fig. S1 shows the number of variant types supported for the first time each year. There was no statistically significant upward or downward trend ($p = 0.212$).

A Shiny app to find VEPs

To identify suitable VEPs, a Shiny app website can be used. The website features a searchable table listing the tools along with the specific variant types and functional impacts they address. Users can filter this table using Sequence Ontology terms relevant to their needs. They can also enter the number of VEPs they wish to implement. The site will then display the tools that maximize the number of impact predictions. For example, the top three tools, SnpEff, FAVOR, and SparkInferno, predict 99 different impacts, thus cover 61% of all possible impacts. In this combination, SnpEff covers 54 functional impacts covering changes in the coding sequence, UTRs, gene structure, regulatory regions, splicing, and others. FAVOR adds 36 annotations related to histone modifications, pathogenicity scores, and disease associations. SparkINFERNO adds 9 annotations related to non-coding RNAs and regulatory regions. Users may also filter VEPs according to the supported operating system and the availability of an online version of the tool. The website also includes a bibliography of review and benchmark articles. Benchmark studies that compare the performance of various tools provide valuable assistance in refining tool selection. One study's results, including sensitivity, specificity, positive predictive value, and negative predictive value, are accessible in a searchable table. REVEL is the best performer according to all four metrics (Ghosh et al. 2017). A

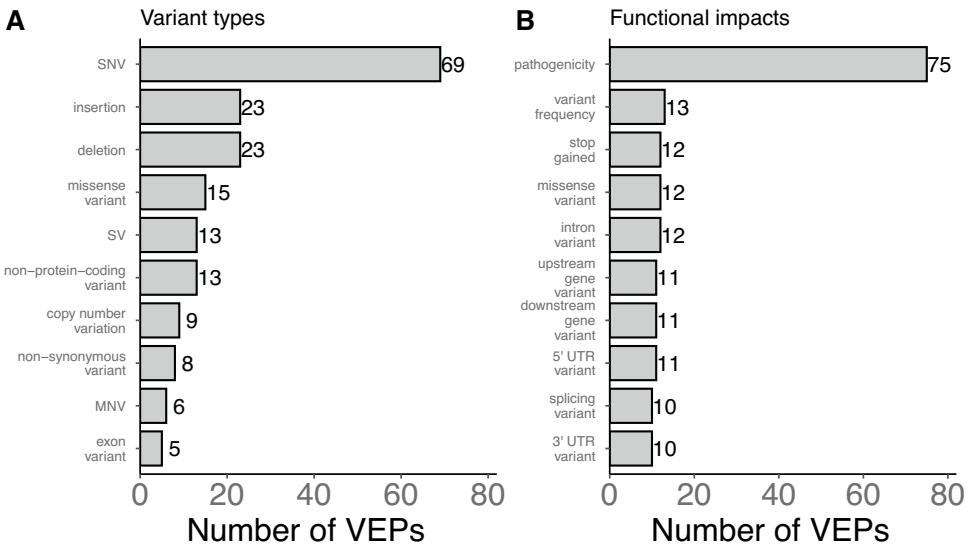

Fig. 3 Barplots of the most commonly annotated variant types and predicted functional impacts. **A** Bars represent the number of tools accepting each of the 10 most commonly accepted variant types. **B** Bars represent the number of tools predicting each of the 10 most commonly predicted functional impacts

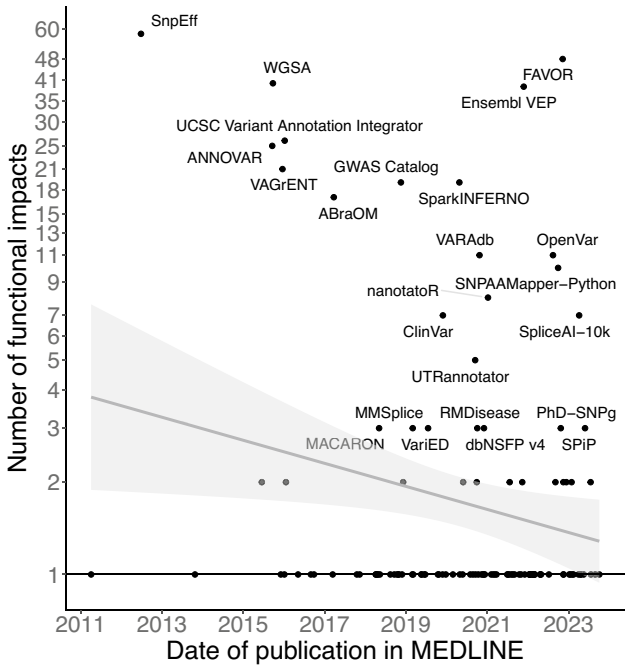

Fig. 4 Number of predicted functional impacts annotated by each tool over time. Tools with ≥3 predictions are labeled. The x-axis shows the day of publication in MEDLINE. The y-axis shows the number of predicted functional impacts in the most recent version of the tool. The grey line represents the least squares regression line. The light grey shaded area surrounding this line represents the 95% pointwise confidence intervals. The flat black line represents the quantile regression line at the median

recent benchmark study identified ClinPred and REVEL as the top pathogenicity predictors in this review, with the ranking of all 55 evaluated predictors accessible via the Shiny app (Livesey and Marsh 2023). While some tools performed better than ClinPred and REVEL, they were excluded from our review for not meeting the inclusion criteria. For example, ESM-1v was not peer-reviewed (Meier et al. 2021), and EVE and DeepSequence did not accept genetic variants (Frazer et al. 2021; Riesselman et al. 2018).

Discussion

This systematic review identified 118 VEPs that together accepted 36 variant types and predicted 161 functional impacts. The functionalities of these numerous VEPs exhibited considerable diversity. Some VEPs accepted only one variant type, while others accepted up to 7. Similarly, some VEPs predicted a single functional impact, while others predicted up to 58. About half of these tools were highly specialized and predicted a single functional impact for one variant type. In contrast, SnpEff, FAVOR, and SparkINFERNO, could predict more than 40 functional impacts each. Using only these three VEPs covered 61% of the predictable functional impacts. Additionally, 75 tools predicted pathogenicity, making them usable as supporting diagnostic evidence according to the ACMG/AMP guidelines (Richards et al. 2015). To facilitate the selection of VEPs, we launched an interactive website that presents a list of tools according to user needs.

Out of 217 full-text articles analyzed, 38 VEPs have been completely discontinued, and another 14 have not been updated since 2019. The lack of maintenance of biological databases and tools is a recurring issue (Imker 2018), which causes difficulty for researchers who depend on these resources. Financial constraints and limited value may justify the discontinuation of a database. However, the database should be archived in a repository to ensure reproducibility (Imker 2018).

Our search was limited to MEDLINE and English language articles, potentially missing relevant studies in other databases or languages. To mitigate these limitations, we examined the references in review and benchmarking articles found by our search to find missed publications. Furthermore, we note that two recent reviews on rare non-coding variant annotation tools encompass 40 and 30 tools, respectively (Kuksa et al. 2022; Tabarini et al. 2022). One benchmarking paper covers 55 VEPs (Livesey and Marsh 2023). Thus, our review stands as the most comprehensive with 118 VEPs described.

In the screening process, we removed tools that were disease-specific, gene-specific, web-only, not updated since 2019, or rely on the hg19 genome build. While some tools may still be useful in specific contexts, we excluded them from our review to focus on broadly applicable, up-to-date, and scalable tools. While web-only databases are easily accessible, they lack the reproducibility, scalability, and privacy of downloadable VEPs.

Another limitation of our review is that it does not provide the total number of annotated variants for each tool. For example, while CADD scored each of the possible ~ 9 billion human SNVs, the ABraOM database contained only 2.3 million variants. In fact, it is difficult to provide the precise number of annotated variants for each tool, as databases are subject to constant updates. Any number reported in the original publication is most likely outdated.

Adoption of a common standardized vocabulary would improve the comparison, integration, and discoverability of VEPs (Brookes and Robinson 2015). Only Ensembl VEP, SnpEff, and VAGrENT used a controlled vocabulary to describe functional impacts (Cingolani et al. 2012; McLaren et al. 2016; Menzies et al. 2015). In this review, we standardized the input and output terms used by each tool according to the Sequence Ontology (Eilbeck et al. 2005). This approach facilitates the search for tools in VEP Finder. For example, users interested in VEPs that accept 5′ UTR

variants can choose '5_prime_UTR_variant' from a drop-down menu, thereby avoiding confusion over non-standard terms. VEP Finder will then display all the tools that accept variants in 5' UTRs. The term 'pathogenicity' is widely used across the 75 pathogenicity predictors to describe variant impact, usually on a scale from 'benign' to 'pathogenic.' However, the inconsistent scale and vocabulary across tools, with some using terms like 'neutral,' 'tolerated,' or 'deleterious,' complicates direct comparisons. While most tools focus on disease relevance, some, such as SIFT, assess the effect on protein function (Vaser et al. 2016). The ACMG/AMP guidelines provide a standardized framework for defining pathogenicity concerning disease, but no similar classification guidelines exist for protein function. Thus, authors must clearly define what they mean by "pathogenicity" and how to interpret the scores.

Selecting suitable VEPs requires considering parameters beyond the accepted input and predicted output. Metrics, such as accuracy and precision, help in identifying tools with higher analytical performance (Livesey and Marsh 2023; Pejaver et al. 2022). Once the selection of VEPs has been made, guidance exists to interpret their outputs (Cheng et al. 2020). For diagnostic purposes, clinicians are advised to consult the ACMG/AMP guidelines to use VEPs (Richards et al. 2015), and for a limited number of genes, more detailed guidance on variant interpretation is available (Fortuno et al. 2021; Lee et al. 2018).

Future research

This review revealed that no VEP accepts gene fusions as input. This gap may be due to their lower frequency in the human population and because of the limitations of second-generation sequencing technologies. However, their clinical importance calls for support soon (Nelson et al. 2017). New variant types were regularly supported (Fig. S1). Should this trend continue, more variant types will likely receive support in the coming years.

The absence of a benchmarking study assessing all 75 pathogenicity predictors highlights the difficulty of this endeavor. A meta-analysis of existing studies could shed light on the best-performing VEPs and might discriminate between the many pathogenicity predictors. This analysis would need to account for the variability in the sets of tools and testing datasets used across different studies.

To maximize the utility of VEPs for clinical and research purposes, further advancements are required to extend predictions specific to isoforms, tissues, and traits to more variants. Such functionality will enhance our understanding of variant effects and facilitate their experimental validation. Moreover, developing trait-specific pathogenicity scores is essential because certain variants may be pathogenic for one disease but benign or even advantageous for another (Taylor et al. 2012). Furthermore, to facilitate interoperability between different tools, we also advocate the use of controlled vocabularies to describe phenotypes (Kohler et al. 2021; Malone et al. 2010). We aim to perform a bigger update of the VEP Finder once per year and to do regular update after user input and evidence.

VEPs predicting many functional impacts, such as SnpEff, FAVOR and WGSA, represent a potential solution to the problem of tool choice. Nevertheless, the rapid evolution of the field necessitates continuous updates to keep them up to date. Furthermore, we expect specialized tools to be continuously released (Fig. 4). Consequently, systematic reviews on VEPs will be needed regularly.

Conclusion

A staggering 118 tools were available to predict approximately 160 functional impacts that ranged from molecular to phenotypic effects. About 60% of these impacts could be predicted by combining just three tools. Unexpectedly, recent tools did not necessarily predict more impacts than older ones. Despite the vast diversity of VEPs, some genetic variants were not yet supported and should be the object of future research.

The abundance of available options can complicate the tool selection process. However, this challenge is mitigated by the Shiny app developed in this review. The app enables users to filter tools based on their specific needs, narrowing down the list of suitable options.

Supplementary Information The online version contains supplementary material available at https://doi.org/10.1007/s00439-024-02670-5.

Acknowledgements We thank Dr. Hugo Solleder for his feedback on the research questions and the VEP Finder website.

Author contributions Design, conception of the study and development of search strategy: Cristian Riccio, Max L. Jansen, Andreas Ziegler. Literature search: Cristian Riccio. Data collection: Cristian Riccio and Linlin Guo. Data analysis and interpretation: Cristian Riccio, Andreas Ziegler. Drafted manuscript: Cristian Riccio, Andreas Ziegler. Critical review and approval of final manuscript: all authors.

Availability of data and material The VEP Finder website is freely available at https://cardio-care.shinyapps.io/VEP_Finder/.

Code availability The scripts for data wrangling, generating plots, and running linear models are stored on Zenodo and can be accessed at https://doi.org/10.5281/zenodo.10255446. They are also available in the Supplementary zip file. The code for the Shiny app is accessible at https://github.com/CristianRiccio/VEP_Finder.

D.11 Protein–protein interactions

Further explanations for Chapter 11.

D.11.1 Experimental methods

- Snider et al. (2015) — Explains the principles of interactome mapping, compares binary assays (yeast two-hybrid and relatives) with co-complex methods such as AP-MS, and discusses their strengths, weaknesses, follow-up validation and the main interaction databases. A good companion to the whole section, including errors, biases and coverage. *(review; CC BY 4.0)*

  Fundamentals of protein interaction network mapping. Snider et al. (2015). *Molecular Systems Biology*. doi:10.15252/msb.20156351

  > Studying protein interaction networks of all proteins in an organism ("interactomes") remains one of the major challenges in modern biomedicine. Such information is crucial to understanding cellular pathways and developing effective therapies for the treatment of human diseases. Over the past two decades, diverse biochemical, genetic, and cell biological methods have been developed to map interactomes. In this review, we highlight basic principles of interactome mapping. Specifically, we discuss the strengths and weaknesses of individual assays, how to select a method appropriate for the problem being studied, and provide general guidelines for carrying out the necessary follow-up analyses. In addition, we discuss computational methods to predict, map, and visualize interactomes, and provide a summary of some of the most important interactome resources. We hope that this review serves as both a useful overview of the field and a guide to help more scientists actively employ these powerful approaches in their research.

- Adames et al. (2018) — Reviews how multi-mutant yeast strains are made for genetic interaction screens, comparing classical methods with CRISPR/Cas-based approaches. Useful technical background to the large yeast genetic interaction maps discussed in the subsection on genetic interactions. *(review; CC BY 4.0)*

  Yeast genetic interaction screens in the age of CRISPR/Cas. Adames et al. (2018). *Current Genetics*. doi:10.1007/s00294-018-0887-8

  > The ease of performing both forward and reverse genetics in Saccharomyces cerevisiae, along with its stable haploid state and short generation times, has made this budding yeast the consummate model eukaryote for genetics. The major advantage of using budding yeast for reverse genetics is this organism's highly efficient homology-directed repair, allowing for precise genome editing simply by introducing DNA with homology to the chromosomal target. Although plasmid- and PCR-based genome editing tools are quite efficient, they depend on rare spontaneous DNA breaks near the target sequence. Consequently, they can generate only one genomic edit at a time, and the edit must be associated with a selectable marker. However, CRISPR/Cas technology is efficient enough to permit markerless and multiplexed edits in a single step. These features have made CRISPR/Cas popular for yeast strain engineering in synthetic biology and metabolic engineering applications, but it has not been widely employed for genetic screens. In this review, we critically examine different methods to generate multi-mutant strains in systematic genetic interaction screens and discuss the potential of CRISPR/Cas to supplement or improve on these methods.

- Marku and Pancaldi (2023) — An overview, written for newcomers, of the main types of algorithms for inferring gene regulatory networks from time-series transcriptomics, with guidance on choosing a method. Useful background for the subsection on network inference. *(review; CC BY 4.0)*

  From time-series transcriptomics to gene regulatory networks: A review on inference methods. Marku & Pancaldi (2023). *PLOS Computational Biology*. doi:10.1371/journal.pcbi.1011254

> Inference of gene regulatory networks has been an active area of research for around 20 years, leading to the development of sophisticated inference algorithms based on a variety of assumptions and approaches. With the ever increasing demand for more accurate and powerful models, the inference problem remains of broad scientific interest. The abstract representation of biological systems through gene regulatory networks represents a powerful method to study such systems, encoding different amounts and types of information. In this review, we summarize the different types of inference algorithms specifically based on time-series transcriptomics, giving an overview of the main applications of gene regulatory networks in computational biology. This review is intended to give an updated reference of regulatory networks inference tools to biologists and researchers new to the topic and guide them in selecting the appropriate inference method that best fits their questions, aims, and experimental data.

D.11.2 Networks

- Koutrouli et al. (2020) — An introduction to graph theory for biologists: graph types, degree distributions, clustering, motifs, network models, clustering algorithms and tools. Covers the network concepts used throughout the section. *(review; CC BY 4.0)*

  A Guide to Conquer the Biological Network Era Using Graph Theory. Koutrouli et al. (2020). *Frontiers in Bioengineering and Biotechnology*. doi:10.3389/fbioe.2020.00034

  > Networks are one of the most common ways to represent biological systems as complex sets of binary interactions or relations between different bioentities. In this article, we discuss the basic graph theory concepts and the various graph types, as well as the available data structures for storing and reading graphs. In addition, we describe several network properties and we highlight some of the widely used network topological features. We briefly mention the network patterns, motifs and models, and we further comment on the types of biological and biomedical networks along with their corresponding computer- and human-readable file formats. Finally, we discuss a variety of algorithms and metrics for network analyses regarding graph drawing, clustering, visualization, link prediction, perturbation, and network alignment as well as the current state-of-the-art tools. We expect this review to reach a very broad spectrum of readers varying from experts to beginners while encouraging them to enhance the field further.

- Sonawane et al. (2019) — Surveys network types and data sources used in network medicine, and how protein interaction, co-expression and gene regulatory networks are combined with phenotype-specific data to study disease, with example applications. *(review; CC BY 4.0)*

  Network Medicine in the Age of Biomedical Big Data. Sonawane et al. (2019). *Frontiers in Genetics*. doi:10.3389/fgene.2019.00294

  > Network medicine is an emerging area of research dealing with molecular and genetic interactions, network biomarkers of disease, and therapeutic target discovery. Large-scale biomedical data generation offers a unique opportunity to assess the effect and impact of cellular heterogeneity and environmental perturbations on the observed phenotype. Marrying the two, network medicine with biomedical data provides a framework to build meaningful models and extract impactful results at a network level. In this review, we survey existing network types and biomedical data sources. More importantly, we delve into ways in which the network medicine approach, aided by phenotype-specific biomedical data, can be gainfully applied. We provide three paradigms, mainly dealing with three major biological network archetypes: protein-protein interaction, expression-based, and gene regulatory networks. For each of these paradigms, we discuss a broad overview of philosophies under which various network methods work. We also provide a few examples in each paradigm as a test case of its successful application. Finally, we delineate several opportunities and challenges in the field of network medicine. We hope this review provides a lexicon for researchers from biological sciences and network theory to come on the same page to work on research areas that require interdisciplinary expertise. Taken together, the understanding gained from combining biomedical data with networks can be useful for characterizing disease etiologies and identifying therapeutic targets, which, in turn, will lead to better preventive medicine with translational impact on personalized healthcare.

- Gu et al. (2019) — Reviews genome-scale metabolic models, which are simulated to predict metabolic fluxes, and their applications from strain engineering to drug targets and human

disease; background for the subsection on systems biology and metabolic modelling. *(review; CC BY 4.0)*

Current status and applications of genome-scale metabolic models. Gu et al. (2019). *Genome Biology*. doi:10.1186/s13059-019-1730-3

> Genome-scale metabolic models (GEMs) computationally describe gene-protein-reaction associations for entire metabolic genes in an organism, and can be simulated to predict metabolic fluxes for various systems-level metabolic studies. Since the first GEM for Haemophilus influenzae was reported in 1999, advances have been made to develop and simulate GEMs for an increasing number of organisms across bacteria, archaea, and eukarya. Here, we review current reconstructed GEMs and discuss their applications, including strain development for chemicals and materials production, drug targeting in pathogens, prediction of enzyme functions, pan-reactome analysis, modeling interactions among multiple cells or organisms, and understanding human diseases.

D.11.3 Prediction methods

- Tsuchiya et al. (2022) — A short review that traces computational prediction of protein complexes from rigid-body docking and scoring to AlphaFold-based methods, with a historical perspective. Useful for the docking and deep learning subsections. *(review; CC BY 4.0)*

  Protein–protein interaction prediction methods: from docking-based to AI-based approaches. Tsuchiya et al. (2022). *Biophysical Reviews*. doi:10.1007/s12551-022-01032-7

  > Protein-protein interactions (PPIs), such as protein-protein inhibitor, antibody-antigen complex, and supercomplexes play diverse and important roles in cells. Recent advances in structural analysis methods, including cryo-EM, for the determination of protein complex structures are remarkable. Nevertheless, much room remains for improvement and utilization of computational methods to predict PPIs because of the large number and great diversity of unresolved complex structures. This review introduces a wide array of computational methods, including our own, for estimating PPIs including antibody-antigen interactions, offering both historical and forward-looking perspectives.

- Kiouri et al. (2025) — Surveys machine-learning and deep-learning methods that use protein structure to predict interactions and interface residues, and discusses limitations such as scarce structural data and the choice of negative examples, which relates to the evaluation subsection. *(review; CC BY 4.0)*

  Structure-Based Approaches for Protein–Protein Interaction Prediction Using Machine Learning and Deep Learning. Kiouri et al. (2025). *Biomolecules*. doi:10.3390/biom15010141

  > Protein-Protein Interaction (PPI) prediction plays a pivotal role in understanding cellular processes and uncovering molecular mechanisms underlying health and disease. Structure-based PPI prediction has emerged as a robust alternative to sequence-based methods, offering greater biological accuracy by integrating three-dimensional spatial and biochemical features. This work summarizes the recent advances in computational approaches leveraging protein structure information for PPI prediction, focusing on machine learning (ML) and deep learning (DL) techniques. These methods not only improve predictive accuracy but also provide insights into functional sites, such as binding and catalytic residues. However, challenges such as limited high-resolution structural data and the need for effective negative sampling persist. Through the integration of experimental and computational tools, structure-based prediction paves the way for comprehensive proteomic network analysis, holding promise for advancements in drug discovery, biomarker identification, and personalized medicine. Future directions include enhancing scalability and dataset reliability to expand these approaches across diverse proteomes.

- Lin et al. (2025) — Reviews the use of AlphaFold 3 for complex structure prediction, compares it with docking tools such as ClusPro and with AlphaPulldown, and discusses its limitations for large complexes, dynamics and mutation effects. The examples are from plant and fungal research but the discussion is general. *(review; CC BY 4.0)*

  Analysing protein complexes in plant science: insights and limitation with AlphaFold 3. Lin et al. (2025). *Botanical Studies*. doi:10.1186/s40529-025-00462-2

AlphaFold 3 (AF3), an artificial intelligence (AI)-based software for protein complex structure prediction, represents a significant advancement in structural biology. Its flexibility and enhanced scalability have unlocked new applications in various fields, specifically in plant science, including improving crop resilience and predicting the structures of plant-specific proteins involved in stress responses, signalling pathways, and immune responses. Comparisons with existing tools, such as ClusPro and AlphaPulldown, highlight AF3's unique strengths in sequence-based interaction predictions and its greater adaptability to various biomolecular structures. However, limitations persist, including challenges in modelling large complexes, protein dynamics, and structures from underrepresented plant proteins with limited evolutionary data. Additionally, AF3 encounters difficulties in predicting mutation effects on protein interactions and DNA binding, which can be improved with molecular dynamics and experimental validation. This review presents an overview of AF3's advancements, using examples in plant and fungal research, and comparisons with existing tools. It also discusses current limitations and offers perspectives on integrating molecular dynamics and experimental validation to enhance its capabilities.

Fundamentals of protein interaction network mapping

Jamie Snider[1], Max Kotlyar[2], Punit Saraon[1], Zhong Yao[1], Igor Jurisica[2] & Igor Stagljar[1,*]

Abstract

Studying protein interaction networks of all proteins in an organism ("interactomes") remains one of the major challenges in modern biomedicine. Such information is crucial to understanding cellular pathways and developing effective therapies for the treatment of human diseases. Over the past two decades, diverse biochemical, genetic, and cell biological methods have been developed to map interactomes. In this review, we highlight basic principles of interactome mapping. Specifically, we discuss the strengths and weaknesses of individual assays, how to select a method appropriate for the problem being studied, and provide general guidelines for carrying out the necessary follow-up analyses. In addition, we discuss computational methods to predict, map, and visualize interactomes, and provide a summary of some of the most important interactome resources. We hope that this review serves as both a useful overview of the field and a guide to help more scientists actively employ these powerful approaches in their research.

Keywords bioinformatics; interactome mapping; PPI technologies; protein-protein interactions (PPIs); proteomics

Mol Syst Biol. (2015) 11: 848

The importance of studying PPIs

As the basic unit of life, cells represent complex biological entities, whose normal function revolves around a delicate interplay between multiple diverse biomolecular systems. Proteins are vital components of these systems, acting as molecular machines, sensors, transporters, and structural elements (among others), with interactions between proteins, hereinafter called protein–protein interactions (PPIs), being key to their function.

Protein–protein interactions are inherently dynamic in nature, adjusting in response to different stimuli and environmental conditions. This provides considerable flexibility in function and allows cells to adapt in a measured way to changing circumstances. Even a subtle dysfunction of PPIs can have major systemic consequences, perturbing interconnected cellular networks and producing disease phenotypes (Barabási *et al*, 2011). Developing in-depth, dynamic PPI maps is therefore critically important in helping us comprehend these complex processes, and identify new proteins and PPIs suitable for therapeutic intervention.

Over the years, we have seen an emergence and growth of a wide range of exciting technologies for the identification and characterization of PPIs. Selecting "the best" technology for a given research application is thus non-trivial. Here, we highlight the strengths and weaknesses of various methodologies, to aid in selecting the appropriate method for the problem at hand. Note that this review does not aim to cover all PPI methods; instead, we focus on newer approaches and earlier methods that remain widely used, and strongly impacted research.

Key considerations

While numerous methods are available for the large-scale study of PPIs, there is no one "perfect" method for all situations, and each has its own strengths and weaknesses. When selecting a suitable method to study interacting partners of a protein of interest, the following factors should be considered:

1) *The Goal of the Study* must be clearly defined. Discovery-driven studies usually aim to explore interactomes in an unbiased manner on a proteome-wide scale. In contrast, targeted interactome studies focus on a subset of PPIs and therefore confine themselves to smaller libraries or arrays corresponding to a defined set of candidate interaction partners. Different methods are better suited to certain classes of proteins as well as to formats and scales, and selection of one that best matches the research goals is critical.
2) *The Distinct Nature of the PPIs Being Studied.* All PPIs have intrinsic biophysical properties, giving each its own unique features. Some important characteristics to consider are the PPI "strength" (binding affinity), and whether the interaction is transient or stable (Perkins *et al*, 2010). Different bioassays display variable sensitivity, and although generally all can detect stable PPIs, only a fraction are capable of detecting transient interactions. It is also important to determine whether or not posttranslational modifications, co-factors, or

© 2015 The Authors. Published under the terms of the CC BY 4.0 license

additional binding partners are required (e.g., a PPI may be mediated indirectly through a protein complex), as well as where in the cell interactions are expected to occur, since the selected assay must be compatible with these elements.

3) *Time/Cost Constraints.* Not all methods scale-up equally, and some, while offering powerful advantages on a smaller-scale, can become significantly more expensive and time-consuming as the number of interactions studied increases. Additionally, the time and cost required to develop the necessary reagents (e.g., specific constructs, libraries) needs to be considered.
4) *Specialized Equipment and Expertise.* Finally, it is important to ensure that all necessary resources and knowledge required to fully take advantage of a particular method are available. Although the majority of methods are straightforward, some do require specific instrumentation and expertise. Most methods, especially those that attempt to study interactomes on a genomewide scale, also require strong bioinformatics support for analysis and data cleaning.

Guide to available methods

While many PPI assays exist, we present below some of the newer and more widely used approaches, providing a concise overview of their key principles, advantages, and limitations. Key references for each technique, including examples of their large-scale application, can also be found in Table 1.

The yeast two hybrid (Y2H)

Principle Originally developed 25 years ago (Fields & Song, 1989), the Y2H assay (Fig 1A) remains one of the most popular PPI methods. Y2H-based systems can be used to detect interactions between two proteins, protein and nucleic acid, and also in small-molecule screens (Hamdi & Colas, 2012; Ferro & Trabalzini, 2013). The classic Y2H involves the physical separation of two functional moieties of a transcription factor, specifically a DNA-binding domain (BD) and a transcriptional activation domain (AD), and their fusion to candidate interacting proteins. If a protein bearing an AD interacts with, or comes in close proximity to, a protein bearing a BD, the AD and BD are able to function together as a transcription factor, and direct expression of a reporter gene (Fields & Song, 1989).

Advantages The Y2H approach is simple, well established, and low cost and can be easily set up in most laboratory environments. Y2H is scalable and effective for use in both large-scale screening studies, and smaller efforts investigating specific PPIs. Another benefit is that the assay is carried out *in vivo* in the context of the yeast cell, helping avoid some of the complications and artifacts associated with cell lysis. This assay is best suited for the detection of binary interactions (Hamdi & Colas, 2012; Ferro & Trabalzini, 2013).

Limitations The use of a yeast host means that the PPIs from other organisms may in some cases not be detectable, due to poor expression, or a lack of necessary posttranslational modifications, cofactors, or other binding partners. The method requires that both interacting proteins access the nucleus (in order to drive transcription of reporter), which means that proteins confined to particular cellular environments (e.g., the membrane) cannot be studied in their full-length form. The proteins used in this method are also often overexpressed, which can lead to non-specific interactions. Altogether, these effects can lead to a high false-positive rate, necessitating careful follow-up analysis to identify true, biologically relevant interactions. The readout of this method is also indirect, preventing spatial or temporal analysis of PPIs (Hamdi & Colas, 2012; Ferro & Trabalzini, 2013).

Membrane yeast two hybrid (MYTH)

Principle The MYTH assay (Fig 1B) is designed for the analysis of the interactions of membrane proteins. It is based on a split-ubiquitin approach, whereby the ubiquitin protein is divided into

two distinct fragments—an N-terminal fragment called "Nub" and a C-terminal fragment called "Cub". The Cub moiety is conjugated to an artificial transcription factor and then fused to a cytosolic terminus of a membrane-bound protein (the "bait"). The Nub moiety is fused to potential interacting partners ("preys"), which can be either membrane-associated or soluble. Interaction of bait and prey proteins brings the Nub and Cub moieties into close proximity, allowing them to form a "pseudoubiquitin" molecule, which is recognized by cellular deubiquitinating enzymes that cleave after the Cub C-terminus. This releases the transcription factor, which then enters the nucleus and activates a reporter system (Stagljar *et al*, 1998; Snider *et al*, 2010).

Advantages Membrane yeast two hybrid is simple, low cost, and scalable for use in both low- and high-throughput (HT) formats. It is easy to establish in any laboratory environment and requires no specialized equipment. The assay is performed *in vivo* in a yeast host, allowing for the study of the interactions of membrane proteins in their full-length form and in the proper context of a membrane environment. This is a significant advantage over the classical Y2H. MYTH is best suited for the detection of binary interactions(Paumi *et al*, 2007; Deribe *et al*, 2009; Snider *et al*, 2010, 2013).

Limitations Membrane yeast two hybrid suffers from some of the same disadvantages as the classical Y2H, including the problems associated with the expression, modification, and interaction of non-native proteins in a yeast host, and artifacts resulting from protein overexpression. Also, MYTH can only be used with membrane proteins that have at least one terminus in the cytosol (where the necessary deubiquitinating enzymes are located). Additionally, soluble proteins cannot be used as baits in the MYTH system, unless they are exceptionally large or anchored to intracellular structures (thereby preventing diffusion of the bait-transcription factor into the nucleus and interaction-independent activation of the reporter system). The readout of this method is also indirect, preventing spatial or temporal analysis of PPIs (Snider *et al*, 2010).

Luminescence-based mammalian interactome mapping (LUMIER)

Principle The LUMIER assay (Fig 1C) is a co-immunoprecipitation-based approach. In this method, one protein ("A") is fused to Renilla luciferase, while another protein ("B") is linked to an affinity tag (e.g., FLAG, HA, protein A). Tagged constructs are transfected into appropriate cell lines where they are overexpressed. Cells are then lysed and protein "B" is immunoprecipitated using an appropriate antibody against the affinity tag. Interaction with protein "A" is assessed by measuring luciferase activity brought down with protein "B" (Barrios-Rodiles *et al*, 2005; Blasche & Koegl, 2013).

Advantages The LUMIER assay is easy to perform and can be used in a HT screening format. It does not require specialized equipment, beyond standard reagents for cell culture and instrumentation to measure bioluminescence. The approach can be used in different cell lines, providing the option of studying PPIs for a given organism in an appropriate *ex vivo* format. Note that this assay is well suited for studying binary interactions, although indirect interactions can also be detected (Barrios-Rodiles *et al*, 2005; Blasche & Koegl, 2013; Taipale *et al*, 2014).

Limitations A major disadvantage of the LUMIER method is that it requires lysis of cells prior to immunoprecipitation, a process that can result in the disruption of weak and transient PPIs, as well as the introduction of potential artifacts (e.g., by bringing together proteins in the lysate, which might not normally interact with one another in the cell, destabilizing proteins and exposing previously concealed non-native binding surfaces). The LUMIER assay must be carefully controlled, to normalize for differences in transfection efficiency and expression, and minimize background signal. The assay is not ideal for studying how PPIs change spatially, over time or in response to different environmental conditions (Barrios-Rodiles *et al*, 2005; Blasche & Koegl, 2013).

Mammalian protein–protein interaction trap (MAPPIT)

Principle The MAPPIT assay (Fig 1D) is designed for use in mammalian cell lines and is based on a cytokine signal transduction mechanism. A "bait" protein is fused to the C-terminus of a cytokine receptor deficient in binding to STAT3 (required for signal transduction), while "prey" proteins are fused to receptor fragments containing functional STAT3 recruitment sites. An interaction between a bait and prey proteins produces a functionally competent receptor, which, in response to cytokine ligand stimulation, activates STAT3 molecules (through intermediate JAK kinase activity), allowing them to enter the nucleus and induce transcription of a reporter system (e.g., luciferase; Ulrichts *et al*, 2009).

Advantages Mammalian protein–protein interaction trap provides a powerful way to examine mammalian PPIs directly in the context of the mammalian cell and is suitable for use in both HT library and array screening formats. The assay is easy to perform and does not require specialized equipment, beyond the necessary cell culture reagents and instrumentation to measure bioluminescence or fluorescence. Note that this method is best suited for studying binary interactions (Lievens *et al*, 2009, 2011). Variations of MAPPIT are effective for use in small-molecule screening approaches (Eyckerman *et al*, 2005; Caligiuri *et al*, 2006; Lievens *et al*, 2011).

Limitations Anchoring of the interaction sensor (i.e., the cytokine receptor) to the plasma membrane requires that PPIs occur in the

 © 2015 The Authors

cytoplasmic submembrane region, preventing detection of interaction with preys localized to other subcellular compartments. This anchoring (and the large size of the bait tag) may also block certain PPIs due to steric issues beyond those occurring in many other methodologies (Lievens *et al*, 2009). Finally, the method is also not compatible with full-length transmembrane proteins and is not suitable for spatial or temporal analysis of PPIs.

Kinase substrate sensor (KISS)

Principle Kinase substrate sensor (Fig 1E) is a recently developed mammalian two-hybrid approach designed to measure intracellular PPIs. In this assay, a "bait" protein is fused to the kinase domain of TYK2, while "preys" are coupled to a gp130 cytokine receptor fragment carrying TYK2 substrate motifs. Interaction of bait and prey results in phosphorylation of gp130 by TYK2, resulting in docking and activation of STAT3, which can then enter the nucleus and activate transcription of a STAT3-dependent reporter system (e.g., luciferase; Lievens *et al*, 2014).

Advantages Kinase substrate sensor allows assessment of PPIs directly in living mammalian cells and is sensitive enough to detect dynamic changes in response to physiological or pharmacological challenges. The method is effective for use with both membrane and cytosolic proteins and is best suited for measuring binary interactions (Lievens *et al*, 2014).

Limitations Like many other assays, the KISS readout is indirect, preventing spatial or temporal analysis of PPIs. The assay relies on endogenous STAT3, making this approach unsuitable for studying interactions involving proteins or stimuli that affect STAT3 signaling (Lievens *et al*, 2014).

Bimolecular fluorescence complementation (BiFC)

Principles Bimolecular fluorescence complementation (Fig 1F) is based on the division of a fluorescent protein (e.g., YFP) into two distinct non-fluorescent fragments, which are then fused to "bait" and "prey" proteins of interest. Interaction between bait and prey allows the two non-fluorescent fragments to associate and form a fluorescent complex, which can be viewed by microscopy or flow cytometry (Kerppola, 2008; Zhang *et al*, 2015).

Advantages Bimolecular fluorescence complementation allows direct visualization of PPIs in living cells, providing spatial information about the subcellular location where PPIs are occurring. The method is highly sensitive and can be used to detect interactions between proteins expressed at endogenous or near-endogenous levels, as well as weak and transient interactions. The method can be used for different organisms, is simple to set up, and is cost-effective. Different fluorescent proteins can also be used in combination, allowing the visualization of multiple PPIs in parallel in single cells. The method is best suited for detecting binary interactions (Hu *et al*, 2002; Kerppola, 2008; Zhang *et al*, 2015).

Limitations Bimolecular fluorescence complementation is not ideal for measuring PPI dynamics or real-time changes, due to a delay in generation of fluorescence upon protein interaction, as well as the irreversible nature of fluorochrome formation (Kerppola, 2008). Another disadvantage of BiFC includes functionality of fusion proteins, as is the case for other techniques involving protein tagging. Lastly, in some cases false-positive fluorescent signals can be detected by BiFC due to fluorescence intensity of reconstituted fragments arising irrespective of (or from non-specific) interaction between two proteins under investigation (Miller *et al*, 2015).

Mammalian membrane two hybrid (MaMTH)

Principle Mammalian membrane two hybrid (Fig 1B) is a recently developed *in vivo* proteomics technology designed for the analysis of mammalian membrane PPIs. The assay is based on the principle of split-ubiquitin, wherein reconstitution of inactive fragments of ubiquitin (Nub and Cub) upon interaction of proteins to which they are fused leads to release of an artificial transcription factor, and subsequent expression of a reporter system (luciferase in the case of MaMTH; Petschnigg *et al*, 2014).

Advantages Mammalian membrane two hybrid allows the analysis of the interactions of full-length mammalian membrane proteins directly in their natural cellular context. The assay is low cost, highly scalable, and readily transferable to virtually any cell line of interest. No specialized equipment is required, beyond standard cell culture reagents and tools necessary for monitoring luciferase activity. One of the key advantages of MaMTH is its high sensitivity, making it suitable for both the measurement of weak/transient interactions, and for monitoring dynamic, "condition-dependent" PPIs (i.e., which change in response to agonist, phosphorylation state, mutation etc.). The method is best suited for the detection of binary PPIs (Petschnigg *et al*, 2014).

Limitations For MaMTH to function, the bait must be associated with the membrane or other intracellular structures, to prevent non-specific activation of the reporter system (note that like MYTH, preys can be either soluble or membrane-bound). Additionally, the termini of the membrane protein fused to Cub must be cytosolic, in order to provide access to the deubiquitinating proteases responsible for cleavage and release of transcription factor. The method is also not suitable for spatial or real-time temporal analysis of PPIs (Petschnigg *et al*, 2014).

Fluorescence resonance energy transfer (FRET)

Principle Fluorescence resonance energy transfer (Fig 1G) is based on the non-radiative transfer of energy from an excited donor fluorophore to a nearby acceptor molecule. Donor and acceptors are selected such that the absorption spectrum of the acceptor fluorophore overlaps with the emission spectrum of the donor. In this approach, one protein of interest is fused to the donor, while the other is fused to the acceptor. If the two proteins interact or come into close proximity with one other, the donor and acceptor fluorophores are also brought together. Excitation of the donor in this case does not lead to photon release, but rather energy transfer to the nearby acceptor, which in turn produces an emission signal. This emission signal is distinct from the signal that would be observed for donor alone, and is used to monitor PPI (Ma *et al*, 2014).

Advantages A major advantage of FRET is its ability to monitor instantaneous, real-time PPIs, allowing the measurement of short-lived transient interactions. In addition, FRET can be used directly in the context of live cells and allows detection of interaction sites. Also,

© 2015 The Authors

due to the reversible nature of the fluorophore interaction, complex interaction dynamics can be monitored such as the dynamic equilibrium between complex formation and dissociation (Ma *et al*, 2014).

Limitations For FRET to function, protein fusions to appropriate fluorophores need to be generated (the technical demands of which may vary depending upon the fluorophores selected). In addition, for a strong FRET readout, close spatial proximity of the fluorophores is required for the energy transfer to occur. FRET also has decreased sensitivity compared to other fluorescence-based approaches like BiFC or BRET, as there tends to be strong background autofluorescence in cells upon sample illumination. For this reason, many controls are necessary to quantify the changes in fluorescence intensity in the presence and absence of energy transfer, and particularly weak interactions producing a signal close to background may be difficult to detect. Depending upon the fluorophores selected, photobleaching can also result in loss of signal over time (Boute *et al*, 2002; Ma *et al*, 2014).

Bioluminescence resonance energy transfer (BRET)

Principle The BRET assay (Fig 1G) has been developed to diminish a major limitation of FRET—the strong background signal that results from the direct excitation between the donor and acceptor fluorophores. In BRET, a protein of interest is fused to *Renilla* luciferase ("RLuc", serving as the energy donor), while its interacting partner is fused to either green or yellow fluorescent protein (GFP or YFP, serving as the energy acceptor). When donors and acceptors are brought into close proximity (< 100 Å) by interaction of their fusion partners, energy transfer occurs, producing fluorescent signal which is monitored to detect the PPIs (Boute *et al*, 2002; Hamdan *et al*, 2006).

Advantages Like FRET, BRET is able to monitor instantaneous real-time PPIs, functions directly in the context of live cells, and provides information about the cellular location at which an interaction occurs (Boute *et al*, 2002; Hamdan *et al*, 2006; Xie *et al*, 2011). However, BRET also has greater sensitivity than FRET, with lower background (Boute *et al*, 2002).

Limitations The major limitations of BRET are similar to those of FRET, including the need for the generation of fusion proteins, and the efficiency of the assay being dependent on close spatial proximity of the donor and acceptor (in order for proper energy transfer to occur; Hamdan *et al*, 2006). BRET signal also tends to be significantly weaker than that produced by FRET (Hamdan *et al*, 2006; Xie *et al*, 2011). In addition, the analysis of PPIs using BRET and FRET is not as easily scalable to HT screening applications as other methods, making it better suited to screens involving a more limited number of potential hits.

Affinity purification–mass spectrometry (AP-MS)

Principle Affinity purification–mass spectrometry (Fig 1H) is a popular technology that has gained considerable attention over the past decade. The general principle involves immobilization of "bait" protein of interest on a solid support (most frequently agarose or magnetic beads), and use of this coupled "bait" to capture target protein(s) from a soluble phase. Once affinity-purified, captured proteins are usually digested with proteases (e.g., trypsin), to generate peptides, which in turn are sub-fractionated using high-pressure liquid chromatography (HPLC) and then ionized and detected using a mass spectrometer. AP-MS can be conducted either with endogenous, native protein baits (using specific antibodies raised against them) or with protein baits to which a standardized "epitope tag" (e.g., TAP-, FLAG-, c-myc-, HA-, His-, protein A-, Strep-Tag) is fused. The choice of the most appropriate affinity purification method depends on a combination of factors, including the availability of antibodies, the type of a protein under investigation, and the scale of the conducted analysis (Dunham *et al*, 2012).

Advantages Affinity purification–mass spectrometry is a library-independent method with true genomewide HT capability. The main advantage of affinity purification using native antibodies against endogenous, native "baits" is that the proteins are purified in their natural form from cell or tissue lysates, eliminating issues associated with protein tagging and allowing multiple isoforms to be interrogated simultaneously. Conversely, the main advantages of epitope tagging are that it allows the study of proteins for which native antibodies are not available, and the analysis of multiple proteins using a single, defined process with a specific antibody (i.e., since many different proteins can be tagged with a single epitope; Dunham *et al*, 2012).

Limitations The major limitation of any AP-MS approach is a need to perform cell lysis and affinity purification. These steps do not allow for the detection of spatial or temporal PPIs and can also prevent detection of weak, transient PPIs. Another major limitation is contamination by abundant proteins co-purified from AP (Dunham *et al*, 2012) and artifacts resulting from exposure of proteins to one another in the unnatural environment of a cellular lysate (e.g., spurious interactions, disruption of protein interactions). In cases where epitope tags and ectopic expression are required, high background can also result from improper folding and mislocalization. However, several strategies do exist, which may help overcome these problems, such as use of appropriate negative controls, further enrichment of true interactions using tandem affinity purification (TAP), quantification approaches (SILAC and other isotopic labeling, and label-free quantification, which usually need special computational tools; Choi *et al*, 2011) and, for smaller experiments, contaminants can be filtered out by comparison with a contaminant repository database (Mellacheruvu *et al*, 2013). With endogenous proteins, low expression levels of proteins of interest may also prevent detection (Dunham *et al*, 2012). Lastly, data analysis of AP-MS experiments is more difficult compared to other PPI assays (i.e., Y2H), due to required expertise with MS and specific bioinformatics tools needed to address the limitations listed above.

Proximity-dependent biotin identification coupled to mass spectrometry (BioID-MS)

Principle Proximity-dependent biotin identification coupled to mass spectrometry (Fig 1I), which is similar in nature to AP-MS, uses a "bait" protein of interest fused to a prokaryotic biotin ligase molecule (BirA). When expressed in cells, proteins in proximity to the BioID fusion protein are biotinylated by BirA, permitting their selective isolation using an avidin/streptavidin-based biotin affinity capture approach. These purified, biotinylated proteins are then identified using MS, providing a list of candidate interacting partners for the bait of interest (Roux *et al*, 2012).

 © 2015 The Authors

Advantages Similar to AP-MS, BioID-MS is also a library-independent method. A major advantage of BioID-MS is that PPIs are detected in their natural cellular context (since biotinylation occurs in the cell prior to lysis). Additionally, issues associated with bait/prey stability and disruption of interactions upon cell lysis are avoided. The method is also well suited for identifying weak or transient interactions and is amenable to temporal regulation (potentially allowing for pulse-chase type applications; Roux *et al*, 2012). The method also appears to be more effective at detecting low-abundance proteins than AP-MS (Lambert *et al*, 2015).

Limitations BioID-MS requires the fusion of bait protein to BirA, which adds significantly to the size of the protein and can potentially compromise its targeting or function. Low expression level of PPI partners can also lead to false negatives. The biotinylation process itself may also affect protein behavior/interactions in certain cases (Roux *et al*, 2012). Finally, like AP-MS, required expertise in MS and specific bioinformatics tools can make data analysis more complex than for other methods.

Proximity ligation assay (PLA)

Principle Proximity ligation assay (Fig 1J) is a powerful method for the *in situ* detection of PPIs in fixed cells and tissues. The general premise of the assay involves the use of proximity probes (i.e., antibodies conjugated with DNA oligonucleotides, which are able to recognize two target proteins of interest). When the Proximity Probes are brought close to one another (i.e., due to interaction of the target proteins to which they are bound), the DNA strands serve as a template to direct ligation of two subsequently added oligonucleotide fragments into a circular molecule. This circular DNA is then amplified using rolling circle amplification (RCA) primed by one of the original proximity probe oligonucleotides, resulting in a long DNA sequence physically linked to the corresponding antibody (and thus the interacting protein pair). This new DNA sequence contains many repetitive elements, which are then bound by fluorophore-labeled complementary oligonucleotide probes, allowing visualization of interactions, at the specific sites where they occur, using a fluorescence microscope (Koos *et al*, 2014).

Advantages The major advantages of PLA are its ability to detect and localize PPIs with single molecule resolution and objectively quantify them in cells and tissues. In addition, transient or weak interactions can be monitored (Koos *et al*, 2014).

Limitations A major disadvantage of PLA is the dependence on enzymes (i.e., for ligation and polymerization), making the approach expensive and highly dependent on enzyme activity and stability. The required use of antibodies in PLA is another potential drawback, as antibodies are often costly, and may also not be readily available against particular proteins of interest (Koos *et al*, 2014). Thus, PLA is not ideally suited for HT PPI screening applications.

Ligand–receptor capture – trifunctional chemoproteomics reagents (LRC-TriCEPS)

Principle The LRC-TriCEPS approach (Fig 1K) has been developed to elucidate potential receptor/ligand interactions. TriCEPS employs a chemoproteomics reagent consisting of three moieties—one that binds ligands of interest containing an amino group, a second that binds glycosylated receptors on live cells, and a biotin tag. The reagent effectively serves as a stable "bridge", covalently linking a ligand of interest to carbohydrate groups on its cognate receptor. Following treatment with TriCEPS, cells are lysed and enzymatically digested with trypsin, and TriCEPS bound peptides are purified via the biotin tag. Receptor peptides are then freed from the TriCEPS reagent and identified using quantitative MS (Frei *et al*, 2012, 2013).

Advantages The major advantages of using LRC-TriCEPS are the ability to detect ligand–receptor interactions without the need for genetic manipulations. This approach is also effective for detecting surface interactions that are very transient in nature, and can be used with both populations of individual cells and tissue samples. In addition, LRC-TriCEPS can be used to identify the cell surface binding partners of many different types of ligands, including peptides, proteins, viral particles, antibodies, and engineered affinity binders (Frei *et al*, 2012, 2013).

Limitations By design, LRC-TriCEPS is only useful for identifying N-glycoprotein receptors, and is ineffective if glycans are sterically inaccessible. Coupling of ligands to TriCEPS reagent may also affect their functionality/proper target binding in some cases (necessitating verification of ligand function following TriCEPS linkage, where possible). TriCEPS may also not be effective in detecting receptor–ligand interactions in situations where ligand binding requires association to other cell surface structures (in addition to a target glycoprotein; Frei *et al*, 2013).

Avidity-based extracellular interaction screen (AVEXIS)

Principle Avidity-based extracellular interaction screen is a PPI assay developed to systematically screen for novel extracellular receptor–ligand pairs involved in cellular recognition processes (Fig 1L). The general premise of this approach involves the expression of secreted recombinant "bait" and "prey" proteins (e.g., natively secreted proteins or the truncated ectodomain of membrane proteins containing an N-terminal secretory peptide) in a mammalian cell-based system so that structurally important posttranslational modifications can occur. Bait proteins are biotinylated, so they can be captured on a streptavidin-coated solid phase, while prey proteins are tagged with β-lactamase and a peptide sequence directing their pentamerization (used to increase effective prey concentration and improve assay sensitivity). Bait and prey isolates are then presented to one another in a binary manner to detect direct interactions using an ELISA-type format (Kerr & Wright, 2012).

Advantages Avidity-based extracellular interaction screen can detect very weak PPIs, which are a typical feature of interactions between membrane-embedded receptor proteins (it has been shown to detect interactions with equilibrium dissociation constants as low as ~10 μM) with a low false-positive rate (Sun *et al*, 2012; Kerr & Wright, 2012). The assay has also been adapted for use on a higher-throughput scale than many other assays designed to detect extracellular interactions (Sun *et al*, 2012).

Limitations Avidity-based extracellular interaction screen is limited to the study of membrane proteins with self-contained

© 2015 The Authors

extracellular domains and is not generally suitable for multipass membrane proteins and other proteins that need to be embedded in the plasma membrane to fold and function properly (Kerr & Wright, 2012; Frei *et al*, 2013). In addition, selecting, preparing, and validating the constructs necessary for AVEXIS can be a lengthy (and relatively costly) process, although the use of a recently reported protein microarray format does help in this regard (Sun *et al*, 2012). The approach may also have difficulty detecting homophilic interactions and is not ideal for quantitatively comparing the strength of different interactions (due to the artificial pentamerization of preys; Kerr & Wright, 2012).

Dynamic protein interaction networks

A major limitation of the available PPI interaction network data is the static representation of these interactions, neglecting the temporal and spatial organization of protein dynamics as well as the effect of posttranslational modifications (PTMs). For instance, a PPI may occur only during specific time periods (e.g., under particular stress conditions, in response to certain signaling events etc.) or if specific PTMs are present. The nature of protein–protein interaction is thus an inherently dynamic process that changes with time, environments, and at different stages of the cell cycle. Recently, dynamic protein interaction networks have been constructed by using proteomic, genomic, and transcriptomic methodologies. In the previous section, we touched briefly on the suitability of some techniques for mapping dynamic interactions. Examples of some of specific proteomic-based approaches employed include Y2H and AP-mass spectrometry (Woodsmith & Stelzl, 2014). For instance, the phosphotyrosine-dependent PPI network was recently studied using Y2H, and identified many novel phosphotyrosine-dependent PPIs of human kinases (Grossmann *et al*, 2015). AP-MS approaches have been employed to study the dynamics of the human 26S proteasome-interacting proteins (Wang & Huang, 2008, 2014), study changes in the interactome of 14-3-3β in response to activation of the insulin-PI3K-AKT pathway (Collins *et al*, 2013), and map phosphotyrosine-dependent interaction sites on ErbB-receptor family members (Schulze *et al*, 2005).

In addition to the temporal and spatial organization of PPIs, perturbations of PPIs from disease-associated alleles have also gained much interest. Such perturbations can be either subtle or dramatic, but often have significant biological consequences, and understanding the nature of these changes can be important in developing new therapeutic strategies. Thousands of genetic variants have been identified in many Mendelian disorders, complex traits, and cancers; however, the effect of these genetic variants on PPI networks is still far from clear. Recent studies have looked into assessing perturbations of protein interactions by disease-associated alleles using the techniques described above. For example, Sahni *et al* (2015) found widespread perturbations of macromolecular interactions caused by disease-specific mutant alleles using a comprehensive genomics/proteomics approach involving LUMIER and Y1H/Y2H technologies. Additionally, Wang *et al* (2012) integrated available protein structure and large-scale PPI data to comprehensively investigate the relationships between mutations, protein interactions, and human disease. Work by Petschnigg *et al* (2014) using the MaMTH assay also identified differential interactors of WT and oncogenic mutant forms of the receptor tyrosine kinase EGFR. For a more thorough examination of protein interactome networks and disease, several excellent reviews are available (Ideker & Sharan, 2008; Vidal *et al*, 2011; Sahni *et al*, 2013).

Analysis of PPI screen data

Once a screen is completed, it is necessary to properly analyze the data in order to validate the results and improve overall interactome quality. In this section, we provide an overview of some key considerations and methods useful for analysis of PPI datasets.

Assessing PPI datasets

Assessing the frequency of false positives and false negatives in PPI datasets has been a long-standing problem, especially for HT screens. Typically, the frequency of false positives is measured as the false discovery rate ($FDR = \frac{false\ positives}{true\ positives + false\ positives}$), and the frequency of false negatives as the false negative rate ($FNR = \frac{false\ negatives}{true\ positives + false\ negatives}$) or sensitivity ($\frac{true\ positives}{true\ positives + false\ negatives}$). The main strategies for assessing FDR and sensitivity have involved testing detected interactions by multiple methods and comparing against interactions from literature. FDR has been, arguably, a greater focus in interactome studies than sensitivity. In small-scale screens, FDR can be assessed and minimized by testing all reported interactions using multiple methods. However, the FDR of small-scale screens may still be uncertain. Edwards *et al* (2002) found that interactions from small-scale screens were not always consistent with known 3D structures of protein complexes. Rolland *et al* (2014) tested interactions reported in single publications and found that the detection rate was just slightly higher than for random protein pairs. Small-scale studies rarely report protein pairs that were tested but not detected. Consequently, the sensitivity of their screens and the assessment of how much of the interactome they have tested are largely unknown (Cusick *et al*, 2009).

Assessing HT screens is more difficult since testing all detected interactions by multiple methods is not feasible. Venkatesan *et al* (2009) developed a rigorous framework for assessing the quality of HT PPI datasets. Their framework calculates four parameters: screening completeness, assay sensitivity, sampling sensitivity, and precision. Screening completeness is the fraction of open reading frame (ORF) pairs tested in the screen. Assay sensitivity is the fraction of interactions that can be identified by the assay, estimated by testing the assay on a gold standard set of interactions, and determining the fraction detected. Sampling sensitivity is the fraction of detectable interactions identified in one trial of the assay, estimated by repeating the assay multiple times and fitting a Bayesian model to the results. Precision, the fraction of detected pairs that are true positives, can be estimated by testing the assay on reference sets of interacting and non-interacting protein pairs, and calculating the fraction of detected pairs that are from the interacting set.

Once the precision and sensitivity of an assay have been estimated, the assay can be used to determine the FDR of interaction datasets. HT studies commonly estimate FDR by retesting a subset of detected protein pairs using different small-scale or HT methods (Yu *et al*, 2008; Simonis *et al*, 2009; Rolland *et al*, 2014). Such estimates need to take into account the precision and sensitivity of the

 © 2015 The Authors

retesting assay. This is especially important as the precision or sensitivity may be quite limited. Braun *et al* (2009) assessed five HT assays on a gold standard dataset comprised of interactions reported by multiple small-scale studies (positive cases) and an equal number of randomly chosen protein pairs. Each HT assay detected only ~20–35% of positive cases, and up to 4% of negative cases. Combined, the five assays detected 59% of positive cases, while FDR increased to 14%. Furthermore, different assays have different systematic biases; for example, affinity purification methods may be biased in favor of high-abundance proteins (Ivanic *et al*, 2009). Another concern, especially difficult to address, is that gold standard datasets may also have biases. Such datasets, often comprising PPIs reported by multiple small-scale studies, may be deficient for certain types of proteins or PPIs due to research bias or limitations of assays (Hakes *et al*, 2008; Edwards *et al*, 2011; Rolland *et al*, 2014; Kotlyar *et al*, 2015; Wang *et al*, 2015).

Computational methods for assessing results

Computational methods provide a means of estimating FDR without retesting detected protein pairs. Furthermore, they can provide error estimates for specific proteins or protein pairs.

D'haeseleer and Church (2004) introduced a method for estimating FDR and assessing the reliability of individual interactions. Their method analyzes the overlap of detected interactions with two other datasets, including a trusted reference set. The variance of FDR estimates can be high if the overlaps are small. However, the authors showed that FDR estimates are not greatly affected by the quality of the chosen datasets.

A statistical model introduced by Huang and Bader for assessing two-hybrid datasets provides global error estimates as well as error estimates for specific baits (Huang & Bader, 2009). Thus, it can determine whether certain baits are responsible for a disproportionate share of the global error rate. For example, in two-hybrid data from worm, it found that the FDR was especially high among proteins involved in cellular metabolic processes.

Computational methods to help improve data quality

One approach for assessing and improving data quality is to examine whether a PPI dataset possesses properties of interacting protein pairs. Methods that use this approach assume that interacting proteins are likely to have co-expressed genes (Deane *et al*, 2002), shared subcellular localization (Sprinzak *et al*, 2003), similar functional and process annotations (Sprinzak *et al*, 2003; Wang *et al*, 2007), and shared interaction partners (Saito *et al*, 2002; Goldberg & Roth, 2003). Evaluating a PPI dataset using such evidence can be problematic: Many interacting protein pairs do not have correlated gene expression, protein annotations such as subcellular localization and function are often incomplete or unavailable, and shared interaction partners are frequently unknown, since the interactomes of most species are largely unmapped. However, ranking detected protein pairs using these types of evidence can help identify true positive interactions. A combination of such evidence has been used in HT studies to define high-confidence (HC) subsets of detected interactions (Miller *et al*, 2005; Havugimana *et al*, 2012). The evidence can also help identify potential false negatives—protein pairs that are not strongly supported by the experimental detection method but have properties of true interactions. Unfortunately, ranking based on this evidence can introduce biases; ranking by correlation of gene expression profiles favors stable interactions (Brown & Jurisica, 2007), while ranking by shared Gene Ontology terms or interaction partners favors well-studied proteins. If the evidence is used multiple times during the planning and analysis of an experiment, there may be a danger of circular reasoning. For example, testing protein pairs with similar functions and then ranking detected pairs by similarity of localizations would be largely ineffective, as functional similarity is correlated with localization similarity.

An approach for improving the quality of AP-MS data involves calculating a score for each co-purified pair, indicating the likelihood of the two proteins being observed together. Such scores have been calculated using various methods: log-ratios of observed versus expected co-occurrences (Gavin *et al*, 2006), machine-learning algorithms (Krogan *et al*, 2006; Collins *et al*, 2007), hypergeometric probabilities (Hart *et al*, 2007), and randomizations (Yu *et al*, 2009). Scores can be used for ranking protein pairs and defining a HC subset of interactions. A score threshold for defining this subset can be determined based on FDR and sensitivity calculated from a gold standard dataset comprising interacting and non-interacting protein pairs. True positive interactions can be distinguished from contaminants by analyzing quantitative information from mass spectrometry data, including spectral counts, signal intensity in the precursor scan of the mass spectrometer, and intensity of product ions after fragmentation (Gingras & Raught, 2012). Analysis of quantitative data using tools such as SAINT (Choi *et al*, 2011) can be especially helpful when aiming to detect transient interactions; preservation of transient interactions in AP-MS experiments requires short incubation times and few washes, resulting in more contaminants that need to be filtered (Gingras & Raught, 2012).

Varjosalo *et al* (2013) filtered AP-MS data in three steps to remove different types of protein contamination. The first filter removed proteins that may have been left over from a proceeding experiment. The second filter removed non-specifically interacting proteins. The third filter removed low-abundance, non-systematic contaminants; bait–prey pairs were assigned weighted spectral-count-based scores reflecting interaction abundance and reproducibility, and pairs with scores below a threshold were removed. This three-step filtering improved reproducibility of resulting networks more than previous filtering methods, wD-score (Behrends *et al*, 2010) and SAINT (Choi *et al*, 2011).

Computational prediction to help improve datasets and the interactome

Computational PPI prediction is similar to previously described methods that assign scores to detected protein pairs, indicating the likelihood of interaction. However, prediction methods provide scores for both detected and undetected PPIs. These scores can be used to improve the quality of experimentally detected PPIs, by identifying high-confidence subsets and potential false negatives, which can help accelerate interactome mapping (Schwartz *et al*, 2009). Also, prediction methods can help fill the gaps in a known interactome by predicting interactions for interactome orphans and low-degree proteins (Kotlyar *et al*, 2015).

PPI prediction methods can be categorized by the data they use: genomic data, protein sequence, protein structure, PPI networks, gene expression, and annotations of gene function,

© 2015 The Authors

localization, and process. Prediction methods based on genomic data analyze conserved operon structure, fusion domains, phylogenetic profiles, and interologs. Analysis of operon structure is based on the idea that genes in close proximity on the genome are more likely to encode interacting proteins, especially if the proximal locations are conserved across species (Dandekar *et al*, 1998; Overbeek *et al*, 1999). Similarly, if two genes exist as a single fused gene in another species, they are likely to encode interacting proteins (Enright *et al*, 1999). Phylogenetic profiles are used to identify gene pairs that tend to co-occur across species—either both are present in a species, or both are absent; such pairs are likely to be functionally related and may encode interacting proteins (Pellegrini *et al*, 1999). Interologs are interactions conserved across species: if a pair of proteins interacts in one species, their orthologs in another species are more likely to interact (Walhout *et al*, 2000; Yu *et al*, 2004).

Many studies have predicted interactions based on protein sequence (Gomez *et al*, 2003; Martin *et al*, 2005; Nanni & Lumini, 2006; Shen *et al*, 2007; Guo *et al*, 2008; Zaki *et al*, 2009; Chang *et al*, 2010; Guo *et al*, 2010; Yu *et al*, 2010). These studies analyze experimentally determined interactions to find patterns that distinguish sequences of an interacting protein pair from those of a non-interacting pair. This is often done using machine-learning algorithms such as support vector machines, random forests (Roy *et al*, 2009), and K-local hyperplane nearest-neighbors (Nanni & Lumini, 2006). Protein sequence can also be used indirectly for prediction; protein domains can be determined from sequence, and pairs of domains enriched among known interacting protein pairs may predict new interactions (Sprinzak & Margalit, 2001; Wojcik & Schächter, 2001; Nguyen & Ho, 2006; Singhal & Resat, 2007). Another approach combines sequence with protein tertiary structure. Although few proteins or complexes have known 3D structure, sequence homology can serve as a link to other proteins. Homologous proteins, especially with conserved binding sites, are likely to interact in similar ways (Aloy & Russell, 2003; Ma *et al*, 2003; Sinha *et al*, 2010). Thus, a protein pair can be predicted to interact based on sequence or structural homology to proteins in solved complexes (Lu *et al*, 2002; Aloy & Russell, 2003; Zhang *et al*, 2012a).

If an interactome is partially known, new interactions may be predicted from known network structure, often based on the idea that interacting proteins tend to share interaction partners (Saito *et al*, 2002; Goldberg & Roth, 2003; Liu *et al*, 2008). Other types of interaction evidence—including correlated gene expression, shared subcellular localization, similar function and process—are typically used in combination with other evidence (Jansen *et al*, 2003; Ben-Hur & Noble, 2005; Rhodes *et al*, 2005; Elefsinioti *et al*, 2011).

PPI prediction methods have a number of limitations and biases, often similar to those of experimental PPI assays. Computational methods tend to have difficulty predicting transient interactions and interactions involving lesser studied proteins, which typically have no tertiary structure data, no detailed Gene Ontology or domain annotations, few known interactions, and few orthologs in different species (Kotlyar *et al*, 2015). Transient interactions are difficult to predict based on correlation of gene expression profiles (Brown & Jurisica, 2007), or analysis of protein sequence or structure. In these interactions, the two encoding genes are not highly correlated (Brown & Jurisica, 2007), interaction interface sequences are not as conserved as in obligate interactions (Perkins *et al*, 2010), interacting proteins often undergo conformational changes (Perkins *et al*, 2010), and interactions are frequently mediated by linear motifs rather than globular domains (Perkins *et al*, 2010). If proteins lack Gene Ontology annotations, known interaction partners, or orthologs, it is difficult to predict their interactions using annotation similarity, network topology, or comparative genomics, respectively. Interestingly, such proteins are also underrepresented in the experimentally detected human interactome (Kotlyar *et al*, 2015). If prediction methods require training, they may acquire the biases of their experimentally detected training set. This may explain the finding of Rolland *et al* that a proteome-wide, structure-focused prediction method, PrePPI (Zhang *et al*, 2012a), had a tendency to report interactions among well-studied proteins (Rolland *et al*, 2014).

Databases: what is available and what do they tell us?

Studies that detect PPIs report their findings in journal articles as free-form text. Consequently, original information about detected PPIs is scattered across thousands of articles and requires manual curation. Converting these data into an easily usable set of interactions and experimental descriptions remains a daunting problem, comprising several key tasks: (i) experiments need to be described with a controlled vocabulary and recorded in a common format, (ii) thousands of articles have to be curated and resulting information has to be easily accessible, and (iii) proteins need to be unambiguously identified. The first task, creation of standard vocabularies and formats for PPI data, was addressed through the Human Proteome Organization Proteomics Standards Initiative (HUPO-PSI) by the Molecular Interaction (MI) workgroup. They created a common controlled vocabulary for experimental techniques, molecular features, and interaction types (Orchard & Kerrien, 2010), and XML (PSI-MI XML) and tab-delimited (MITAB) formats for recording and transferring data (Kerrien *et al*, 2007). Most major PPI databases adopted the vocabulary and data formats, allowing users to easily integrate datasets and analyze them with programs such as Cytoscape (Su *et al*, 2014) and NAViGaTOR (Brown *et al*, 2009).

The second task, curating articles and providing results through online databases, started with the DIP (Salwinski *et al*, 2004) and BIND (Bader *et al*, 2003) database projects and has continued with the creation of many similar resources (Table 2 and Fig 2A). These resources were especially important given the rapid increase in the number of human PPIs (Fig 2B) detected by various experimental methods. Initially, the focus was on experimentally detected PPIs in yeast and human, but the scope has greatly expanded. Some databases now include computationally predicted interactions (e.g., STRING (Szklarczyk *et al*, 2015), FpClass (Kotlyar *et al*, 2015), IID (Kotlyar *et al*, 2016)), functionally related protein pairs (e.g., STRING (Szklarczyk *et al*, 2015)), interactions between proteins and other molecule types (e.g., BIND (Bader *et al*, 2003), BindingDB (Liu *et al*, 2007), IntAct (Kerrien *et al*, 2012)), interactions in a range of organisms (e.g., DIP (Salwinski *et al*, 2004), IntAct (Kerrien *et al*, 2012), MINT (Licata *et al*, 2012), BioGRID (Chatr-Aryamontri *et al*, 2015), IID (Kotlyar *et al*, 2016)), and interactions involving

 © 2015 The Authors

specific types of proteins (e.g., extracellular matrix—MatrixDB (Chautard *et al*, 2011), immune related—InnateDB (Breuer *et al*, 2013)).

Databases also differ in several other respects: the level of detail recorded about experiments (shallow versus deep), the way information is acquired (manual curation of literature or automatic approaches such as text mining or PPI prediction), and the sources of information—peer-reviewed articles (primary sources) or other databases (secondary sources). Manual curation of articles is the most trusted method for acquiring data and is carried out by most databases. Several approaches have been used to assist with curation: curation guidelines have been established, an automated syntax checker was implemented to test for compliance with accepted formats, and guidelines were created for reporting PPIs in papers, so that curation of papers is easier and more accurate (Orchard *et al*, 2007). However, manually curating all previously published literature and keeping up with new publications is a huge task. The IMEx consortium (Orchard *et al*, 2012) was created to better organize the curation effort across major PPI databases. Members of the consortium avoid curating the same papers and follow the same curation rules.

Although current PPI databases provide easy access to their PPI data, obtaining the most complete up-to-date network can be challenging: the latest data has to be downloaded from multiple databases and merged. The PSICQUIC (Aranda *et al*, 2011) query interface simplifies these tasks. It enables multiple PPI databases to be searched with the same query, and a clustering algorithm provided with PSICQUIC helps merge results by grouping interaction evidence based on primary identifiers.

Unfortunately, the third task, unambiguously identifying proteins, has not been entirely resolved. Most PPI databases use UniProtKB (Magrane & Consortium, 2011) protein identifiers, which can represent peptides, fusion proteins, specific isoforms, or proteins whose isoforms are not specified. However, some databases use Ensembl (Flicek *et al*, 2014), Entrez (Maglott *et al*, 2011), RefSeq (Pruitt *et al*, 2012), and species-specific identifiers. Mapping between different types of identifiers is not always possible. When databases use different protein identifiers, PSICQUIC is unable to identify redundant data. However, this problem is being addressed as more providers of PSICQUIC clients include commonly used identifiers in export files (Orchard, 2012).

Visualization, analysis, and biological validation of PPI data

Visualization Tools

A number of tools are available for visualization and analysis of PPI data including Cytoscape (Su *et al*, 2014), NAViGaTOR (Brown *et al*, 2009), and packages from R and Bioconductor (e.g., Rintact (Chiang *et al*, 2008) combined with RBGL). The main types of functionality supported by these tools include loading PSI-MI files, visualizing networks, annotating networks, and conducting network analysis. Data can be loaded from tab-delimited or PSI-MI XML files, and visualized as a graph, with nodes representing proteins and edges representing interactions. Multiple graph layouts are supported, including grids and force-directed layouts. Annotations for nodes and edges can be included in the original data files, retrieved from other text files, or imported from databases. The appearance of nodes and edges can be set based on annotations. Network analysis capabilities include clustering to identify protein complexes, motifs, or graphlets, calculating centrality measures, and identifying shortest paths or flows.

Identifying complexes in PPI networks

Although PPI networks focus on pairwise interactions, cellular processes are often carried out by protein complexes. Complexes typically have a "core"—a central functional unit present in most isoforms of the complex, and "attachments"—proteins present in some isoforms of the complex (Gavin *et al*, 2006). The attachments may include "modules"—sets of proteins that always appear together in different complexes (Gavin *et al*, 2006).

Experimental methods for detecting PPIs cannot easily identify complexes. For example, Y2H methods only identify binary interactions, and while TAP and HMS-PCI identify potential complexes, reliably identifying complex members requires "reverse purification"—repeatedly applying the detection method, using candidate members of the complex as baits (Gavin *et al*, 2002).

(B) Major human PPI databases and the number of PPIs they contain.

Computational methods can predict complexes by analyzing PPI networks and integrating networks with information such as gene function or co-expression. Most complex prediction methods share the same main steps: (i) assigning confidence scores to detected interactions, (ii) identifying complexes by clustering PPI networks or analyzing additional data, and (iii) evaluating resulting complexes by comparing with gold standard datasets. The first step assigns confidence scores to detected interactions; scores can be used to filter interactions or can be included as input to clustering algorithms. Any of the scoring approaches described earlier may be used (see section "Computational methods to help improve data quality"). Often, complexes are determined from AP-MS data, and scoring approaches specific to this data are used.

Most prediction methods assume that complexes correspond to highly connected regions of PPI networks and cluster the networks to identify these regions. The clustering approaches can be categorized as agglomerative or divisive, and overlapping or non-overlapping. Agglomerative approaches (Bader & Hogue, 2003; Li *et al*, 2005; Liu *et al*, 2009; Wang *et al*, 2009; Nepusz *et al*, 2012) start with seeds—individual nodes or cliques—and expand them into larger clusters by adding single nodes or merging with other clusters. Divisive approaches (van Dongen, 2000; Pu *et al*, 2007; Friedel *et al*, 2009) start with an entire network and partition it into highly connected regions. Overlapping approaches (Wang *et al*, 2009; Nepusz *et al*, 2012) allow nodes to be members of multiple clusters, to reflect overlap between complexes, while non-overlapping approaches (van Dongen, 2000; Bader & Hogue, 2003; Liu *et al*, 2009) assign nodes to single clusters. Some methods (Wu *et al*, 2009; Leung *et al*, 2009; Srihari *et al*, 2010; Chin *et al*, 2010) try to identify core and attachment sections of complexes.

Several methods combine network clustering with information about protein function, orthology, or structure. To increase the reliability of predicted complexes, these methods look for clusters whose members have similar functions (King *et al*, 2004; Li *et al*, 2007), highly conserved orthologs in the same set of species (i.e., the complex is conserved as a functional unit (Sharan *et al*, 2005; Hirsh & Sharan, 2007)), and protein structures enabling simultaneous interactions with multiple complex members (Ozawa *et al*, 2010; Jung *et al*, 2010). Several surveys (Brohée & van Helden, 2006; Vlasblom & Wodak, 2009; Li *et al*, 2010; Srihari & Leong, 2013) evaluated complex prediction methods by comparing their results against experimentally determined complexes. The Markov Cluster Algorithm (van Dongen, 2000; van Dongen & Abreu-Goodger, 2012) was found to be a top clustering method in three surveys (Brohée & van Helden, 2006; Vlasblom & Wodak, 2009; Li *et al*, 2010), and integration of network clustering with other information significantly improved performance (Srihari & Leong, 2013).

Identifying interaction conditions

Understanding how PPIs produce specific phenotypes requires information on their context: when, where, and under what conditions interactions occur. Computational methods can help determine this information by text mining of the PubMed database (Chowdhary *et al*, 2012), or more commonly, by integrating transcriptomic and other data with PPI networks. Usually, these methods aim to identify cell types, tissues, and disease states in which interactions occur.

Direct evidence for interactions occurring in a given cell type or tissue is often unavailable since PPI detection is typically done in yeast cells or common cell lines. By contrast, HT gene expression data are available for a wide variety of organisms, cell types, tissues, and conditions (Barrett *et al*, 2013; Kolesnikov *et al*, 2015). A common approach for assigning PPIs to tissues is to check whether the genes encoding an interacting protein pair are both expressed in a tissue (Bossi & Lehner, 2009; Lopes *et al*, 2011). Proteomics data (Uhlen *et al*, 2015) are less extensive but can be used analogously. The TissueNet (Barshir *et al*, 2013) database uses both gene and protein expression data to assign PPIs to tissues. Assigning tissues on the basis of gene or protein expression has limitations; absence of gene expression may not indicate absence of protein expression, and presence of gene or protein expression may not mean that proteins interact. Also, since this approach estimates the presence or absence of proteins, it can only indicate whether all interactions involving a protein are absent, but not whether a specific interaction is absent. Correlation of gene expression profiles can provide information on specific interactions; a pair of genes with correlated expression profiles in a tissue or cell type may have interacting protein products (Camargo & Azuaje, 2007).

Interactions that change in disease or other conditions can be identified by similar approaches. An interaction may be disease-related if the two encoding genes are both expressed only in the disease state (or are upregulated in the disease state; Ideker *et al*, 2002), or the genes have correlated expression profiles in disease states (Camargo & Azuaje, 2007; Guo *et al*, 2007; Xiao *et al*, 2012).

 © 2015 The Authors

Differential correlation of gene expression profiles can provide more specific information about an interaction: if two genes have significantly different correlation levels in two conditions, then the interaction of their protein products may change between conditions (Lin *et al*, 2010; Yoon *et al*, 2011; Zhang *et al*, 2012b; Yu *et al*, 2013).

Integrating PPI networks with other omics data

Integrating PPI networks with other omics data, such as genomic, transcriptomic, and proteomic, is essential for understanding the molecular basis of phenotypes. Just as gene expression data can provide context for PPIs, and link them with specific conditions, PPI networks can provide context for other data, and link it with phenotype.

One of the most common types of integration combines PPI networks and gene-phenotype data, to uncover relationships between genes and diseases. Goh *et al* (2007) showed that essential genes and disease genes have distinct network properties: essential genes tend to encode hub proteins, while disease genes encode proteins in the periphery of the network. Genes implicated in similar diseases tend to encode proteins that are close in PPI networks—either interacting directly (Goh *et al*, 2007; Schadt, 2009) or members of the same complex (Lage *et al*, 2007), pathway (Wood *et al*, 2007), or subnetwork (Lim *et al*, 2006). Based on this idea, it is possible to identify novel disease genes by mapping known disease-associated genes to nodes in PPI networks, and applying random walk (Kohler *et al*, 2008; Smedley *et al*, 2014), network flow (Yeger-Lotem *et al*, 2009; Chen *et al*, 2011), label propagation (Lee *et al*, 2011a), or other related algorithms (Vanunu *et al*, 2010; Winter *et al*, 2012). Random walk algorithms have been shown to be especially effective (Navlakha & Kingsford, 2010).

Integrating PPI networks with protein–DNA interactions, gene expression, phenotype, and drug information can provide insights into disease and drug mechanisms and can help identify new treatments. PPI networks combined with protein–DNA interactions have been used to model cellular regulatory networks—identifying regulatory circuits (Yeger-Lotem *et al*, 2004) and signaling-regulatory pathways (Ourfali *et al*, 2007). More recently, networks were used to predict disease mechanisms by modeling pathogen induced perturbations (Gulbahce *et al*, 2012), and effects of node or edge removal (Zhong *et al*, 2009; Sahni *et al*, 2013). Networks have also been effective for developing treatments: identifying drug targets (Yeh *et al*, 2012; Emig *et al*, 2013), understanding drug mechanism of action (Perez-Lopez *et al*, 2015), predicting side effects (Huang *et al*, 2013b), predicting drug–drug interactions (Huang *et al*, 2013a), and characterizing drug-regulated genes and toxicity (Kotlyar *et al*, 2012).

Biological validations

Direct experimental validation of the biological relevance of interactions is the final important step in any interactome mapping project. While complete validation of all novel interactions detected is seldom possible within the context of a single study, demonstrating that a particular interactome provides information of practical biological importance can be done by further analysis of a representative subset of interactions.

Selection of the subset of interactions to study is highly situational, and will depend largely on the nature of the proteins being investigated and the information currently available about them, as well as the size of the interactome and the specific goals of the study. For example, if studying the interactions of a protein whose mutation is known to be associated with disease, interactions which differ between the WT and mutant forms of the protein would likely be highly informative candidates for initial validation. Interactions involving members specifically associated with a given process of interest, which have not been previously demonstrated to interact, also represent a good starting point. Integrating the interactome with other datasets, combined with various predictive algorithms (as described above), is valuable in this selection process, and can help identify candidates based on a more complex range of user-defined criteria.

The specific validation experiments to be performed also vary on a case-by-case basis. Typical initial characterization experiments involve disrupting the level of individual members of an interaction pair (e.g., by gene deletion/knockdown or overexpression), and then looking for changes in the properties or function of the other member. For example, if studying the interactions of a particular receptor, one could investigate the effect of altering gene expression levels of identified interactors on downstream signaling cascades controlled by the receptor. Alternatively, effects on protein stability, protein trafficking, posttranslational modification, or responsiveness to known ligands/substrates could be probed. Investigations can be as specific as centering on molecular effects on individual proteins, or more broadly explore general phenotypic change (e.g., increased sensitivity to particular drugs, inability to grow under certain conditions). Mutational analysis of proteins can also be useful in identifying regions important for mediating and regulating interactions. For examples of proteomics screens followed by functional follow-ups, we refer the reader to several recent studies (Babu *et al*, 2012; Snider *et al*, 2013; Petschnigg *et al*, 2014).

The importance of performing these validations cannot be understated, as they provide a clear demonstration of the usefulness of any newly generated interactome in providing a solid starting point for the identification and characterization of biologically important processes. If an interactome cannot easily provide this information, then it is unlikely to be of widespread value to the scientific community, and further improvements are necessary. It is also critical to note that carrying out proper validations may represent a significant effort, and researchers must take this into account when planning and implementing any interactome mapping project, regardless of scale.

Concluding remarks

High-throughput PPI mapping and analysis enables researchers to generate data and investigate biological processes on a previously unprecedented scale (Yao *et al*, 2015). Selecting and implementing the method best suited for a particular biological question can be a significant challenge, however, one which is further complicated by the emergence of an ever increasing number of new interaction proteomics technologies. Here, we have presented the general principles of the most frequently used PPI methods and have highlighted the advantages and limitations of each, as well as provided a summary of available bioinformatics approaches and resources for use in the interpretation of interactome data. It is our hope that this review serves as a useful guide to "wet" and "dry" laboratory

© 2015 The Authors

methodologies and the analytical tools required to properly make use of these exciting approaches, and will help more scientists actively employ them in their research efforts.

Abstract
Protein–protein interactions (PPIs), such as protein–protein inhibitor, antibody–antigen complex, and supercomplexes play diverse and important roles in cells. Recent advances in structural analysis methods, including cryo-EM, for the determination of protein complex structures are remarkable. Nevertheless, much room remains for improvement and utilization of computational methods to predict PPIs because of the large number and great diversity of unresolved complex structures. This review introduces a wide array of computational methods, including our own, for estimating PPIs including antibody–antigen interactions, offering both historical and forward-looking perspectives.

Keywords Protein–protein interaction · Antibody–antigen interaction · Epitope prediction · Docking simulation · AlphaFold · Profile–profile comparison

Introduction

Protein–protein interactions (PPIs) play fundamentally important roles in cellular functions and biological processes, and structural understanding of the PPIs is important for the elucidation of those functions (Jones and Thornton 1995, 1996). In 2001, the Critical Assessment of PRediction of Interactions (CAPRI, 2022) began as a community-wide experiment designed to assess methods for predicting PPIs based on the estimation of PPIs for previously solved structures of protein complexes. The latest experiment (Round 54) was conducted during May–August in 2022 (CAPRI Round 54, 2022). A recent report of a CAPRI experiment (Lensink et al. 2020) indicated that the increase of structures of protein complexes deposited in the Protein Data Bank (PDB) enables their use as structural complex templates for predicting the structures of other protein complexes, particularly in homo protein–protein docking. That finding implies that classical docking may no longer be strictly necessary for the prediction of homo PPIs. Nevertheless, these methods have not yet been successfully applied to the prediction of hetero PPIs, including antibody–antigen interactions, and this area of research has room for improvement. In this review, we place our focus on computational docking-based approaches and AI-based approaches, introducing a wide array of methods, including our own, for PPI prediction.

Protein–protein docking

Traditional protein–protein docking methods have been of central importance for sampling the conformational space of protein complexes (Smith and Sternberg 2002). In the last 10 years, sophisticated high-precision docking methods such as HADDOCK (van Zundert et al. 2015), ClusPro (Desta et al. 2020), ZDOCK (Pierce et al. 2014), and LightDock (Jiménez-García et al. 2018) have been developed and continually improved. To sample conformations more efficiently, they have used not only three-dimensional structural information in both modeling and scoring steps, but also evolutionary information and information obtained from experiments of several types (van Noort et al. 2021). Evolutionary information has been used for the prediction of PPIs based on the idea that mutations of the residues involved in the interaction on a protein engender mutations of the interface residues on the partner protein (Jothi et al. 2006). The InterEvDock docking pipeline integrates a coarse-grained potential accounting for interface coevolution

based on multiple sequence alignments (MSAs) of paired proteins (Yu et al. 2016). For many targets in recent CAPRI experiments, this method predicted several high-quality models (Lensink et al. 2020).

Professor Nakamura and his colleagues, including one of the authors of the present review (Y.T.), participated in CAPRI about 10 years ago (Fleishman et al. 2011; Moretti et al. 2013; Lensink et al. 2014). For each CAPRI experiment target, the docking of two component (mainly unbound) protein structures was performed to generate many complex models, and the position and relative geometry of the predicted interfaces were evaluated based on the scoring function. We constructed docking methods with and without evolutional tracing using conservation information, where the conservation information contributed to model selections particularly for the targets of enzyme and signal transduction proteins (Kanamori et al. 2007).

Recently, data of low-resolution shapes obtained by small-angle scattering methods such as SAXS, were also used for the filtering of docked models in several docking methods (van Noort et al. 2021), e.g., pyDockSAXS (Jiménez-García et al. 2015) and HADDOCK (van Zundert et al. 2015).

Scoring models

After sampling complex models, the most "appropriate" model(s) must usually be selected using some method such as scoring function, clustering, or consensus (Lensink and Wodak 2010). In CAPRI, the "scorer" performance is measured and reported as part of the competition (Lensink and Wodak 2010). Predicted models for each target were pooled and provided for the scoring experiment. Based on the idea that the accumulation of complementary interactions on local (residue or atomic level) surface regions forms the PPI between two proteins and strengthens their interaction, we specifically examined the complementarities of physicochemical properties such as electrostatic potential and hydrophobicity, and shapes of the surfaces to assess PPIs on the molecular surfaces of proteins (Tsuchiya et al. 2006a, b).

Machine-learning (ML) and AI-based scoring methods have been developed in the past few years (Lensink et al. 2020). The ML-based iScore is a linearly combined score of GraphRank with HADDOCK energetic terms (Geng et al. 2020). The GraphRank score is based on a support vector machine (SVM) classification between the interface graphs of native and non-native protein–protein interfaces, where the graph consists of nodes (interface residues with evolutionary conservation scores) and edges (their contacts) (Geng et al. 2020). The iScore separated native from non-native interfaces much better than the case of individual usage of the GraphRank or HADDOCK score, when the GraphRank contribution is higher than the energetic terms. Das et al. also developed an SVM classification-based scoring scheme by particularly addressing differences between native and non-native protein–protein interface features such as binding energy (ΔG), frequencies of hydrogen bonds and salt-bridges, and accessible and buried surface areas (Das and Chakrabarti 2021). Their findings demonstrated the accessible surface area as the most distinguishable feature. In native interfaces, the buried surface areas of Phe, Tyr, and Ile are markedly high whereas that of Lys is low, and hydrogen bonds in Arg with Asp or Glu are more important (Das and Chakrabarti 2021). Scoring based on these features led to higher accuracy than that provided by PatchDock scores (Schneidman-Duhovny et al. 2005). Additionally, we have developed the Protein Interface Analysis using COvarying signals (PIACO 2019), a method for identifying biological interfaces in protein crystal structures. PIACO is a statistical classifier that uses covariation calculated from MSAs as input (Fukasawa and Tomii 2019).

Another recently developed AI-based scoring method, known as DOVE, is based on the use of three-dimensional (3D) convolutional neural networks (Wang et al. 2020). It first maps the inputted decoy structures into a 3D grid, then scans and examines the protein–protein interfaces in terms of inter-atom interaction patterns and their energetic contributions. Finally, DOVE judges whether the decoy structure is close to the native structure, or not.

Hot spots

In PPI prediction, a hot spot is a prominent feature that allows one to distinguish between native and non-native interface models (DeLano 2002). Typically, a hot spot is a small set of residues that contribute greatly to PPI formation (Thorn and Bogan 2001). From the converse perspective, blocking hot spot residues might engender the disruption of the PPIs (Lu et al. 2020). Hot spots are fundamentally identified based on changes in binding free energy (ΔΔG) obtained by alanine scanning mutagenesis, whereas computational methods of the accurate predictions of hot spots have also been developed (Ovek et al. 2022). Ovek et al. introduce two interesting examples in their recent review (Ovek et al. 2022): disease-causing single mutations are likely to occur on hot spots (Ozdemir et al. 2018) and disease-causing PPI can be disrupted by a small molecule that binds to the target hot spots on the PPI (Lim et al. 2019). These findings suggest that hot spot information might contribute to the discovery of drugs that disrupt the disease-causing PPI (Ovek et al. 2022).

When we participated in the CAPRI experiment, several groups tried to predict hot spots to select near native models. Of those, Fernandez-Recio's group predicted hot spots using the normalized interface propensity values derived

from rigid-body docking, with electrostatics and desolvation scoring, which required no structural information of protein–protein complexes (Grosdidier and Fernández-Recio 2008). The same group recently constructed a method to detect protein–protein inhibitor (small molecule) binding sites by integrating molecular dynamics simulations for the generation of transient cavities on the interface with hot-spot predictions (Rosell and Fernández-Recio 2020). It generated and selected the transient cavities that were similar to known inhibitor binding sites (Rosell and Fernández-Recio 2020).

Template-based method

As we mentioned, protein–protein docking has been centrally important to PPI prediction. However, along with the increase of solved complex structures, it has been found to be more helpful to use them as templates for PPI prediction. As mentioned earlier (Lensink et al. 2020), found that the use of solved complex structures as templates is particularly appropriate for homo PPI prediction because of the abundance of such homo PPI structures within the PDB.

As an example, we introduce work from our own group in which we have developed a profile–profile comparison method: Fold Recognition TEchnique (FORTE) (Tomii and Akiyama 2004). The method was developed originally for predicting protein structures. We recognized that detecting and using complex templates is effective for PPI prediction (even for hetero PPI in some cases) through participation in past CAPRI-CASP assembly prediction experiments (Lensink et al. 2016, 2018; Nakamura et al. 2018). We also found that FORTE is helpful for selecting an appropriate form of the protein complex, even for cases with multiple forms of complexes observed among homologous proteins of a target (Nakamura et al. 2018). Indeed, as we mentioned below, most of AI-based approaches which utilize information of templates are powerful for PPI, except in the case of antibody–antigen interaction prediction (Ambrosetti et al. 2020).

As a general rule, the prediction capability for generating accurate target structures depends on the existence of available templates in the PDB (Lafita et al. 2018). In CAPRI-CASP12, according to the assessors' definition, there were three levels of difficulty for estimating target complexes—EASY, MEDIUM, and HARD. We showed that template-based models based on profile–profile comparison methods are useful for predicting protein complexes, even for MEDIUM/HARD targets (Nakamura et al. 2018; Lafita et al. 2018; Lensink et al. 2018). This finding implies that PPIs also tend to be conserved and/or limited for many cases, although it is considered that complex structures are often not conserved during evolution (Poupon and Janin 2010).

Earlier attempts of application of AlphaFold2 to PPI prediction

When the great achievement of AlphaFold2 (AF2) for the modeling of monomeric structures of protein in CASP14 was announced, it was assumed that AF2 would be useful for the modeling of protein–protein complexes, even though it was originally trained on individual protein chains (Jumper et al. 2021). RoseTTaFold, the first attempt to replicate AF2 before the release of the AF2 codes, confirmed that deep neural network model trained for monomer structure prediction can predict protein–protein complex models with some degree of accuracy (Baek et al. 2021). They used the pseudo-multimer sequence, two or more sequences with a gap separating them, (and templates) as input instead of a monomer sequence. AF2 and RoseTTaFold have since been used for predicting PPIs in proteomes of human (Burke et al. 2022) and yeast (Humphreys et al. 2021).

Similar tricks to that developed in RoseTTaFold were also applied for AF2, such as AF2-Gap (in ColabFold (Mirdita et al. 2022)) and AF2-Linker (Moriwaki 2021; Evans et al. 2021). Other groups applied similar protocols for protein–peptide docking (Ko and Lee 2021; Lei et al. 2021; Tsaban et al. 2022). All of these used the pseudo-multimer sequence linking the peptide to the protein via poly-glycine as input. The protocol that was tested for the benchmark set shows higher performance than the previous state-of-the-art method (Tsaban et al. 2022). FoldDock, another sophisticated AF2-based multimer prediction method using a paired MSA, was developed and tested for a large benchmark set of heterodimers (Bryant et al. 2022a). These results underscore the superiority of AF2-based methods to other docking methods. Although the method described above is powerful for dimers (or trimer, perhaps), they might have limitations because of the difficulty in preparing good MSAs of larger complexes as their input. In contrast, MolPC is an ambitious attempt for using AF2 to build a larger complex (more than 10 chains) combining the predicted subcomponents using Monte Carlo tree search (Bryant et al. 2022b). The AF2Complex uses the MSAs of each chain by padding the gaps and templates as inputs and by generating complex models by the AF2 deep learning model after multiple recycling steps (Gao et al. 2022).

A combination of AF2 and an existing docking method was also tested (Ghani et al. 2021). The AF2-ClusPro method was adopted for the protein–protein docking benchmark 5.0 (BM5) (Vreven et al. 2015). Then we selected 17 heteromers which appeared in the PDB after May 2020 (the last date of structures utilized in the AF2 training set). The systematic benchmark of 152 diverse

heterodimers from BM5.5 data set (Vreven et al. 2015; Guest et al. 2021) was expanded by adding more antibody–antigen cases to BM5, with results revealing a significant ability of AF2-based methods for all categories of modeling of complexes (except for modeling of antibody–antigen complexes) (Yin et al. 2022), approaches represented early attempts for AF2-based multimer prediction done mainly during the period between the release of the original AF2 (ver. 2.0.0) and that of the specifically trained AF2 for multimer prediction (ver. 2.1.0).

Multimetric version of AF2 and recent attempts to go beyond AF2

The multimeric version of AF2, AF2-Multimer, appeared recently (Evans et al. 2021). Benchmarking results obtained for the selected 17 heteromer and a large data set composed of recently released 4433 complexes was compared with AF2-Gap, AF2-linker and AF2-ClusPro, and it showed improvement in multimer prediction accuracy compared with those input-adjustment AF2-based multimer predictions. It was also demonstrated that the performance is generally higher for homomeric prediction than for heteromeric prediction, and that it is poor for prediction of the antibody–antigen complex. The latter result was also clarified by the benchmark of another group (Yin et al. 2022).

More recently, two avenues of approaches were used to go beyond the AF2 and AF2-Multimer which involved the development of replication of AF2 with a larger training dataset and development of the predictor using the protein language model (pLM) instead of MSA. Among the follow-up replicative studies of AF2, such as OpenFold (Ahdritz et al. 2022), Uni-Fold (Li et al. 2022a, b), MegaFold (Liu et al. 2022), and HelixFold (Wang et al. 2022), it was only Uni-Fold and Uni-Fold-symmetry (Li et al. 2022b) that could succeed not only in monomer prediction but also in multimer prediction upon using the original trained parameters or protocols. No third-party group has yet published a large benchmark result. Actually, pLM-based predictors such as OmegaFold (Wu et al. 2022), ESMFold (Lin et al. 2022), and IgFold (Ruffolo et al. 2022) are anticipated as the next breakthroughs in structure prediction because they omit the construction of MSA, which is crucially important for performance, and which is the most time-consuming part of AF2. In spite of these expectations, no MSA-free method has achieved performance equal to that of AF2, with no explicit implementation of multimer modeling with the exception that IgFold was built specifically for antibody modeling.

Although no explicit implementation of multimer treatment in OmegaFold has been described, it is relatively straightforward to use pseudo-multiple sequence inputs as an AF2-linker which we designate as OmegaFold-linker. Figure 1 presents multimer modeling results in terms of the DockQ score (Basu and Wallner 2016) using methods developed post AF2 such as OmegaFold-linker, AF2-Multimer (v2.1.1) with parameters released on Nov. 2021, and AF2-Multimer (v.2.2.0) with parameters released on Mar. 2022. In the construction of Fig. 1, AF2 was run with "max_template_date = 2020–10–01". The targets are taken from those of CASP14 (not included in the training set of AF2 and AF2-multimer, but two of these structures (PDB IDs: 6N64 and 6YA2) of them are released before 2020–10–01). They are all dimers, and the target IDs are T1032 (PDB ID: 6N64), T1038 (PDB ID: 6YA2), T1054 (PDB ID: 6V4V), T1078 (PDB ID: 7CWP), H1045 (PDB ID: 6XOD), and H1065 (PDB ID: 7M5F). For OmegaFold-linker, due to the memory-limitation, T1032 with more than 500 residues

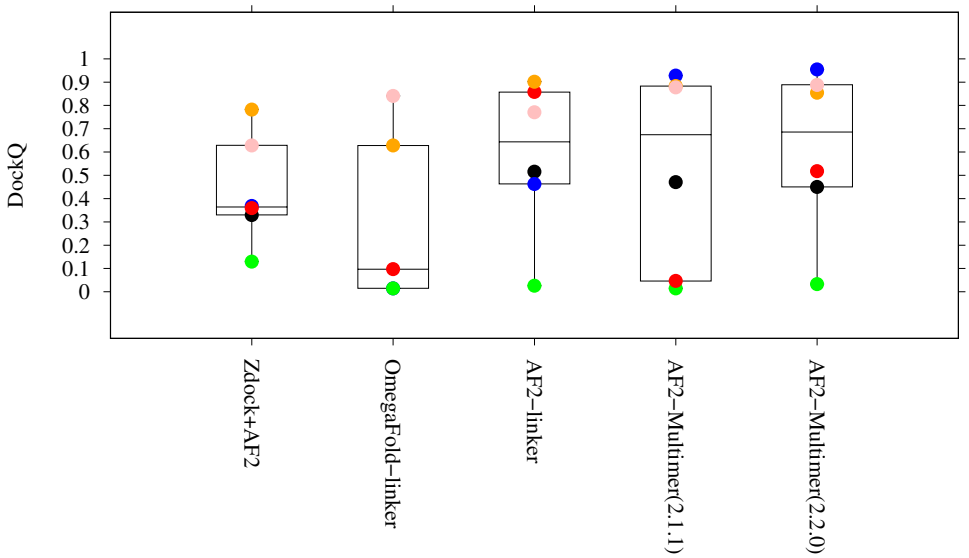

Fig. 1 Distributions of DockQ scores as boxplots for different modeling methods: ZDOCK with AF2 models, OmegaFold-linker, AF2-linker, AF2-Multimer (v.2.1.1), and AF2-Multimer (v2.2.0). Six targets (T1032 (shown in black dot), T1038 (blue), T1054 (green), T1078 (red), H1045 (orange), and H1065 (pink)) are taken from CASP14 (see text). For the case of OmegaFold-linker, T1032 was omitted because its amino acid length is beyond the limitation of OmegaFold

was omitted. For Omega-linker and AF2-linker, the input sequences were connected via 21 length poly-GLY-GLY-SER linker according to the previous research (Evans et al. 2021). For comparison, DockQ scores of docking structures calculated using ZDOCK (Pierce et al. 2014) are also shown. As the initial monomer structures of ZDOCK, the same models predicted by AF2-Multimer (v.2.2.0) were used. Basically, the prediction difficulty depends on targets. For instance, all methods except ZDOCK show 0.77 or more for H1065, while all methods show DockQ < 0.04 for T1054. These trends, except for T1038 (6YA2) whose structure was released before 2020–10–01, are generally similar to those observed in CASP14. Although, this may imply that the prediction difficulty of PPI depends on the availability of "good" templates, the results accord with those reported from benchmark research (Evans et al. 2021; Bryant et al. 2022a): AF2-Multimer shows the highest performance, and AF2-based methods using parameters trained for monomers are still comparable in some cases.

Antibody–antigen interaction

The prediction of PPI between antibody and antigen proteins is not an easy task because of the flexibility of the antibody's hypervariable loops, particularly the complementary determining loop 3 in the heavy chain (CDR-H3 loop). Four high-precision docking software suites ClusPro (Brenke et al. 2012), LightDock (Jiménez-García et al. 2018), ZDOCK (Pierce et al. 2014), and HADDOCK (van Zundert et al. 2015) were used to examine which structural information contributes to the accuracy of the model building of an antibody–antigen complex, such as the structural information of CDR loops, paratope (antigen-binding residues on an antibody CDR), antigen surface, and epitope (antibody-binding residues on an antigen) (Ambrosetti et al. 2020). The findings showed for all docking methods that the overall performance decreased without epitope information. They were improved by consideration of the low-resolution epitope information. Accurate modeling of the structure of the long CDR-H3 loop remains challenging. However, the flexible refinement of HADDOCK led to the improvement of the prediction accuracy of CDR-H3 loop conformations if the epitope information was available, even though the resolution of the information is low (Ambrosetti et al. 2020).

The AI-based prediction of antibody–antigen interfaces has been developed as PECAN (Pittala and Bailey-Kellogg 2020). Here, antibody and antigen structures are presented as the respective graphs. They are input to the neural network that consists of graph convolution, attention, and fully connected layers. The network discriminates antibody and antigen residues between interface and non-interface residues. The predictive accuracies of PECAN achieved when using the datasets provided with epitope (Krawczyk et al. 2014), and paratope prediction methods (Daberdaku and Ferrari 2019) were found to have higher precision and recall rates than these providers' methods. It is noteworthy that the providers' methods also predict epitope and paratope regions with high accuracies. Epitope prediction, using the program EpiPred, predicts epitopes based on geometric fitting and knowledge-based asymmetric antibody–antigen scoring (Krawczyk et al. 2014). The paratope prediction method uses a SVM classifier to distinguish interface surface patches from non-interface ones based on 3D Zernike descriptors that represent global and local protein surface shapes and physicochemical properties on the surfaces (Daberdaku and Ferrari 2019). Again, note that even recent AI-based approaches, such as AF2-Multimer, suffer from an inability to predict accurate antibody-antigen complex structures (as mentioned above).

To obtain information about antibody-specific epitopes, some improvements in the accuracy of docking and affinity predictions must be achieved. For this purpose, a large and non-redundant benchmark set for antibody–antigen docking and affinity prediction was constructed. It includes camelid nanobodies, therapeutic monoclonal antibodies, and broadly neutralizing antibodies that target viral glycoproteins (Guest et al. 2021).

Another possible approach is the search of similar regions on proteins to known antibody-binding epitopes. This approach is based on the fact that some antibodies can cross-reactively recognize different antigen proteins having similar surface regions in the structures and properties (Vieths et al. 2006; Negi and Braun 2017). Information about cross-reactivity might provide information about the repurposing of antibody drugs. We are striving to develop a database of known and putative epitopes on proteins (PoSSuMAg 2022), which has a similar scheme to that of the PoSSuM database (PoSSuM 2021), which is helpful to detect putative pockets that are similar to known ligand-binding sites on protein structures (Tabei et al. 2010; Ito et al. 2012b, a, 2015). Our new database presents information about putative epitopes that are similar to known epitopes on the antigen proteins in complex with antibodies, including antibody drugs. Information about known and putative epitopes on SARS-CoV-2 proteins will also be available. Although the current version includes information of putative epitopes on non-redundant protein structures, we expect to increase the data through future studies.

Concluding remarks

Here we have introduced and discussed a diverse range of computational methods, from docking-based to AI-based approaches, for PPI prediction. Along with the increase in

the amount of information related to protein sequences and structures, AI-based approaches, especially those based on evolutionary information and templates, are expected to become more powerful and useful. Yet, prediction of hetero PPIs leaves room for improvement. Particularly, antibody–antigen interaction predictions remain very limited in terms of their accuracy, although many sophisticated prediction methods have been developed (Ambrosetti et al. 2020).

Acknowledgements We thank the organizers of the issue for extending this opportunity to us.

Author contribution YT, YY, and KT contributed to the design of the study and wrote the manuscript. PPI predictions in this study were performed by YY. All authors read and approved the final manuscript.

Funding The study was supported by Platform Project for Supporting Drug Discovery and Life Science Research (Basis for Supporting Innovative Drug Discovery and Life Science Research (BINDS)) from AMED under Grant Number JP22ama121028.

Data Availability All the data associated with Fig. 1 are available from our figshare repository (Yamamori et al. 2022).

D.12 Machine learning

Further explanations for Chapter 12.

D.12.1 Basics

- Chicco (2017) — Practical advice on the whole workflow, from data preparation and splitting to hyperparameter tuning, imbalanced classes and the choice of evaluation metric. A short and accessible complement to the section on generalisation, overfitting and evaluation. *(tutorial; CC BY 4.0)*

  Ten quick tips for machine learning in computational biology. Chicco (2017). *BioData Mining*. doi:10.1186/s13040-017-0155-3

  > Machine learning has become a pivotal tool for many projects in computational biology, bioinformatics, and health informatics. Nevertheless, beginners and biomedical researchers often do not have enough experience to run a data mining project effectively, and therefore can follow incorrect practices, that may lead to common mistakes or over-optimistic results. With this review, we present ten quick tips to take advantage of machine learning in any computational biology context, by avoiding some common errors that we observed hundreds of times in multiple bioinformatics projects. We believe our ten suggestions can strongly help any machine learning practitioner to carry on a successful project in computational biology and related sciences.

- Miller et al. (2024) — Overviews evaluation metrics for clustering, classification and regression, their advantages and disadvantages, and common pitfalls in model evaluation, with examples from genomics. Useful for the evaluation subsection. *(review; CC BY 4.0)*

  A review of model evaluation metrics for machine learning in genetics and genomics. Miller et al. (2024). *Frontiers in Bioinformatics*. doi:10.3389/fbinf.2024.1457619

  > Machine learning (ML) has shown great promise in genetics and genomics where large and complex datasets have the potential to provide insight into many aspects of disease risk, pathogenesis of genetic disorders, and prediction of health and wellbeing. However, with this possibility there is a responsibility to exercise caution against biases and inflation of results that can have harmful unintended impacts. Therefore, researchers must understand the metrics used to evaluate ML models which can influence the critical interpretation of results. In this review we provide an overview of ML metrics for clustering, classification, and regression and highlight the advantages and disadvantages of each. We also detail common pitfalls that occur during model evaluation. Finally, we provide examples of how researchers can assess and utilise the results of ML models, specifically from a genomics perspective.

D.12.2 A short history of machine learning in bioinformatics

- Ben-Hur et al. (2008) — A tutorial introduction to support vector machines and kernels, including kernels for biological sequences, written for computational biologists. It explains the margin, soft margins and model selection clearly. *(tutorial; CC BY 4.0)*

  Support Vector Machines and Kernels for Computational Biology. Ben-Hur et al. (2008). *PLoS Computational Biology*. doi:10.1371/journal.pcbi.1000173

- Yoon (2009) — Introduces hidden Markov models, the Viterbi, forward and Baum–Welch algorithms, and profile HMMs, with applications in sequence analysis. Gives more detail than the section on how HMMs are decoded and trained. *(review; CC BY (Europe PMC))*

  Hidden Markov Models and their Applications in Biological Sequence Analysis. Yoon (2009). *Current Genomics*. doi:10.2174/138920209789177575

> Hidden Markov models (HMMs) have been extensively used in biological sequence analysis. In this paper, we give a tutorial review of HMMs and their applications in a variety of problems in molecular biology. We especially focus on three types of HMMs: the profile-HMMs, pair-HMMs, and context-sensitive HMMs. We show how these HMMs can be used to solve various sequence analysis problems, such as pairwise and multiple sequence alignments, gene annotation, classification, similarity search, and many others.

- Touw et al. (2012) — Describes how random forests work and how they are used in the life sciences, including variable importance measures and their pitfalls. Licence is non-commercial, so it is suitable only as a link. *(review; CC BY-NC (link only))*

  Data mining in the Life Sciences with Random Forest: a walk in the park or lost in the jungle?. Touw et al. (2012). *Briefings in Bioinformatics*. doi:10.1093/bib/bbs034

  > In the Life Sciences 'omics' data is increasingly generated by different high-throughput technologies. Often only the integration of these data allows uncovering biological insights that can be experimentally validated or mechanistically modelled, i.e. sophisticated computational approaches are required to extract the complex non-linear trends present in omics data. Classification techniques allow training a model based on variables (e.g. SNPs in genetic association studies) to separate different classes (e.g. healthy subjects versus patients). Random Forest (RF) is a versatile classification algorithm suited for the analysis of these large data sets. In the Life Sciences, RF is popular because RF classification models have a high-prediction accuracy and provide information on importance of variables for classification. For omics data, variables or conditional relations between variables are typically important for a subset of samples of the same class. For example: within a class of cancer patients certain SNP combinations may be important for a subset of patients that have a specific subtype of cancer, but not important for a different subset of patients. These conditional relationships can in principle be uncovered from the data with RF as these are implicitly taken into account by the algorithm during the creation of the classification model. This review details some of the to the best of our knowledge rarely or never used RF properties that allow maximizing the biological insights that can be extracted from complex omics data sets using RF.

D.12.3 Deep learning

- Angermueller et al. (2016) — An introduction to deep neural networks for biologists, covering training, regularisation, convolutional networks and applications in regulatory genomics and imaging, with practical recommendations. Predates transformers and language models. *(review; CC BY 4.0)*

  Deep learning for computational biology. Angermueller et al. (2016). *Molecular Systems Biology*. doi:10.15252/msb.20156651

  > Technological advances in genomics and imaging have led to an explosion of molecular and cellular profiling data from large numbers of samples. This rapid increase in biological data dimension and acquisition rate is challenging conventional analysis strategies. Modern machine learning methods, such as deep learning, promise to leverage very large data sets for finding hidden structure within them, and for making accurate predictions. In this review, we discuss applications of this new breed of analysis approaches in regulatory genomics and cellular imaging. We provide background of what deep learning is, and the settings in which it can be successfully applied to derive biological insights. In addition to presenting specific applications and providing tips for practical use, we also highlight possible pitfalls and limitations to guide computational biologists when and how to make the most use of this new technology.

- Lee et al. (2022) — Short, practical guidance on when deep learning is appropriate, comparing with simple baselines, avoiding overfitting and leakage, and interpreting and sharing models. Complements the subsections on training and on interpretability and reporting. *(tutorial; CC BY 4.0)*

  Ten quick tips for deep learning in biology. Lee et al. (2022). *PLOS Computational Biology*. doi:10.1371/journal.pcbi.1009803

- Zhang et al. (2023) — Explains the transformer architecture and self-supervised pre-training, and surveys their use for protein, DNA and RNA sequences and other biological data. Relevant to the subsection on language models for proteins and DNA. *(review; CC BY 4.0)*

  Applications of transformer-based language models in bioinformatics: a survey. Zhang et al. (2023). *Bioinformatics Advances*. doi:10.1093/bioadv/vbad001

  > The transformer-based language models, including vanilla transformer, BERT and GPT-3, have achieved revolutionary breakthroughs in the field of natural language processing (NLP). Since there are inherent similarities between various biological sequences and natural languages, the remarkable interpretability and adaptability of these models have prompted a new wave of their application in bioinformatics research. To provide a timely and comprehensive review, we introduce key developments of transformer-based language models by describing the detailed structure of transformers and summarize their contribution to a wide range of bioinformatics research from basic sequence analysis to drug discovery. While transformer-based applications in bioinformatics are diverse and multifaceted, we identify and discuss the common challenges, including heterogeneity of training data, computational expense and model interpretability, and opportunities in the context of bioinformatics research. We hope that the broader community of NLP researchers, bioinformaticians and biologists will be brought together to foster future research and development in transformer-based language models, and inspire novel bioinformatics applications that are unattainable by traditional methods. Supplementary information Supplementary data are available at Bioinformatics Advances online.

D.12.4 Generative models

- Lopez et al. (2020) — Explains the principles of deep generative models, in particular variational autoencoders and GANs, and how they are used for single-cell data, sequences and images. Predates the use of diffusion models in biology. *(review; CC BY 4.0)*

  Enhancing scientific discoveries in molecular biology with deep generative models. Lopez et al. (2020). *Molecular Systems Biology*. doi:10.15252/msb.20199198

  > Generative models provide a well-established statistical framework for evaluating uncertainty and deriving conclusions from large data sets especially in the presence of noise, sparsity, and bias. Initially developed for computer vision and natural language processing, these models have been shown to effectively summarize the complexity that underlies many types of data and enable a range of applications including supervised learning tasks, such as assigning labels to images; unsupervised learning tasks, such as dimensionality reduction; and out-of-sample generation, such as de novo image synthesis. With this early success, the power of generative models is now being increasingly leveraged in molecular biology, with applications ranging from designing new molecules with properties of interest to identifying deleterious mutations in our genomes and to dissecting transcriptional variability between single cells. In this review, we provide a brief overview of the technical notions behind generative models and their implementation with deep learning techniques. We then describe several different ways in which these models can be utilized in practice, using several recent applications in molecular biology as examples.

- Strokach and Kim (2022) — A concise review of deep generative models of protein sequences and structures and how they are used, together with predictive models, to propose and select new protein designs. *(review; CC BY 4.0)*

  Deep generative modeling for protein design. Strokach & Kim (2022). *Current Opinion in Structural Biology*. doi:10.1016/j.sbi.2021.11.008

  > Deep learning approaches have produced substantial breakthroughs in fields such as image classification and natural language processing and are making rapid inroads in the area of protein design. Many generative models of proteins have been developed that encompass all known protein sequences, model specific protein families, or extrapolate the dynamics of individual proteins. Those generative models can learn protein representations that are often more informative of protein structure and function than hand-engineered features. Furthermore, they can be used to quickly propose millions of novel proteins that resemble the native counterparts in terms of expression level, stability, or other attributes. The protein design process can further be guided by discriminative oracles to select candidates with the highest probability of having the desired properties. In this review, we discuss five classes of generative

models that have been most successful at modeling proteins and provide a framework for model guided protein design.

- Mardikoraem et al. (2023) — Describes the architecture and mathematics of self-supervised and generative models for protein sequences and their use in protein engineering and fitness prediction. *(review; CC BY 4.0)*

  Generative models for protein sequence modeling: recent advances and future directions. Mardikoraem et al. (2023). *Briefings in Bioinformatics*. doi:10.1093/bib/bbad358

  > The widespread adoption of high-throughput omics technologies has exponentially increased the amount of protein sequence data involved in many salient disease pathways and their respective therapeutics and diagnostics. Despite the availability of large-scale sequence data, the lack of experimental fitness annotations underpins the need for self-supervised and unsupervised machine learning (ML) methods. These techniques leverage the meaningful features encoded in abundant unlabeled sequences to accomplish complex protein engineering tasks. Proficiency in the rapidly evolving fields of protein engineering and generative AI is required to realize the full potential of ML models as a tool for protein fitness landscape navigation. Here, we support this work by (i) providing an overview of the architecture and mathematical details of the most successful ML models applicable to sequence data (e.g. variational autoencoders, autoregressive models, generative adversarial neural networks, and diffusion models), (ii) guiding how to effectively implement these models on protein sequence data to predict fitness or generate high-fitness sequences and (iii) highlighting several successful studies that implement these techniques in protein engineering (from paratope regions and subcellular localization prediction to high-fitness sequences and protein design rules generation). By providing a comprehensive survey of model details, novel architecture developments, comparisons of model applications, and current challenges, this study intends to provide structured guidance and robust framework for delivering a prospective outlook in the ML-driven protein engineering field.

D.12.5 Foundation models

- Li et al. (2024) — Reviews foundation models for sequences, structures and omics data, how they are pre-trained and adapted to downstream tasks, and their current limitations. *(review; CC BY 4.0)*

  Progress and opportunities of foundation models in bioinformatics. Li et al. (2024). *Briefings in Bioinformatics*. doi:10.1093/bib/bbae548

  > Bioinformatics has undergone a paradigm shift in artificial intelligence (AI), particularly through foundation models (FMs), which address longstanding challenges in bioinformatics such as limited annotated data and data noise. These AI techniques have demonstrated remarkable efficacy across various downstream validation tasks, effectively representing diverse biological entities and heralding a new era in computational biology. The primary goal of this survey is to conduct a general investigation and summary of FMs in bioinformatics, tracing their evolutionary trajectory, current research landscape, and methodological frameworks. Our primary focus is on elucidating the application of FMs to specific biological problems, offering insights to guide the research community in choosing appropriate FMs for tasks like sequence analysis, structure prediction, and function annotation. Each section delves into the intricacies of the targeted challenges, contrasting the architectures and advancements of FMs with conventional methods and showcasing their utility across different biological domains. Further, this review scrutinizes the hurdles and constraints encountered by FMs in biology, including issues of data noise, model interpretability, and potential biases. This analysis provides a theoretical groundwork for understanding the circumstances under which certain FMs may exhibit suboptimal performance. Lastly, we outline prospective pathways and methodologies for the future development of FMs in biological research, facilitating ongoing innovation in the field. This comprehensive examination not only serves as an academic reference but also as a roadmap for forthcoming explorations and applications of FMs in biology.

- Guo et al. (2025) — A broad overview of language and foundation models for proteins, nucleic acids and single-cell data, with discussion of evaluation and open problems. *(review; CC BY 4.0)*

  Foundation models in bioinformatics. Guo et al. (2025). *National Science Review*. doi:10.1093/nsr/nwaf028

> With the adoption of foundation models (FMs), artificial intelligence (AI) has become increasingly significant in bioinformatics and has successfully addressed many historical challenges, such as pre-training frameworks, model evaluation and interpretability. FMs demonstrate notable proficiency in managing large-scale, unlabeled datasets, because experimental procedures are costly and labor intensive. In various downstream tasks, FMs have consistently achieved noteworthy results, demonstrating high levels of accuracy in representing biological entities. A new era in computational biology has been ushered in by the application of FMs, focusing on both general and specific biological issues. In this review, we introduce recent advancements in bioinformatics FMs employed in a variety of downstream tasks, including genomics, transcriptomics, proteomics, drug discovery and single-cell analysis. Our aim is to assist scientists in selecting appropriate FMs in bioinformatics, according to four model types: language FMs, vision FMs, graph FMs and multimodal FMs. In addition to understanding molecular landscapes, AI technology can establish the theoretical and practical foundation for continued innovation in molecular biology.

- Baek et al. (2025) — Explains how single-cell foundation models, typically transformers pre-trained on large collections of transcriptomes, are built and used, and discusses their current challenges. *(review; CC BY 4.0)*

  Single-cell foundation models: bringing artificial intelligence into cell biology. Baek et al. (2025). *Experimental & Molecular Medicine*. doi:10.1038/s12276-025-01547-5

  > A foundation model, a large-scale deep learning model pretrained on vast datasets, has revolutionized data interpretation through self-supervised learning with capacity for various downstream tasks. Concurrently, single-cell genomics is in urgent need of unified frameworks capable of integrating and comprehensively analyzing the rapidly expanding data repositories. Inspired by advances in foundation models, researchers have extended these techniques to single-cell analysis, giving rise to single-cell foundation models (scFMs). Typically, these models use transformer architectures to incorporate diverse omics data and extract latent patterns at both cell and gene/feature levels for the analysis of cellular heterogeneity and complex regulatory networks. Despite their promise, scFMs face challenges including the nonsequential nature of omics data, inconsistency in data quality and the computational intensity required for training and fine-tuning. Furthermore, interpreting the biological relevance of latent embeddings and model representations remains nontrivial. Here we provide an overview of scFMs, highlighting their key concepts and applications across downstream tasks. We critically assess the current limitations and propose future directions aimed at enhancing the robustness, interpretability and scalability of scFMs. Ultimately, addressing these challenges will be crucial for establishing scFMs as pivotal tools in advancing single-cell genomics and unlocking deeper insights into cellular function and disease mechanisms.

D.12.6 AI in research practice

- Smith et al. (2024) — Practical rules for using LLMs responsibly in research, including verifying output, protecting data, disclosure and reproducibility. Matches the risks listed in the section. *(tutorial; CC BY 4.0)*

  Ten simple rules for using large language models in science, version 1.0. Smith et al. (2024). *PLOS Computational Biology*. doi:10.1371/journal.pcbi.1011767

  > Box 1-An LLM suggests 10 simple rules governing its own usage in scienceHere, we ask ChatGPT to generate a list of 10 simple rules for using LLMs in science in order to illustrate its ability to provide detailed, human-like responses to short prompts.Q1: Can you provide me with a list of ten simple rules for using large language models in science?R1 (ChatGPT 3.5): Certainly!Here are ten simple rules for using large language models in science:1. Understand the limitations: Recognize that large language models like GPT-3 are powerful but not infallible.They may produce accurate-sounding information, but they can also generate false or biased content.Exercise caution and critical thinking.2. Validate and verify: Always cross-reference information generated by language models with reliable sources.Verify the accuracy of claims, check for

  Multi-Omics Factor Analysis—a framework for unsupervised integration of multi-omics data sets. Argelaguet et al. (2018). *Molecular Systems Biology*. doi:10.15252/msb.20178124

Multi-omics studies promise the improved characterization of biological processes across molecular layers. However, methods for the unsupervised integration of the resulting heterogeneous data sets are lacking. We present Multi-Omics Factor Analysis (MOFA), a computational method for discovering the principal sources of variation in multi-omics data sets. MOFA infers a set of (hidden) factors that capture biological and technical sources of variability. It disentangles axes of heterogeneity that are shared across multiple modalities and those specific to individual data modalities. The learnt factors enable a variety of downstream analyses, including identification of sample subgroups, data imputation and the detection of outlier samples. We applied MOFA to a cohort of 200 patient samples of chronic lymphocytic leukaemia, profiled for somatic mutations, RNA expression, DNA methylation and ex vivo drug responses. MOFA identified major dimensions of disease heterogeneity, including immunoglobulin heavy-chain variable region status, trisomy of chromosome 12 and previously underappreciated drivers, such as response to oxidative stress. In a second application, we used MOFA to analyse single-cell multi-omics data, identifying coordinated transcriptional and epigenetic changes along cell differentiation.

Deep learning for computational biology

Christof Angermueller[1,†], Tanel Pärnamaa[2,3,†], Leopold Parts[2,3,*] & Oliver Stegle[1,**]

Abstract

Technological advances in genomics and imaging have led to an explosion of molecular and cellular profiling data from large numbers of samples. This rapid increase in biological data dimension and acquisition rate is challenging conventional analysis strategies. Modern machine learning methods, such as deep learning, promise to leverage very large data sets for finding hidden structure within them, and for making accurate predictions. In this review, we discuss applications of this new breed of analysis approaches in regulatory genomics and cellular imaging. We provide background of what deep learning is, and the settings in which it can be successfully applied to derive biological insights. In addition to presenting specific applications and providing tips for practical use, we also highlight possible pitfalls and limitations to guide computational biologists when and how to make the most use of this new technology.

Introduction

Machine learning methods are general-purpose approaches to learn functional relationships from data without the need to define them *a priori* (Hastie *et al*, 2005; Murphy, 2012; Michalski *et al*, 2013). In computational biology, their appeal is the ability to derive predictive models without a need for strong assumptions about underlying mechanisms, which are frequently unknown or insufficiently defined. As a case in point, the most accurate prediction of gene expression levels is currently made from a broad set of epigenetic features using sparse linear models (Karlic *et al*, 2010; Cheng *et al*, 2011) or random forests (Li *et al*, 2015); how the selected features determine the transcript levels remains an active research topic. Predictions in genomics (Libbrecht & Noble, 2015; Märtens *et al*, 2016), proteomics (Swan *et al*, 2013), metabolomics (Kell, 2005) or sensitivity to compounds (Eduati *et al*, 2015) all rely on machine learning approaches as a key ingredient.

Most of these applications can be described within the canonical machine learning workflow, which involves four steps: data cleaning and pre-processing, feature extraction, model fitting and evaluation (Fig 1A). It is customary to denote one data sample, including all covariates and features as *input* x (usually a vector of numbers), and label it with its response variable or *output* value y (usually a single number) when available.

A supervised machine learning model aims to learn a function $f(x) = y$ from a list of training pairs (x_1,y_1), (x_2,y_2), ... for which data are recorded (Fig 1B). One typical application in biology is to predict the viability of a cancer cell line when exposed to a chosen drug (Menden *et al*, 2013; Eduati *et al*, 2015). The input features (x) would capture somatic sequence variants of the cell line, chemical make-up of the drug and its concentration, which together with the measured viability (output label y) can be used to train a support vector machine, a random forest classifier or a related method (functional relationship f). Given a new cell line (unlabelled data sample x^*) in the future, the learnt function predicts its survival (output label y^*) by calculating $f(x^*)$, even if f resembles more of a black box, and its inner workings of why particular mutation combinations influence cell growth are not easily interpreted. Both regression (where y is a real number) and classification (where y is a categorical class label) can be viewed in this way. As a counterpart, unsupervised machine learning approaches aim to discover patterns from the data samples x themselves, without the need for output labels y. Methods such as clustering, principal component analysis and outlier detection are typical examples of unsupervised models applied to biological data.

The inputs x, calculated from the raw data, represent what the model "sees about the world", and their choice is highly problem-specific (Fig 1C). Deriving most informative features is essential for performance, but the process can be labour-intensive and requires domain knowledge. This bottleneck is especially limiting for high-dimensional data; even computational feature selection methods do not scale to assess the utility of the vast number of possible input combinations. A major recent advance in machine learning is automating this critical step by learning a suitable representation of the data with *deep artificial neural networks* (Bengio *et al*, 2013; LeCun *et al*, 2015; Schmidhuber, 2015) (Fig 1D). Briefly, a deep neural network takes the raw data at the lowest (input) layer and transforms them into increasingly abstract feature representations by successively combining outputs from the preceding layer in a data-driven manner, encapsulating highly complicated functions in the

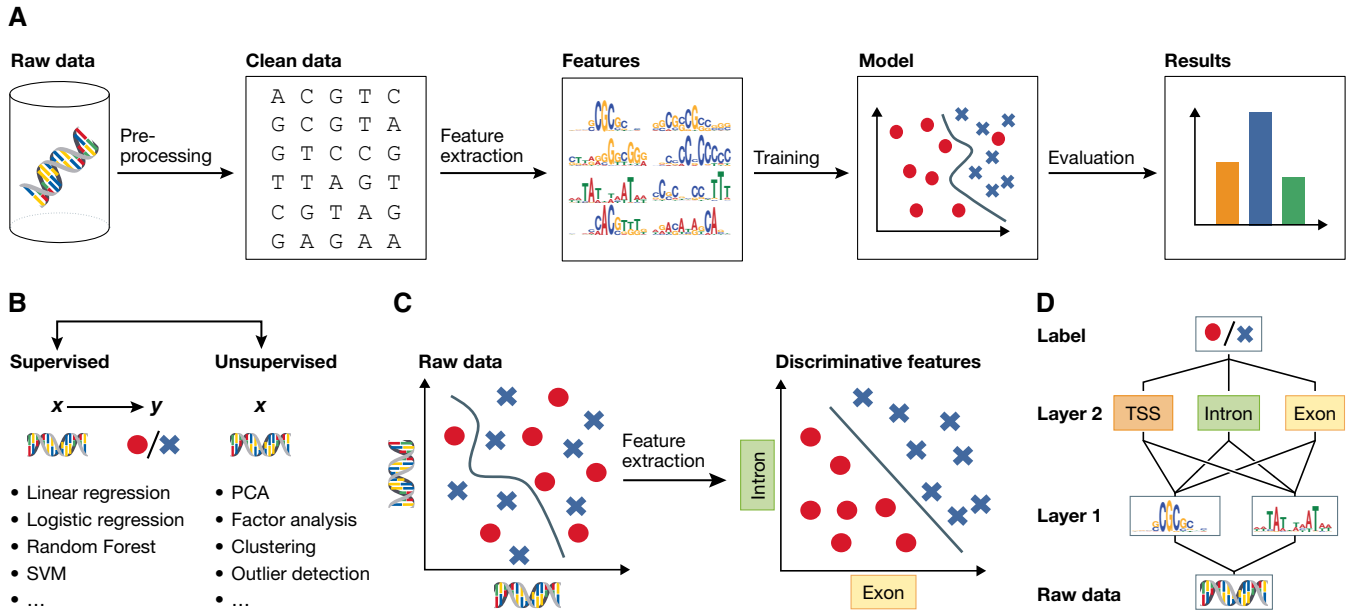

Figure 1. Machine learning and representation learning.
(A) The classical machine learning workflow can be broken down into four steps: data pre-processing, feature extraction, model learning and model evaluation. (B) Supervised machine learning methods relate input features *x* to an output label *y*, whereas unsupervised method learns factors about *x* without observed labels. (C) Raw input data are often high-dimensional and related to the corresponding label in a complicated way, which is challenging for many classical machine learning algorithms (left plot). Alternatively, higher-level features extracted using a deep model may be able to better discriminate between classes (right plot). (D) Deep networks use a hierarchical structure to learn increasingly abstract feature representations from the raw data.

process (Box 1). Deep learning is now one of the most active fields in machine learning and has been shown to improve performance in image and speech recognition (Hinton *et al*, 2012; Krizhevsky *et al*, 2012; Graves *et al*, 2013; Zeiler & Fergus, 2014; Deng & Togneri, 2015), natural language understanding (Bahdanau *et al*, 2014; Sutskever *et al*, 2014; Lipton, 2015; Xiong *et al*, 2016), and most recently, in computational biology (Eickholt & Cheng, 2013; Dahl *et al*, 2014; Leung *et al*, 2014; Sønderby & Winther, 2014; Alipanahi *et al*, 2015; Wang *et al*, 2015; Zhou & Troyanskaya, 2015; Kelley *et al*, 2016).

The potential of deep learning in high-throughput biology is clear: in principle, it allows to better exploit the availability of increasingly large and high-dimensional data sets (e.g. from DNA sequencing, RNA measurements, flow cytometry or automated microscopy) by training complex networks with multiple layers that capture their internal structure (Fig 1C and D). The learned networks discover high-level features, improve performance over traditional models, increase interpretability and provide additional understanding about the structure of the biological data.

In this review, we discuss recent and forthcoming applications of deep learning, with a focus on applications in regulatory genomics and biological image analysis. The goal of this review was not to provide comprehensive background on all technical details, which can be found in the more specialized literature (Bengio, 2012; Bengio *et al*, 2013; Deng, 2014; Schmidhuber, 2015; Goodfellow *et al*, 2016). Instead, we aimed to provide practical pointers and the necessary background to get started with deep architectures, review current software solutions and give recommendations for applying them to data. The applications we cover are deliberately broad to illustrate differences and commonalities between approaches; reviews focusing on specific domains can be found elsewhere (Park & Kellis, 2015; Gawehn *et al*, 2016; Leung *et al*, 2016; Mamoshina *et al*, 2016). Finally, we discuss both the potential and possible pitfalls of deep learning and contrast these methods to traditional machine learning and classical statistical analysis approaches.

Deep learning for regulatory genomics

Conventional approaches for regulatory genomics relate sequence variation to changes in molecular traits. One approach is to leverage variation between genetically diverse individuals to map quantitative trait loci (QTL). This principle has been applied to identify regulatory variants that affect gene expression levels (Montgomery *et al*, 2010; Pickrell *et al*, 2010), DNA methylation (Gibbs *et al*, 2010; Bell *et al*, 2011), histone marks (Grubert *et al*, 2015; Waszak *et al*, 2015) and proteome variation (Vincent *et al*, 2010; Albert *et al*, 2014; Parts *et al*, 2014; Battle *et al*, 2015) (Fig 2A). Better statistical methods have helped to increase the power to detect regulatory QTL (Kang *et al*, 2008; Stegle *et al*, 2010; Parts *et al*, 2011; Rakitsch & Stegle, 2016); however, any mapping approach is intrinsically limited to variation that is present in the training population. Thus, studying the effects of rare mutations in particular requires data sets with very large sample size.

An alternative is to train models that use variation between regions within a genome (Fig 2A). Splitting the sequence into windows centred on the trait of interest gives rise to tens of thousands of training examples for most molecular traits even when using a single individual. Even with large data sets, predicting molecular traits from DNA sequence is challenging due to multiple layers

Box 1: Artificial Neural Network

An artificial neural network, initially inspired by neural networks in the brain (McCulloch & Pitts, 1943; Farley & Clark, 1954; Rosenblatt, 1958), consists of layers of interconnected compute units (neurons). The depth of a neural network corresponds to the number of hidden layers, and the width to the maximum number of neurons in one of its layers. As it became possible to train networks with larger numbers of hidden layers, artificial neural networks were rebranded to "deep networks".

In the canonical configuration, the network receives data in an input layer, which are then transformed in a nonlinear way through multiple hidden layers, before final outputs are computed in the output layer (panel A). Neurons in a hidden or output layer are connected to all neurons of the previous layer. Each neuron computes a weighted sum of its inputs and applies a nonlinear activation function to calculate its output $f(x)$ (panel B). The most popular activation function is the rectified linear unit (ReLU; panel B) that thresholds negative signals to 0 and passes through positive signal. This type of activation function allows faster learning compared to alternatives (e.g. sigmoid or tanh unit) (Glorot *et al*, 2011).

The weights $w^{(i)}$ between neurons are free parameters that capture the model's representation of the data and are learned from input/output samples. Learning minimizes a loss function $L(w)$ that measures the fit of the model output to the true label of a sample (panel A, bottom). This minimization is challenging, since the loss function is high-dimensional and non-convex, similar to a landscape with many hills and valleys (panel C). It took several decades before the *backward propagation algorithm* was first applied to compute a loss function gradient via chain rule for derivatives (Rumelhart *et al*, 1988), ultimately enabling efficient training of neural networks using stochastic gradient descent. During learning, the predicted label is compared with the true label to compute a loss for the current set of model weights. The loss is then backward propagated through the network to compute the gradients of the loss function and update (panel A). The loss function $L(w)$ is typically optimized using gradient-based descent. In each step, the current weight vector (red dot) is moved along the direction of steepest descent dw (direction arrow) by learning rate η (length of vector). Decaying the learning rate over time allows to explore different domains of the loss function by jumping over valleys at the beginning of the training (left side) and fine-tune parameters with smaller learning rates in later stages of the model training. While learning in deep neural networks remains an active area of research, existing software packages (Table 1) can already be applied without knowledge of the mathematical details involved.

Alternative architectures to such fully connected feedforward networks have been developed for specific applications, which differ in the way neurons are arranged. These include convolutional neural networks, which are widely used for modelling images (Box 2), recurrent neural networks for sequential data (Sutskever, 2013; Lipton, 2015), or restricted Boltzmann machines (Salakhutdinov & Larochelle, 2010; Hinton, 2012) and autoencoders (Hinton & Salakhutdinov, 2006; Alain *et al*, 2012; Kingma & Welling, 2013) for unsupervised learning. The choice of network architecture and other parameters can be made in a data-driven and objective way by assessing the model performance on a validation data set.

of abstraction between the effect of individual DNA variants and the trait of interest, as well as the dependence of the molecular traits on a broad sequence context and interactions with distal regulatory elements.

The value of deep neural networks in this context is twofold. First, classical machine learning methods cannot operate on the sequence directly, and thus require pre-defining features that can be extracted from the sequence based on prior knowledge (e.g. the presence or absence of single-nucleotide variants (SNVs), k-mer frequencies, motif occurrences, conservation, known regulatory variants or structural elements). Deep neural networks can help circumventing the manual extraction of features by learning them from data. Second, because of their representational richness, they can capture nonlinear dependencies in the sequence and interaction effects and span wider sequence context at multiple genomic scales. Attesting to their utility, deep neural networks have been successfully applied to predict splicing activity (Leung *et al*, 2014; Xiong *et al*, 2015), specificities of DNA- and RNA-binding proteins

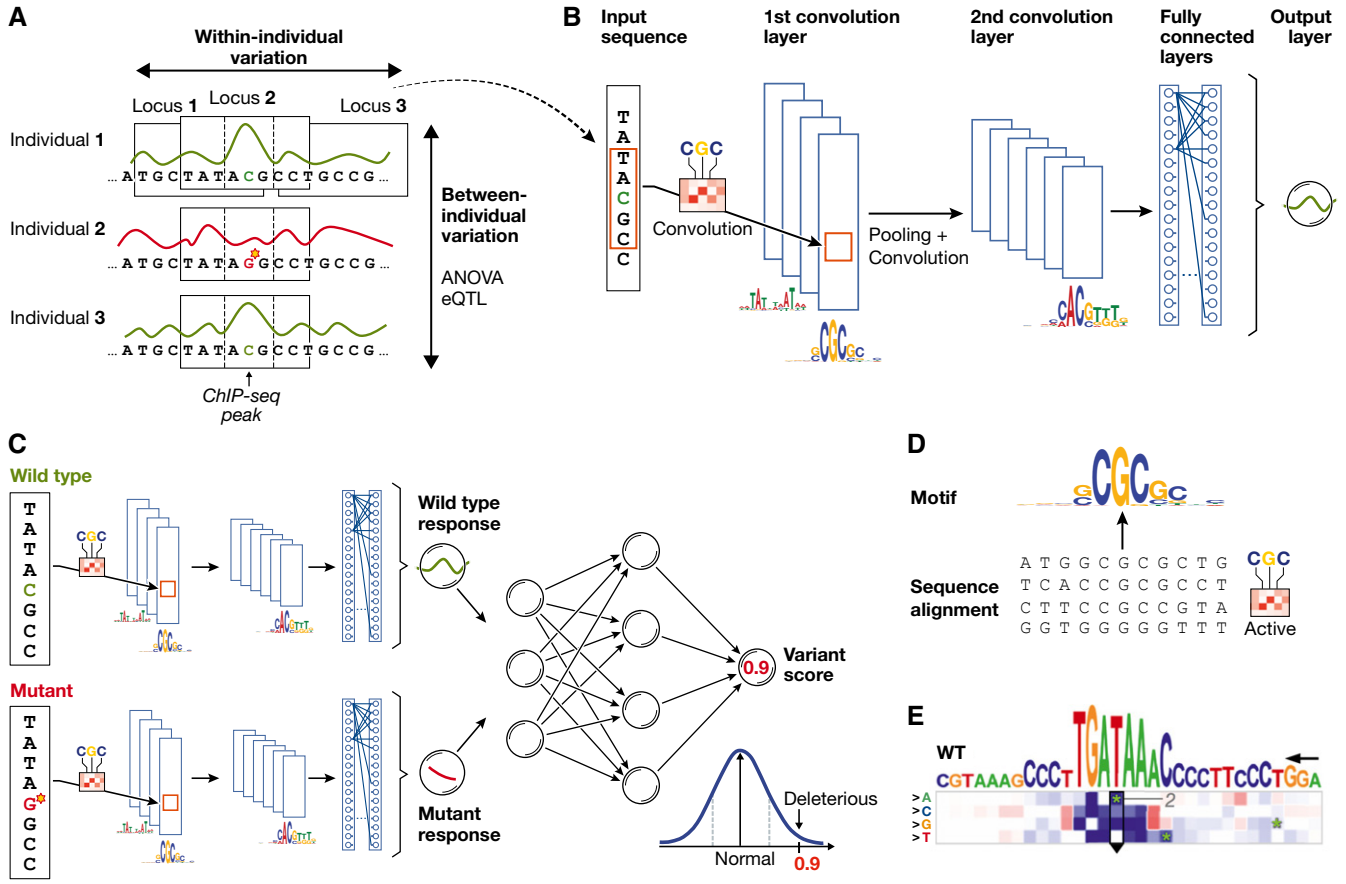

Figure 2. Principles of using neural networks for predicting molecular traits from DNA sequence.
(A) DNA sequence and the molecular response variable along the genome for three individuals. Conventional approaches in regulatory genomics consider variations between individuals, whereas deep learning allows exploiting intra-individual variations by tiling the genome into sequence DNA windows centred on individual traits, resulting in large training data sets from a single sample. (B) One-dimensional convolutional neural network for predicting a molecular trait from the raw DNA sequence in a window. Filters of the first convolutional layer (example shown on the edge) scan for motifs in the input sequence. Subsequent pooling reduces the input dimension, and additional convolutional layers can model interactions between motifs in the previous layer. (C) Response variable predicted by the neural network shown in (B) for a wild-type and mutant sequence is used as input to an additional neural network that predicts a variant score and allows to discriminate normal from deleterious variants. (D) Visualization of a convolutional filter by aligning genetic sequences that maximally activate the filter and creating a sequence motif. (E) Mutation map of a sequence window. Rows correspond to the four possible base pair substitutions, columns to sequence positions. The predicted impact of any sequence change is colour-coded. Letters on top denote the wild-type sequence with the height of each nucleotide denoting the maximum effect across mutations (figure panel adapted from Alipanahi *et al*, 2015).

(Alipanahi *et al*, 2015) or epigenetic marks and to study the effect of DNA sequence alterations (Zhou & Troyanskaya, 2015; Kelley *et al*, 2016).

Early applications of neural networks in regulatory genomics

The first successful applications of neural networks in regulatory genomics replaced a classical machine learning approach with a deep model, without changing the input features. For example, Xiong *et al* (2015) considered a fully connected feedforward neural network to predict the splicing activity of individual exons. The model was trained using more than 1,000 pre-defined features extracted from the candidate exon and adjacent introns. Despite the relatively low number of 10,700 training samples in combination with the model complexity, this method achieved substantially higher prediction accuracy of splicing activity compared to simpler approaches, and in particular was able to identify rare mutations implicated in splicing misregulation.

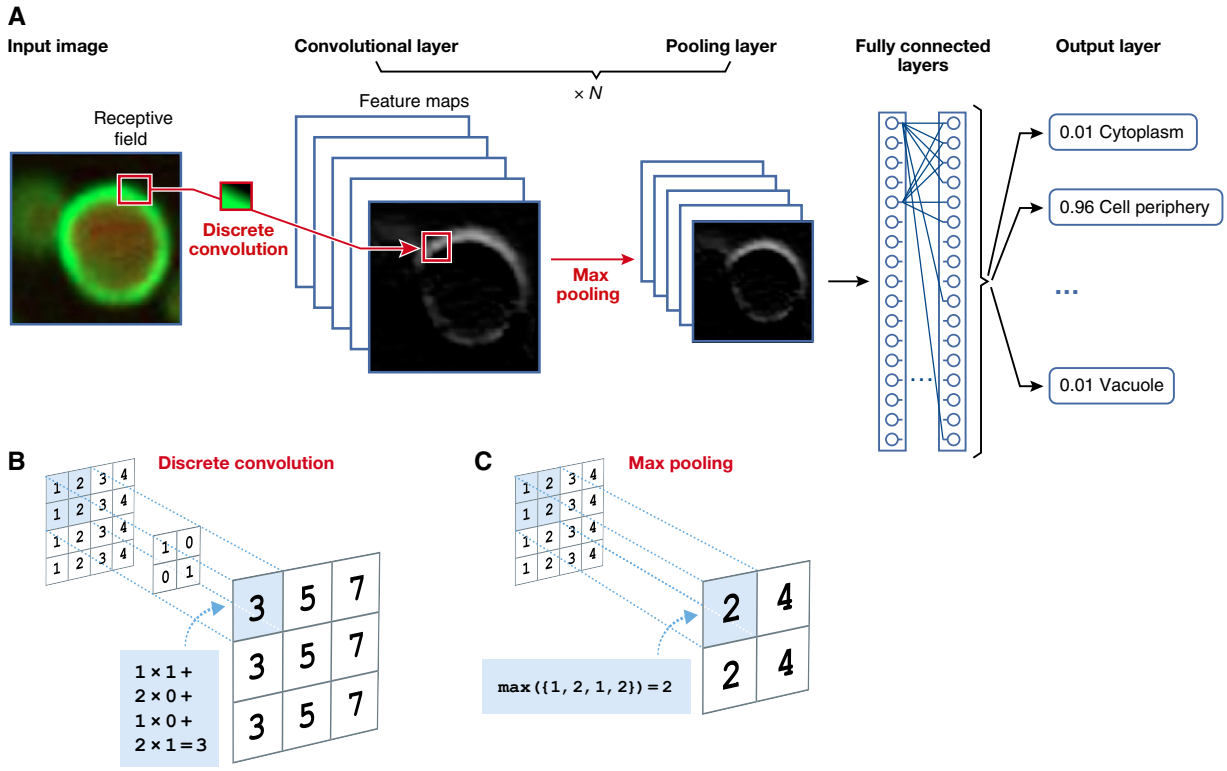
Convolutional designs

More recent work using convolutional neural networks (CNNs) allowed direct training on the DNA sequence, without the need to define features (Alipanahi *et al*, 2015; Zhou & Troyanskaya, 2015; Angermueller *et al*, 2016; Kelley *et al*, 2016). The CNN architecture allows to greatly reduce the number of model parameters compared to a fully connected network by applying convolutional operations to only small regions of the input space and by sharing parameters between regions. The key advantage resulting from this approach is the ability to directly train the model on larger sequence windows (Box 2; Fig 2B).

Alipanahi *et al* (2015) considered convolutional network architectures to predict specificities of DNA- and RNA-binding proteins.

 © 2016 The Authors

Box 2: Convolutional Neural Network



Convolutional neural networks (CNNs) were originally inspired by cognitive neuroscience and Hubel and Wiesel's seminal work on the cat's visual cortex, which was found to have simple neurons that respond to small motifs in the visual field, and complex neurons that respond to larger ones (Hubel & Wiesel, 1963, 1970).

CNNs are designed to model input data in the form of multidimensional arrays, such as two-dimensional images with three colour channels (LeCun *et al*, 1989; Jarrett *et al*, 2009; Krizhevsky *et al*, 2012; Zeiler & Fergus, 2014; He *et al*, 2015; Szegedy *et al*, 2015a) or one-dimensional genomic sequences with one channel per nucleotide (Alipanahi *et al*, 2015; Wang *et al*, 2015; Zhou & Troyanskaya, 2015; Angermueller *et al*, 2016; Kelley *et al*, 2016). The high dimensionality of these data (up to millions of pixels for high-resolution images) renders training a fully connected neural network challenging, as the number of parameters of such a model would typically exceed the number of training data to fit them. To circumvent this, CNNs make additional assumptions on the structure of the network, thereby reducing the effective number of parameters to learn.

A convolutional layer consists of multiple maps of neurons, so-called feature maps or filters, with their size being equal to the dimension of the input image (panel A). Two concepts allow reducing the number of model parameters: local connectivity and parameter sharing. First, unlike in a fully connected network, each neuron within a feature map is only connected to a local patch of neurons in the previous layer, the so-called receptive field. Second, all neurons within a given feature map share the same parameters. Hence, all neurons within a feature map scan for the same feature in the previous layer, however at different locations. Different feature maps might, for example, detect edges of different orientation in an image, or sequence motifs in a genomic sequence. The activity of a neuron is obtained by computing a discrete convolution of its receptive field, that is computing the weighted sum of input neurons, and applying an activation function (panel B).

In most applications, the exact position and frequency of features is irrelevant for the final prediction, such as recognizing objects in an image. Using this assumption, the pooling layer summarizes adjacent neurons by computing, for example, the maximum or average over their activity, resulting in a smoother representation of feature activities (panel C). By applying the same pooling operation to small image patches that are shifted by more than one pixel, the input image is effectively down-sampled, thereby further reducing the number of model parameters.

A CNN typically consists of multiple convolutional and pooling layers, which allows learning more and more abstract features at increasing scales from small edges, to object parts, and finally entire objects. One or more fully connected layers can follow the last pooling layer (panel A). Model hyper-parameters such as the number of convolutional layers, number of feature maps or the size of receptive fields are application-dependent and should be strictly selected on a validation data set.

Their *DeepBind* model outperformed existing methods, was able to recover known and novel sequence motifs, and could quantify the effect of sequence alterations and identify functional SNVs. A key innovation that enabled training the model directly on the raw DNA sequence was the application of a one-dimensional convolutional layer. Intuitively, the neurons in the convolutional layer scan for motif sequences and combinations thereof, similar to conventional position weight matrices (Stormo *et al*, 1982). The learning signal from deeper layers informs the convolutional layer which motifs are the most relevant. The motifs recovered by the model can then be visualized as heatmaps or sequence logos (Fig 2D).

In silico prediction of mutation effects

An important application of deep neural networks trained on the raw DNA sequence is to predict the effect of mutations *in silico*. Such model-based assessments of the effect of sequence changes complement methods based on QTL mapping, and can in particular help to uncover regulatory effects of rare SNVs or to fine-map likely causal genes. An intuitive approach for visualizing such predicted regulatory effects is mutation maps (Alipanahi *et al*, 2015), whereby the effect of all possible mutations for a given input sequence is represented in a matrix view (Fig 2E). The authors could further reliably identify deleterious SNVs by training an additional neural network with predicted binding scores for a wild-type and mutant sequence (Fig 2C).

Joint prediction of multiple traits and further extensions

Following their initial successes, convolutional architectures have been extended and applied to a range of tasks in regulatory genomics. For example, Zhou and Troyanskaya (2015) considered these architectures to predict chromatin marks from DNA sequence. The authors observed that the size of the input sequence window is a major determinant of model performance, where larger windows (now up to 1 kb) coupled with multiple convolutional layers enabled capturing sequence features at different genomic length scales. A second innovation was to use neural network architectures with multiple output variables (so-called multitask neural networks) to predict multiple chromatin states in parallel. Multitask architectures allow learning shared features between outputs, thereby improving generalization performance, and markedly reducing the computational cost of model training compared to learning independent models for each trait (Dahl *et al*, 2014).

In a similar vein, Kelley *et al* (2016) developed the open-source deep learning framework *Basset*, to predict DNase I hypersensitivity across multiple cell types and to quantify the effect of SNVs on chromatin accessibility. Again, the model improved prediction performance compared to conventional methods and was able to retrieve both known and novel sequence motifs that are associated with DNase I hypersensitivity. A related architecture has also been considered by Angermueller *et al* to predict DNA methylation states in single-cell bisulphite sequencing studies (Angermueller *et al*, 2016). This approach combined convolutional architectures to detect informative DNA sequence motifs with additional features derived from neighbouring CpG sites, thereby accounting for methylation context. Most recently, Koh, Pierson and Kundaje applied CNNs to de-noise genomewide chromatin immunoprecipitation followed by sequencing data in order to obtain a more accurate prevalence estimate for different chromatin marks (Koh *et al*, 2016).

At present, CNNs are among the most widely used architectures to extract features from fixed-size DNA sequence windows. However, alternative architectures could also be considered. For example, recurrent neural networks (RNNs) are suited to model sequential data (Lipton, 2015) and have been applied for modelling natural language and speech (Hinton *et al*, 2012; Graves *et al*, 2013; Sutskever *et al*, 2014; Che *et al*, 2015; Deng & Togneri, 2015; Xiong *et al*, 2016), protein sequences (Agathocleous *et al*, 2010; Sønderby & Winther, 2014), clinical medical data (Che *et al*, 2015; Lipton *et al*, 2015) and to a limited extent DNA sequences (Xu *et al*, 2007; Lee *et al*, 2015). RNNs are appealing for applications in regulatory genomics, because they allow modelling sequences of variable length, and to capture long-range interactions within the sequence and across multiple outputs. However, at present, RNNs are more difficult to train than CNNs, and additional work is needed to better understand the settings where one should be preferred over the other.

Complementary to supervised methods, unsupervised deep learning architectures learn low-dimensional feature representations from high-dimensional unlabelled data, similarly to classical principal component analysis or factor analysis, but using a nonlinear model. Examples of such approaches are stacked autoencoders (Vincent *et al*, 2010), restricted Boltzmann machines and deep belief networks (Hinton *et al*, 2006). The learnt features can be used to visualize data or as input for classical supervised learning tasks. For example, sparse autoencoders have been applied to classify cancer cases using gene expression profiles (Fakoor *et al*, 2013) or to predict protein backbones (Lyons *et al*, 2014). Restricted Boltzmann machines can also be used for unsupervised pre-training of deep networks to subsequently train supervised models of protein secondary structures (Spencer *et al*, 2015), disordered protein regions (Eickholt & Cheng, 2013) or amino acid contacts (Eickholt & Cheng, 2012). Skip-gram neural networks have been applied to learn low-dimensional representations of protein sequences and improve protein classification (Asgari & Mofrad, 2015). In general, unsupervised models are a powerful approach if large quantities of unlabelled data are available to pre-train complex models. Once trained, these models can help to improve performance on classification tasks, for which smaller numbers of labelled examples are typically available.

Deep learning for biological image analysis

Historically, perhaps the most important successes of deep neural networks have been in image analysis. Deep architectures trained on millions of photographs can famously detect objects in pictures better than humans do (He *et al*, 2015). All current state-of-the-art models in image classification, object detection, image retrieval and semantic segmentation make use of neural networks.

The convolutional neural network (Box 2) is the most common network architecture for image analysis. Briefly, a CNN performs pattern matching (convolution) and aggregation (pooling) operations (Box 2). At a pixel level, the convolution operation scans the image with a given pattern and calculates the strength of the match for every position. Pooling determines the presence of the pattern in a region, for example by calculating the maximum pattern match in smaller patches (max-pooling), thereby aggregating region information into a single number. The successive application of convolution and pooling operations is at the core of most network architectures used in image analysis (Box 2).

First applications in computational biology—pixel-level classification

The early applications of deep networks for biological images focused on pixel-level tasks, with additional models building on the network outputs. For example, Ning *et al* (2005) applied

 © 2016 The Authors

convolutional neural networks in a study that predicted abnormal development in *C. elegans* embryo images. They trained a CNN on 40 × 40 pixel patches to classify the centre pixel to cell wall, cytoplasm, nucleus membrane, nucleus or outside medium, using three convolutional and pooling layers, followed by a fully connected output layer. The model predictions were then fed into an energy-based model for further analysis. CNNs have outperformed standard methods, for example Markov random fields and conditional random fields (Li, 2009) in such raw data analysis tasks, for example restoring noisy neural circuitry images (Jain *et al*, 2007).

Adding layers allows moving from clearing up pixel noise to modelling more abstract image features. Ciresan *et al* (2013) used five convolutional and pooling layers, followed by two fully connected layers, to find mitosis in breast histology images. This model won the mitosis detection challenge at the International Conference of Pattern Recognition 2012, outperforming competitors by a substantial margin. The same approach was also used to segment neuronal structures in electron microscopy images, classifying each pixel as membrane or non-membrane (Ciresan *et al*, 2012). In these applications, while the CNNs were trained in an end-to-end manner, additional post-processing was required to obtain class probabilities from the outputs for new images.

Successive pooling operations lose information on localization, as only summaries are retained from larger and larger regions. To avoid this, skip links can be added to carry information from early, fine-grained layers forward to deeper ones. The currently best-performing pixel-level classification method for neuronal structures (*U-Net;* Ronneberger *et al*, 2015) employs an architecture in which neurons take inputs from lower layers to localize high-resolution features, as well as to overcome the arbitrary choice of context size.

Analysis of whole cells, cell populations and tissues

In many cases, pixel-level predictions are not required. For example, Xu *et al* directly classified colon histopathology images into cancerous and non-cancerous, finding that supervised feature learning with deep networks was superior to using handcrafted features (Xu *et al*, 2014). Pärnamaa and Parts used CNNs to classify pre-segmented image patches of individual yeast cells carrying a fluorescent protein to different subcellular localization patterns (Pärnamaa & Parts, 2016). Again, deep networks outperformed methods based on traditional features. Further, Kraus *et al* combined the segmentation and classification tasks into a single architecture that can be learned end-to-end and applied the model to full resolution yeast microscopy images (Kraus *et al*, 2015). This approach allowed classifying entire images without performing segmentation as a pre-processing step. CNNs have even been applied to count bacterial colonies in agar plates (Ferrari *et al*, 2015). Since the early denoising applications on the pixel level, the field has been moving towards end-to-end image analysis pipelines that make use of large bioimage data sets, and the representational power of CNNs.

Reusing trained models

Training convolutional neural networks requires large data sets. While biological data acquisition can be expensive, this does not mean that deep neural networks cannot be used when millions of images are not available. Regardless of image source, lower levels of the network tend to capture similar signal (edges, blobs) that are not specific to the training data and the application, but instead recur in perceptual tasks in general. Thus, convolutional neural networks can reuse pictures from a similar domain to help with learning, or even be pre-trained on other data, thereby requiring fewer images to fine-tune the model for the task of interest. Indeed, Donahue *et al* (2013) and Razavian *et al* (2014) showed that features learned from millions of images to classify objects, can successfully be used in image retrieval, detection or classification on new domains where only hundreds of images are labelled. The effectiveness of such an approach depends on the similarity between the training data and the new domain (Yosinski *et al*, 2014).

The concept of transferring model parameters has also been successful in bioimage analysis. For example, Zhang *et al* (2015) showed that features learned from natural images can be transferred to biological data, improving the prediction of *Drosophila melanogaster* developmental stages from *in situ* hybridization images. The model was first pre-trained on data from the ImageNet (Russakovsky *et al*, 2015), an open corpus of more than one million diverse images, to extract rich features at different scales. Xie *et al* (2015) further used synthetic images to train a CNN for automatic cell counting in microscopy images. We expect that network repositories that host pre-trained models will emerge for biological image analysis; such efforts already exist for general image processing tasks (see learning section below). These trained models could be downloaded and used as feature extractors (Fig 3), or further fine-tuned and adapted to a particular task on small-scale data.

Interpreting and visualizing convolutional networks

Convolutional neural networks have been successful across many domains. In interpreting their performance, it is useful to understand the features they capture.

Visualizing input weights

One way to understand what a particular neuron represents is to look for inputs that maximally activate it. Under some mathematical constraints, these patterns are proportional to the incoming weights (see also Box 1). Krizhevsky *et al* visualized weights in the first convolutional layer (Krizhevsky *et al*, 2012) and found that these maximally activating patterns correspond to colour blobs, edges at different orientations and Gabor-like filters (Fig 4). Gabor filters are widely used pre-defined features in image analysis; neural networks rediscover them in a data-driven way as a useful component of the image model. Higher layer weights can be visualized as well, but as the inputs are not pixels, their weights are more difficult to interpret.

Finding images that maximize neuron activity

To understand the deeper layers in terms of input pixels, Girshick *et al* (2014) retrieved and Simonyan *et al* (2013) generated images that maximize the output of individual neurons (Fig 4). While this approach yields no explicit representation, it can provide an overview of the type of features that differentiate images with large neuron activity from all others. Such visualizations tend to show that second-layer features combine edges from the first layer,

© 2016 The Authors

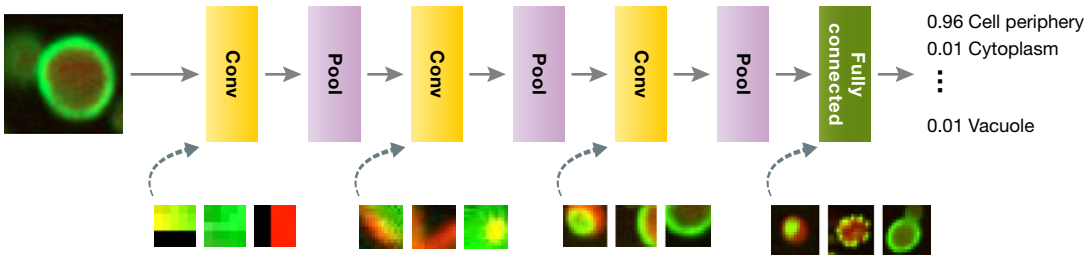

Figure 3. Convolution and pooling operators are stacked, thereby creating a deep network for image analysis.
In standard applications, convolution layers are followed by a pooling layer (Box 2). In this example, the lowest level convolutional units operate on 3 × 3 patches, but deeper ones use and capture information from larger regions. These convolutional pattern-matching layers are followed by one or multiple fully connected layers to learn which features are most informative for classification. For each layer with learnable weights, three example images that maximize some neuron output are shown.

thereby detecting corners and angles; deeper layer neurons activate for specific object parts (e.g. noses, eyes); and the deepest layers detect whole objects (e.g. faces, cars). It is complicated to hand-engineer features that look specifically for noses, eyes or faces, but neural networks can learn these features solely from input–output examples.

Hiding important image parts

To understand which image parts are important for determining the value of each feature, Zeiler and Fergus (2014) occluded images with smaller grey boxes. The parts that are most influential will drastically change the feature value when occluded. In a similar vein, Simonyan *et al* (2013) and Springenberg *et al* (2014) visualized which individual pixels make the most difference in the feature, and Bach, Binder and colleagues developed pixel relevance for individual classification decisions in a more general framework (Bach *et al*, 2015). This information can also be used for object localization or segmentation, as the sensitive image pixels usually correctly correspond to the true object. Kraus *et al* (2015) used this idea to effectively localize cells in large microscopy images.

Visualizing similar inputs in two dimensions

Visualizing the CNN representations can help gauge what inputs get mapped to similar feature vectors, and hence understand what the model has learned. Donahue *et al* (2013) projected CNN features into two dimensions to show that each subsequent layer transforms data to be more and more separable by a linear classifier. In general, different CNN visualization methods show that higher layer features are more specific to the learning task, while low-level features tend to capture general aspects of images, such as edges and corners.

Off-the-shelf tools and practical considerations

Deep learning frameworks

Deep learning frameworks have been developed to easily build neural networks from existing modules on a high level. The most popular ones are Caffe (Jia *et al*, 2014), Theano (Bastien *et al*, 2012), Torch7 (Collobert *et al*, 2011) and TensorFlow (Abadi *et al*, 2016; Rampasek & Goldenberg, 2016) (Table 1), which differ in modularity, ease of use and the way models are defined and trained.

Caffe (Jia *et al*, 2014) is developed by the Berkeley Vision and Learning Center and is written in C++. The network architecture is specified in a configuration file and models can be trained and used via command line, without writing code at all. Additionally, Python and MATLAB interfaces are available. Caffe offers one of the most efficient implementations for CNNs and provides multiple pre-trained models for image recognition, making it well suited for computer vision tasks. As a downside, custom models need to be implemented in C++, which can be difficult. Additionally, Caffe is not optimized for recurrent architectures.

Theano (Bastien *et al*, 2012; Team *et al*, 2016) is developed and maintained by the University of Montreal and written in Python and C++. Model definitions follow a declarative instead of an imperative programing paradigm, which means that the user specifies what needs to be done, not in which order. A neural network is declared as a computational graph, which is then compiled to native code and executed. This design allows Theano to optimize computational steps and to automatically derive gradients—one of its main strengths. Consequently, Theano is well suited for building custom models and offers particularly efficient implementations for RNNs. Software wrappers such as Keras (https://github.com/fchollet/keras) or Lasagne (https://github.com/Lasagne/Lasagne) provide additional abstraction and allow building networks from existing components, and reusing pre-trained networks. The major drawback of Theano is frequently long compile times when building larger models.

Torch7 (Collobert *et al*, 2011) was initially developed at the University of New York and is based on the scripting language LuaJIT. Networks can be easily built by stacking existing modules and are not compiled, hence making it more suited for fast prototyping than Theano. Torch7 offers an efficient CNN implementation and access to a range of pre-trained models. A possible downside is the need of the user to be familiar with the LuaJIT scripting language. Also, LuaJIT is less suited for building custom recurrent networks.

TensorFlow (Abadi *et al*, 2016) is the most recent deep learning framework developed by Google. The software is written in C++ and offers interfaces to Python. Similar to Theano, a neural network is declared as a computational graph, which is optimized during compilation. However, the shorter compile time makes it more suited for prototyping. A key strength of TensorFlow is native support for parallelization across different devices, including CPUs and GPUs, and using multiple compute nodes on a cluster. The accompanying tool TensorBoard allows to conveniently visualize networks in a web browser and to monitor training progress, for example learning curves or parameter updates. At present,

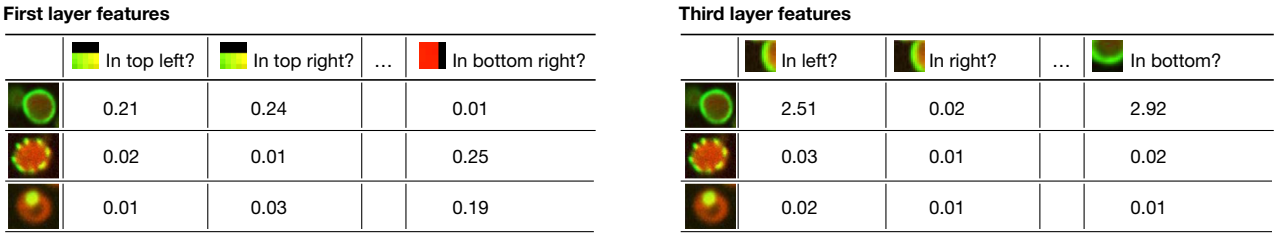

Figure 4. A pre-trained network can be used as a generic feature extractor.
Feeding input into the first layer (left) gives a low-level feature representation in terms of patterns (left to right) present in smaller patches in every cell (top to bottom). Neuron activations extracted from deeper layers (right) give rise to more abstract features that capture information from a larger segment of the image.

TensorFlow provides the most efficient implementation for RNNs. The software is recent and under active development; hence, only few pre-trained models are currently available.

Data preparation

Training data are key for every machine learning application. Since more data with informative features usually result in better performance, effort should be spent on collecting, labelling, cleaning and normalizing data.

Required data set sizes

Most of the successful applications of deep learning have been in supervised learning settings, where sufficient labelled training samples are available to fit complex models. As a rule of thumb, the number of training samples should be at least as high as the number of model parameters, although special architectures and model regularization can help to avoid overfitting if training data are scarce (Bengio, 2012).

Central problems in regulatory genomics, for example predicting molecular traits from genotype, are limited in the number of training instances; hundreds to at most tens of thousands of training examples are typical. The strategy of considering sequence windows centred on the trait of interest (e.g. splice site, transcription factor binding site or epigenetic marks; see Fig 2A) is now a widely used approach and helps increasing the number of input–output pairs from a single individual.

In image analysis, data can be abundant, but manually curated and labelled training examples are typically difficult to obtain. In such instances, the training set can be augmented by scaling, rotating or cropping the existing images, an approach that also enhances robustness (Krizhevsky *et al*, 2012). Another strategy is to reuse a network that was pre-trained on a large data set for image recognition [e.g. AlexNet (Krizhevsky *et al*, 2012), VGG (Simonyan & Zisserman, 2014), GoogleNet (Szegedy *et al*, 2015b) or ResNet (He *et al*, 2015)], and to fine-tune its parameters on the data set of interest (e.g. microscopy images for a particular segmentation task). Such an approach exploits the fact that different data sets share important characteristics and features, such as edges or curves, which can be transferred between them. Caffe, Lasagne, Torch and to a limited extend TensorFlow provide repositories with pre-trained models.

Partitioning data into training, validation and test sets

Machine learning models need to be trained, selected and tested on independent data sets to avoid overfitting and assure that the model will generalize to unseen data. Holdout validation, partitioning the data into a training, validation and test sets, is the standard for deep neural networks (Fig 5C). The training set is used to learn models with different hyper-parameters, which are then assessed on the validation set. The model with best performance, for example prediction accuracy or mean-squared error, is selected and further evaluated on the test set to quantify the performance on unseen data and for comparison to other methods. Typical data set proportions are 60% for training, 10% for validation and 30% for model testing. If the data set is small, k-fold cross-validation or bootstrapping can be used instead (Hastie *et al*, 2005).

Normalization of raw data

Appropriate choices for data normalization can help to accelerate training and the identification of a good local minimum.

Categorical features such as DNA nucleotides first need to be encoded numerically. They are typically represented as binary vectors with all but one entry set to zero, which indicates the category (*one-hot coding*). For example, DNA nucleotides (categories)

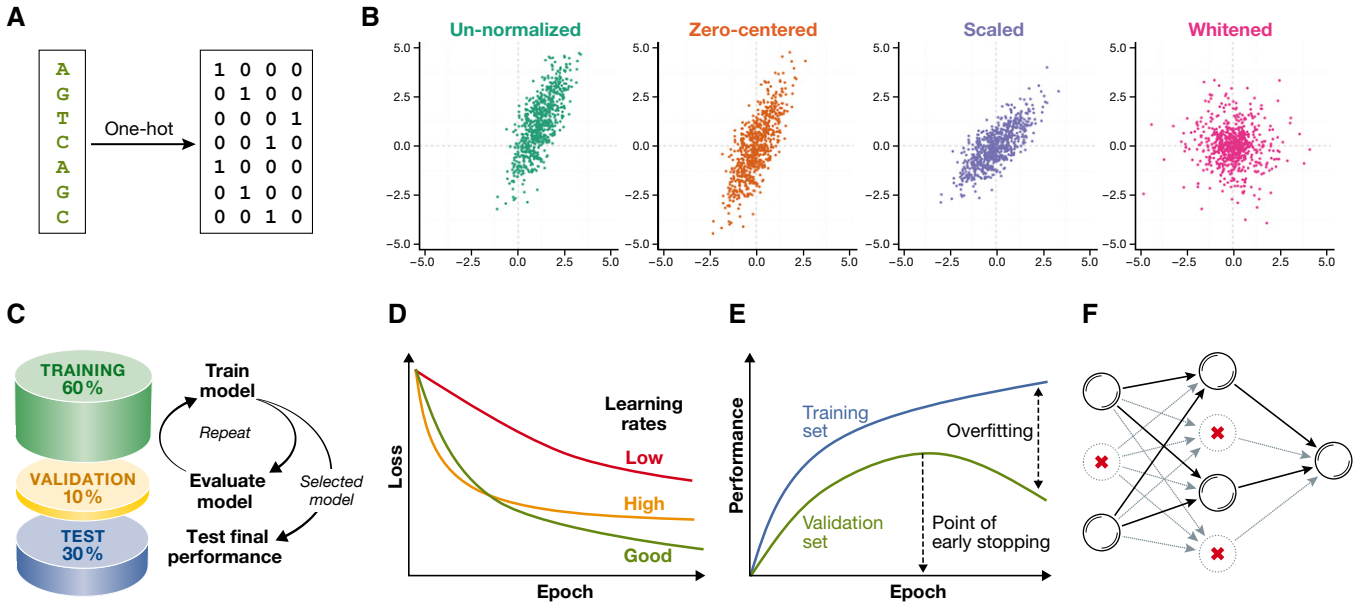

Figure 5. Data normalization for and pre-processing for deep neural networks.
(A) DNA sequence one-hot encoded as binary vectors using codes A = 1 0 0 0, G = 0 1 0 0, C = 0 0 1 0 and T = 0 0 0 1. (B) Continuous data (green) after zero-centring (orange), scaling to unit variance (blue) and whiting (purple). (C) Holdout validation partitions the full data set randomly into training (~60%), validation (~10%) and test set (~30%). Models are trained with different hyper-parameters on the training set, from which the model with the highest performance on the validation set is selected. The generalization performance of the model is assessed and compared with other machine learning methods on the test set. (D) The shape of the learning curve indicates if the learning rate is too low (red, shallow decay), too high (orange, steep decay followed by saturation) or appropriate for a particular learning task (green, gradual decay). (E) Large differences in the model performance on the training set (blue) and validation set (green) indicate overfitting. Stopping the training as soon as the validation set performance starts to drop (early stopping) can prevent overfitting. (F) Illustration of the dropout regularization. Shown is a feedforward neural network after randomly dropping out neurons (crossed out), which reduces the sensitivity of neurons to neurons in the previous layer due to non-existent inputs (greyed edges).

are commonly encoded as A = (1 0 0 0), G = (0 1 0 0), C = (0 0 1 0) and T = (0 0 0 1) (Fig 5A). A DNA sequence can then be represented as a binary string by concatenating the encoding nucleotides, and treating each nucleotide as an independent input feature of a feedforward neural network. In a CNN, the four bits of each encoded base are commonly considered analogously to colour channels of an image to preserve the entity of a nucleotide.

Numerical features are typically zero-centred by subtracting their mean value. Image pixels are usually not zero-centred individually, but jointly by subtracting the mean pixel intensity per colour channel. An additional common normalization step is to standardize features to unit variance. Whiting can be used to decorrelate features (Fig 5B), but can be computationally involved, since it requires computing the feature covariance matrix (Hastie *et al*, 2005). If the distribution of features is skewed due to a few extreme values, log transformations or similar processing steps may be appropriate. Validation and test data need to be normalized consistently with the training data. For example, features of the validation data need to be zero-centred by subtracting the mean computed on the training data, not on the validation data.

Model building

Choice of model architecture

After preparing the data, design choices about the model architectures need to be made. The default architecture is a feedforward neural network with fully connected hidden layers, which is an appropriate starting point for many problems. Convolutional architectures are well suited for multi- and high-dimensional data, such as two-dimensional images or abundant genomic data. Recurrent neural networks can capture long-range dependencies in sequential data of varying lengths, such as text, protein or DNA sequences. More sophisticated models can be built by combining different architectures. To describe the content of an image, for example, a CNN can be combined with an RNN, where the CNN encodes the image and the RNN generates the corresponding image description (Vinyals *et al*, 2015; Xu *et al*, 2015). Most deep learning frameworks provide modules for different architectures and their combinations.

Determining the number of neurons in a network

The optimal number of hidden layers and hidden units is problem-dependent and should be optimized on a validation set. One common heuristic is to maximize the number of layers and units without overfitting the data. More layers and units increase the number of representable functions and local optima, and empirical evidence shows that it makes finding a good local optimum less sensitive to weight initialization (Dauphin *et al*, 2014).

Model training

The goal of model training is to find parameters w that minimize an objective function $L(w)$, which measures the fit between the predictions the model parameterized by w and the actual observations.

 © 2016 The Authors

The most common objective functions are the cross-entropy for classification and mean-squared error for regression. Minimizing $L(w)$ is challenging since it is high-dimensional and non-convex (Fig 5C); see also Box 1 and Fig 2.

Stochastic gradient descent

Stochastic gradient descent is widely used to train deep models. Starting from an initial set of parameters w_0, the gradient dw of L with respect to w is computed for a random batch of only few, for example 128, training samples. dw points to the direction of steepest descent, towards which w is updated with step size eta, the learning rate (Fig 1C). At each step, the parameters are updated into the direction of steepest descent until a minimum is reached, analogously to a ball running down a hill to a valley (Bengio, 2012). The training performance strongly depends on parameter initialization, learning rate and batch size.

Parameter initialization

In general, model parameters should be initialized randomly to avoid local optima determined by a fixed initialization. Starting points for model parameters can be sampled independently from a normal distribution with small variance, or more commonly from a normal distribution with its variance scaled inversely by the number of hidden units in the input layer (Glorot & Bengio, 2010; He *et al*, 2015).

Learning rate and batch size

The learning rate and batch size of stochastic gradient descent need to be chosen with care, since they can strongly impact training speed and model performance. Different learning rates are usually explored on a logarithmic scale such as 0.1, 0.01 or 0.001, with 0.01 as the recommended default value (Bengio, 2012). A batch size of 128 training samples is suitable for most applications. The batch size can be increased to speed up training or decreased to reduce memory usage, which can be important for training complex models on memory-limited GPUs. The optimum learning rate and batch size are connected, with larger batch sizes typically requiring smaller learning rates.

Learning rate decay

The learning rate can be gradually reduced during training, which is based on the idea that larger steps may be helpful in early training stages in order to overcome possible local optima, whereas smaller step sizes allow exploring narrow parameter regions of the loss function in advanced stages of training. Common approaches include to linearly reduce the learning rate by a constant factor such as 0.5 after the validation loss stops improving, or exponentially after every training iteration or epoch (Bengio, 2012; Gawehn *et al*, 2016).

Momentum

Vanilla stochastic gradient descent can be extended by "momentum", which usually improves training (Sutskever *et al*, 2013). Instead of updating the current parameter vector w_t at time t by the gradient vector dw_{t+1} directly, a fraction of the previous update is added to the current one. With momentum rate v, weights are updated by a momentum vector $m_{t+1} = v \cdot m_t - \in dW_{t+1}$. This approach can help to take larger steps in directions where gradients point consistently, and therefore speed up the convergence. The momentum rate v can be set between [0, 1], and a typical value is 0.9. Nesterov momentum (Nesterov, 1983, 2013) is a special form of the same concept, which sometimes provides additional advantages.

Per-parameter adaptive learning rate methods

To reduce the sensitivity to the specific choice of the learning rate, adaptive learning rate methods, such as RMSprop, Adagrad (Srivastava *et al*, 2014) and Adam (Kingma & Ba, 2014), have been developed in order to appropriately adapt the learning rate per parameter during training. The most recent method, Adam, combines the strengths of previous methods RMSprop and Adagrad and is generally recommended for many applications.

Batch normalization

Batch normalization (Ioffe & Szegedy, 2015) is a recently described approach to reduce the dependency of training to the parameter initialization, speed up training and reduce overfitting. It is easy to implement, has marginal additional compute costs and has hence become common practice. Batch normalization zero centres and normalizes data not only at the input layer, but also at hidden layers before the activation function. This approach allows using higher learning rates and hence also accelerates training.

Analysing the learning curve

To validate the learning process, the loss should be monitored as a function of the number of training epochs, that is the number of times the full training set has been traversed (Fig 5D). If the learning curve decreases slowly, the learning rate may be too small and should be increased. If the loss decreases steeply at the beginning but saturates quickly, the learning rate may be too high. Extreme learning rates can result in an increasing or fluctuating learning curve (Bengio, 2012).

Monitoring training and validation performance

In parallel with the training loss, it is recommended to monitor the target performance such as the accuracy for both the training and validation set during training (Fig 5E). A low or decreasing validation performance relative to the training performance indicates overfitting (Bengio, 2012).

Avoiding overfitting

Deep neural networks are notoriously difficult to train, and overfitting to data is a major challenge, since they are nonlinear and have many parameters. Overfitting results from a too complex model relative to the size of the training set, and can thus be reduced by decreasing the model complexity, for example the number of hidden layers and units, or by increasing the size of the training set, for example via data augmentation. The following training guidelines can help to avoid overfitting.

Dropout (Srivastava *et al*, 2014) is the most common regularization technique and often one of the key ingredients to train deep models. Here, the activation of some neurons is randomly set to zero ("dropped out") during training in each forward pass, which intuitively results in an ensemble of different networks whose

© 2016 The Authors

predictions are averaged (Fig 5E). The dropout rate corresponds to the probability that a neuron is dropped out, where 0.5 is a sensible default value. In addition to dropping out hidden units, input units can be dropped, however usually at a lower rate. Dropout is often combined with regularizing the magnitude or parameter values by the L2 norm, and less commonly the L1 norm.

Another popular regularization method is "early stopping". Here, training is stopped as soon as the validation performance starts to saturate or deteriorate, and the parameters with the best performance on the validation set chosen.

Layerwise pre-training (Bengio *et al*, 2007; Salakhutdinov & Hinton, 2012) should be considered if the model overfits despite the mentioned regularization techniques. Instead of training the entire network at once, layers are first pre-trained unsupervised using autoencoders or restricted Boltzmann machines. Afterwards, the entire network is fine-tuned using the actual supervised learning objective.

Hyper-parameter optimization

Table 2 summarizes recommendations and starting points for the most common hyper-parameters, excluding architecture-dependent hyper-parameters such as the size and number of filters of a CNN. Since the best hyper-parameter configuration is data- and application-dependent, models with different configurations should be trained and their performance be evaluated on a validation set. As the number of configurations grows exponentially with the number of hyper-parameters, trying all of them is impossible in practice (Bengio, 2012). It is therefore recommended to optimize the most important hyper-parameters such as the learning rate, batch size or length of convolutional filters independently via line search, which is exploring different values while keeping all other hyper-parameters constant. The refined hyper-parameter space can then be further explored by random sampling, and settings with the best performance on the validation set are chosen. Frameworks such as Spearmint (Snoek *et al*, 2012), Hyperopt (Bergstra & Cox, 2013) or SMAC (Hutter *et al*, 2011) allow to automatically explore the hyper-parameter space using Bayesian optimization. However, although conceptually more powerful, they are at present more difficult to apply and parallelize than random sampling.

Table 2. Central parameters of a neural network and recommended settings.

Name	Range	Default value
Learning rate	0.1, 0.01, 0.001, 0.0001	0.01
Batch size	64, 128, 256	128
Momentum rate	0.8, 0.9, 0.95	0.9
Weight initialization	Normal, Uniform, Glorot uniform	Glorot uniform
Per-parameter adaptive learning rate methods	RMSprop, Adagrad, Adadelta, Adam	Adam
Batch normalization	Yes, no	Yes
Learning rate decay	None, linear, exponential	Linear (rate 0.5)
Activation function	Sigmoid, Tanh, ReLU, Softmax	ReLU
Dropout rate	0.1, 0.25, 0.5, 0.75	0.5
L1, L2 regularization	0, 0.01, 0.001	

Training on GPUs

Training neural networks is more time-consuming compared to shallow models and can take hours, days or even weeks, depending on the size of training set and model architecture. Training on GPUs can considerably reduce the training time (commonly by tenfold or more) and is therefore crucial for evaluating multiple models efficiently. The reason for this speedup is that learning deep networks requires large numbers of matrix multiplications, which can be parallelized efficiently on GPUs. All state-of-the-art deep learning frameworks provide support to train models on either CPUs or GPUs without requiring any knowledge about GPU programming. On desktop machines, the local GPU card can often be used if the framework supports the specific brand. Alternatively, commercial providers provide GPU cloud compute clusters.

Pitfalls

No single method is universally applicable, and the choice of whether and how to use deep learning approaches will be problem-specific. Conventional analysis approaches will remain valid and have advantages when data are scarce or if the aim is to assess statistical significance, which is currently difficult using deep learning methods. Another limitation of deep learning is the increased training complexity, which applies both to model design and the required compute environment.

Conclusion

Deep learning methods are a powerful complement to classical machine learning tools and other analysis strategies. Already, these approaches have found use in a number of applications in computational biology, including regulatory genomics and image analysis. The first publicly available software frameworks have helped to reduce the overhead of model development and provided a rich, accessible toolbox to practitioners. We expect that continued improvement of software infrastructure will make deep learning applicable to a growing range of biological problems.

Competing interests: I have read the journal's policy and have the following conflicts: AG filed a patent application with the Wisconsin Alumni Research Foundation related to classifying activated T cells. KHY is the inventor of a quantitative pathology analytical system (U.S. Patent 10,832,406). This invention is not related to this work. EJF is a Scientific Advisory Board member at Viosera Therapeutics. AAK is a co-inventor on 4 patent applications related to machine learning applications in biology.

can recognize patterns in data and use them for predictive modeling, as opposed to having domain experts developing rules for prediction tasks manually. Artificial neural networks are a particular class of machine learning algorithms and models that evolved into what is now described as "deep learning". Deep learning encompasses neural networks with many layers and the algorithms that make them perform well. These neural networks comprise artificial neurons arranged into layers and are modeled after the human brain, even though the building blocks and learning algorithms may differ [1]. Each layer receives input from previous layers (the first of which represents the input data), and then transmits a transformed version of its own weighted output that serves as input into subsequent layers of the network. Thus, the process of "training" a neural network is the tuning of the layers' weights to minimize a cost or loss function that serves as a surrogate of the prediction error. The loss function is differentiable so that the weights can be automatically updated to attempt to reduce the loss. Deep learning uses artificial neural networks with many layers (hence the term "deep"). Given the computational advances made in the last decade, it can now be applied to massive data sets and in innumerable contexts. In many circumstances, deep learning can learn more complex relationships and make more accurate predictions than other methods. Therefore, deep learning has become its own subfield of machine learning. In the context of biological research, it has been increasingly used to derive novel insights from high-dimensional biological data [2]. For example, deep learning has been used to predict protein–drug binding kinetics [3], to identify the lab-of-origin of synthetic DNA [4], and to uncover the facial phenotypes of genetic disorders [5].

To make the biological applications of deep learning more accessible to scientists who have some experience with machine learning, we solicited input from a community of researchers with varied biological and deep learning interests. These individuals collaboratively contributed to this manuscript's writing using the GitHub version control platform [6] and the Manubot manuscript generation toolset [7]. The goal was to articulate a practical, accessible, and concise set of guidelines and suggestions to follow when using deep learning (Fig 1). For readers who are new to machine learning, we recommend reviewing general machine learning principles [8] before getting started with deep learning.

In the course of our discussions, several themes became clear: the importance of understanding and applying machine learning fundamentals as a baseline for utilizing deep learning, the necessity for extensive model comparisons with careful evaluation, and the need for critical thought in interpreting results generated by deep learning, among others. The major similarities between deep learning and traditional computational methods also became apparent. Although deep learning is a distinct subfield of machine learning, it is still a subfield. It is subject to the many limitations inherent to machine learning, and most best practices for machine learning [9–11] also apply to deep learning. As with all computational methods, deep learning should be applied in a systematic manner that is reproducible and rigorously tested. Ultimately, the tips we collate range from high-level guidance to best practices for implementation. It is our hope that they will provide actionable, deep learning–specific instructions for both new and experienced deep learning practitioners. By making deep learning more accessible for use in biological research, we aim to improve the overall usage and reporting quality of deep learning in the literature and to enable increasing numbers of researchers to utilize these state-of-the art techniques effectively and accurately.

Tip 1: Decide whether deep learning is appropriate for your problem

In recent years, the number of projects and publications implementing deep learning in biology has risen tremendously [12–14]. This trend is likely driven by deep learning's usefulness

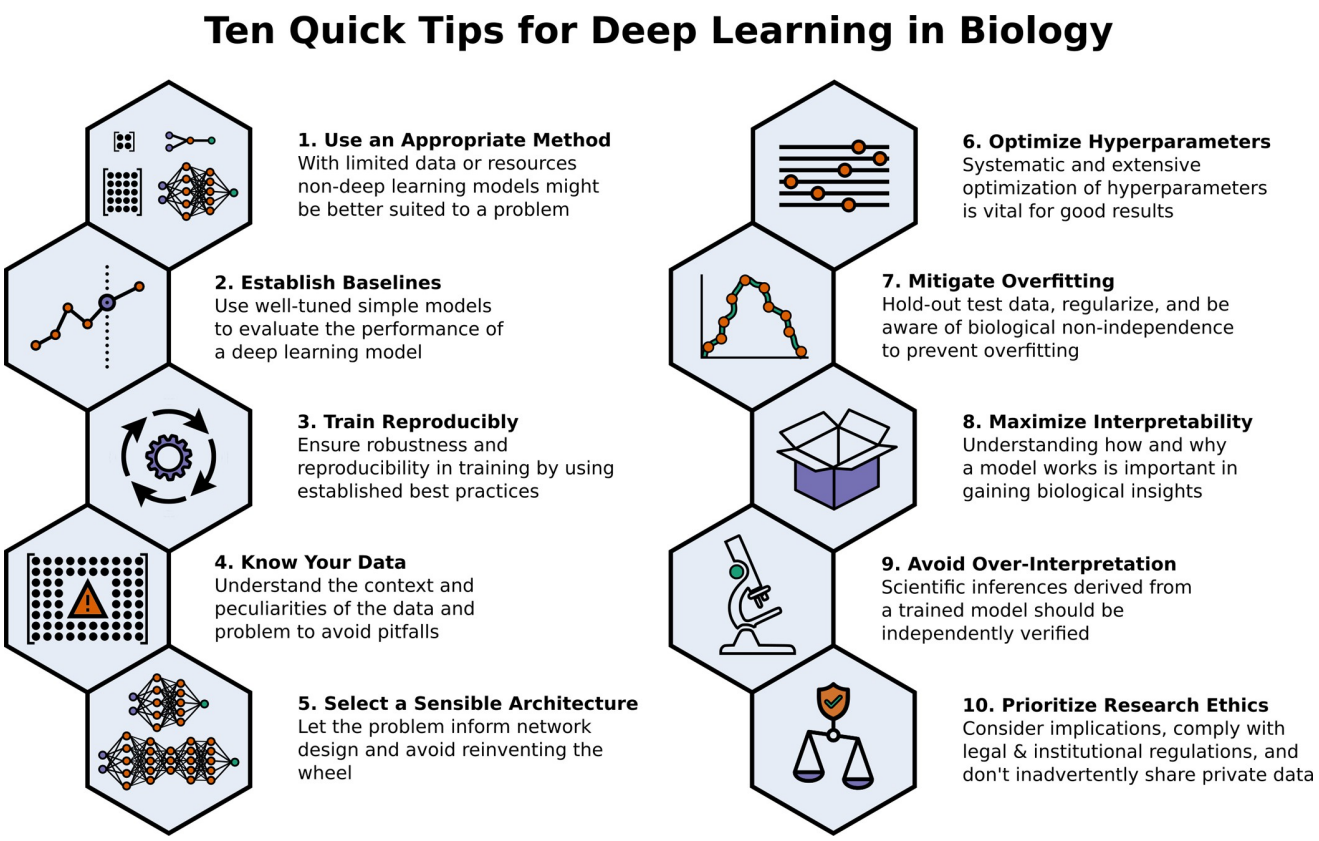

Fig 1. A summary overview of the 10 tips for using deep learning in biological research.

https://doi.org/10.1371/journal.pcbi.1009803.g001

across a range of scientific questions and data modalities and can contribute to the appearance of deep learning as a panacea for nearly all modeling problems. Indeed, neural networks are universal function approximators and derive tremendous power from this theoretical capacity to learn any function [15,16]. However, in reality, deep learning is not suited to every modeling situation and can be significantly limited by its large demands for data, computing power, programming skill, and modeling expertise.

While large amounts of high-quality data may be available in the areas of biology where data collection is thoroughly automated, such as DNA sequencing, areas of biology that rely on manual data collection may not possess enough data to train and apply deep learning models effectively. Methods that try to increase the amount of training data, such as data augmentation (in which existing data is slightly manipulated in an attempt to yield "new" samples) [17] and weak supervision (in which simple labeling heuristics are combined to produce noisy, probabilistic labels) [18] are valuable for small- to medium-scale datasets. For example, when classifying microalgae using models trained on 21,000 images, data augmentation improved the prediction accuracy by 17% [19]. In a text detection context based on a small dataset of 229 fully annotated scene text images, weakly supervised learning improved the precision by 11% [20]. However, methods cannot overcome substantial data shortages in many practical scenarios, and recent research investigating machine learning methods in neuroimaging studies of depression suggests that high prediction accuracies obtained from small datasets may be caused by misestimation due to insufficient test dataset sizes [21].

In the fields of computer vision and natural language processing, deep neural networks are routinely trained on sample sizes ranging from hundreds of thousands to millions of training examples [22,23]. Datasets of this size are often not available in many biological contexts. Still, it has been found that, under certain circumstances, deep learning can be considered for datasets with only 100 samples per class [24]. Nonetheless, deep learning is generally best suited for datasets that contain orders of magnitude more samples.

Training deep learning models often requires extensive computing infrastructure and patience to achieve state-of-the-art performance [25]. In some deep learning contexts, such as generating human-like text, state-of-the-art models have over 100 billion parameters [26] and require very costly and time-consuming training procedures [27]. These types of large language models are being used in biology to learn representations of protein sequences [28–30]. Even though most deep learning applications in biology rarely require this much training, they can still require computational resources beyond those available on consumer-grade devices such as laptops or office desktops. Specialized hardware such as discrete graphics processing units (GPUs) and custom deep learning accelerators can dramatically reduce the time and cost required to train models [14]. Still, this hardware is not universally accessible, and cloud-based rentals add additional cost and complexity. These specialized hardware solutions are likely to be more broadly available as deep learning becomes more popular. For example, recent-generation iPhones already have such hardware. In contrast to the large-scale computational demands of deep learning, traditional machine learning models can often be trained on laptops (or even on a $5 computer [31]) in seconds to minutes. Therefore, due to this enormous disparity in resource demand alone, traditional machine learning approaches may be desirable in various biological applications.

Beyond requiring more data and computational capacity, building and training deep learning models often requires more expertise than training traditional machine learning models. While popular programming frameworks for deep learning such as TensorFlow [32] and PyTorch [33] allow users to create and deploy entirely novel model architectures, this flexibility combined with the rapid development of the deep learning field has resulted in large and complex frameworks that can be daunting to new users. For readers new to software development but experienced in biology, gaining computational skills while also interfacing with such complex industrial-grade tools can be a prohibitive challenge. Conversely, traditional machine learning methods are generally more straightforward to apply and are also more accessible through popular frameworks [34]. Furthermore, there are currently more tools for automating the model selection and training process for traditional machine learning models than for deep learning models. For example, automated machine learning (Auto ML) tools, such as TPOT [35] and Turi Create [36], are able to test and optimize multiple machine learning models automatically and can allow users to achieve competitive performance with only a few lines of code. There are efforts underway to extend these and other automation frameworks to reduce the expertise required to build and use deep learning models. TPOT, Turi Create, and Auto Keras [37] are already capable of abstracting away much of the programming required for "standard" deep learning tasks, and high-level interfaces such as Keras [38] and Fastai [39] make it increasingly straightforward to design and test custom deep learning architectures. In the future, projects such as these are likely to make deep learning accessible to a much wider range of researchers.

Despite these limitations, deep learning is strongly indicated over traditional machine learning for specific research questions and problems. In general, these include problems that feature hidden patterns across the data, complex relationships, and interrelated variables. Problems in computer vision and natural language processing often exhibit these very features, which helps explain why these areas were some of the first to experience significant breakthroughs during the recent deep learning revolution [40]. As long as large amounts of accurate

and labeled data are available, applications to areas of life sciences with related data characteristics, such as genetic medicine [41], radiology [42], microscopy [43], and pharmacovigilance [44], are similarly likely to benefit from deep learning techniques. For example, Ferreira and colleagues used deep learning to recognize individual birds from images [45] despite this problem being very difficult historically. By combining automatic data collection using radio-frequency identification tags with data augmentation and transfer learning, the authors were able to use deep learning to achieve 90% accuracy across several species. Another research area where deep learning excels is generative modeling, where new samples are created based on the training data [46]. For example, deep learning can generate realistic compendia of gene expression samples [47]. One other area of machine learning that has been revolutionized by deep learning is reinforcement learning, which is concerned with training agents to interact with an environment [48]. Reinforcement learning has been applied to design drug like small molecules [49]. Overall, initial evaluation as to whether similar problems (including analogous ones in other domains) have been solved successfully using deep learning can inform researchers about the potential for deep learning to address their needs.

On the other hand, depending on the amount and type of data available and the nature of the problem set, deep learning may not always outperform conventional methods [50,51]. As an illustration, Rajkomar and colleagues [52] found that simpler baseline models achieved performance comparable with deep learning in several clinical prediction tasks using electronic health records. Another example is provided by Koutsoukas and colleagues, who benchmarked several traditional machine learning approaches against deep neural networks for modeling bioactivity data on moderately sized datasets [53]. The researchers found that while well-tuned deep learning approaches generally tend to outperform conventional classifiers, simple methods such as Naive Bayes classification tend to outperform deep learning as the dataset's noise increases. Similarly, Chen and colleagues [54] tested deep learning and a variety of traditional machine learning methods such as logistic regression and random forests on 5 different clinical datasets. They found that traditional methods matched or exceeded the accuracy of the deep learning model in all cases despite requiring an order of magnitude less training time.

In conclusion, deep learning should only be used after a robust consideration of its strengths and weaknesses for the problem at hand. After choosing deep learning as a potential solution, practitioners should still consider traditional methods as performance baselines.

Tip 2: Use traditional methods to establish performance baselines

Deep learning requires practitioners to consider a larger number and variety of tuning parameters (that is, algorithmic settings) than more traditional machine learning methods. These settings are often called hyperparameters. Their extensiveness can make it easy to fall into the trap of performing an unnecessarily convoluted analysis. Hence, before applying deep learning to a given problem, it is ideal to implement simpler models with fewer hyperparameters at the beginning of each study [11]. Such models include logistic regression, random forests, k-nearest neighbors, Naive Bayes, and support vector machines. They can help to establish baseline performance expectations and the difficultly of a specific prediction problem. While performance baselines available from existing literature can also serve as helpful guides, an implementation of a simpler model that uses the same software framework as planned for deep learning can greatly help with assessing the correctness of data processing steps, performance evaluation pipelines, resource requirement estimates, and computational performance estimates. Furthermore, in some cases, it can even be useful to combine simpler baseline models with deep neural networks, as such hybrid models can improve generalization performance, model interpretability, and confidence estimation [55,56].

Another potential pitfall arises from comparing the performance of baseline conventional models trained with default settings with the performance of deep learning models that have undergone rigorous tuning and optimization. Since conventional off-the-shelf machine learning algorithms (for example, support vector machines and random forests) are also likely to benefit from hyperparameter tuning, such incongruity prevents the comparison of equally optimized models and can lead to false conclusions about model efficacy. Hu and Greene [57] discuss this under the umbrella of what they call the "Continental Breakfast Included" effect. They describe how the unequal tuning of hyperparameters across different learning algorithms can especially skew evaluation when the performance of an algorithm varies substantially with modest changes to its hyperparameters. Therefore, practitioners should tune the settings of both traditional machine learning and deep learning–based methods before making claims about relative performance differences. Performance comparisons among machine learning and deep learning models are only informative when the models are equally well optimized.

In sum, practitioners are encouraged to create and fully tune several traditional models and standard pipelines before implementing a deep learning model.

Tip 3: Understand the complexities of training deep neural networks

Correctly training deep neural networks is nontrivial. There are many different options and potential pitfalls at every stage. To get good results, one must often train networks across a wide range of different hyperparameter settings. Such training can be made more difficult by the demanding nature of these deep networks, which often require extensive time investments into tuning and computing infrastructure to achieve state-of-the-art performance [25]. Furthermore, this experimentation is often noisy, which necessitates increased repetition and exacerbates the challenges inherent to deep learning. On the whole, all code, random seeds, parameters, and results must be carefully corralled using general coding standards and best practices (for example, version control [58] and continuous integration [59]) to be reproducible and interpretable [60–62]. For application-based research, this organization is also fundamental to the efficient sharing of research work and the ability to keep models up to date as new data becomes available.

The use of nondeterministic algorithms, often by default, is a specific reproducibility pitfall that is often missed in applying deep learning. For example, GPU acceleration libraries like CUDA/CuDNN, which facilitate the parallelized computing powering state-of-the-art deep learning, often use default algorithms that produce different outcomes from iteration to iteration even with the same hardware and software. Achieving reproducibility in this context requires explicitly specifying the use of deterministic algorithms, which are typically available within deep learning libraries [63]. This step is distinct from and in addition to the setting of random seeds that typically achieve reproducibility by controlling pseudorandom deterministic procedures such as shuffling and initialization.

Similar to the suggestions above about starting with simpler models, starting with relatively small networks and then increasing the size and complexity as needed can help prevent practitioners from wasting significant time and resources on running highly complex models that feature numerous unresolved problems. Again, practitioners must be aware of the choices made implicitly (that is, by default settings) by deep learning libraries. These seemingly trivial details, such as the selection of optimization algorithm, can have significant effects on model performance. For example, adaptive methods often lead to faster convergence during training but may lead to worse generalization performance on independent datasets [64]. These nuanced elements are easy to overlook, but it is critical to consider them carefully and to evaluate their potential impact.

In short, researchers should use smaller and simpler networks to enable faster prototyping, follow general software development best practices to maximize reproducibility, and check software documentation to understand default choices.

Tip 4: Know your data and your question

Having a well-defined scientific question and a clear analysis plan is crucial for carrying out a successful deep learning project. Just like it would be inadvisable to set foot in a laboratory and begin experiments without having a defined endpoint, a deep learning project should not be undertaken without defined goals. Foremost, it is important to assess if a dataset exists that can answer the biological question of interest using a deep learning–based approach. If so, obtaining this data (and associated metadata) and reviewing the study protocol should be pursued as early on in the project as possible. This can help to ensure that data is as expected and can prevent the wasted time and effort that occur when issues are discovered later on in the analytic process. For example, a publication or resource might purportedly offer an appropriate dataset that is found to be inadequate upon acquisition. The data may be unstructured when it is supposed to be structured, crucial metadata such as sample stratification might be missing, or the usable sample size may be different than expected. Any of these data issues might limit a researcher's ability to use deep learning to address the biological question at hand or might otherwise require adjustment before it can be used. Data collection should also be carefully documented, or a data collection protocol should be created and specified in the project documentation.

Information about the resources used, download dates, and dataset versions are critical to preserve. Doing so will help to minimize operational confusion and will increase the reproducibility of the analysis. Best practices for reproducibility also include sharing the collected dataset and metadata upon publication of the study, ideally in a public dataset repository if there are no ethical or privacy concerns and no copyright restrictions. While recommended and recognized dataset repositories may differ across disciplines, a list of general dataset repositories includes the Dryad repository [65] (https://datadryad.org/), Fig share [66] (https://figshare.com), Zenodo [67] (https://zenodo.org), and the Open Science Framework [68] (https://osf.io). In addition, Gundersen and colleagues [69] provide useful checklists summarizing best data sharing practices for reproducible research and open science.

Once the dataset is obtained, it is important to learn why and how the data was collected before beginning the analysis. The standardized metadata that exists in many fields can help with this (for example, see [70]). If at all possible, consulting with a subject matter expert who has experience with the type of data being used will minimize guesswork and likely increase the success rate of a deep learning project. For example, one might presume that data collected to test the impact of an intervention are derived from a randomized controlled trial. However, this is not always the case, as ethical or practical concerns often necessitate an observational study design that features prospectively or retrospectively collected data. In order to ensure similar distributions of important characteristics across study groups in the absence of randomization, such a study may have selected individuals in a fashion that best matches attributes such as age, gender, or weight. Passively collected datasets can have their own peculiarities, and other study designs can include samples that originate from the same study site, the oversampling of ethnic groups or zip codes, or sample processing differences. Such information is critical to accurate data analysis, and so it is imperative that practitioners learn about study design assumptions and data specificities prior to performing modeling. Other study design considerations that should not be overlooked include knowing whether a study involves biological or technical replicates or both. For example, the existence in a dataset of samples collected from the same individuals at different time points can have significant effects on analyses that make assumptions

about sample size and independence (that is, non independence can lower the effective sample size). Another potential issue is the existence of systematic biases, which can be induced by confounding variables and can lead to artifacts or so-called "batch effects." Consequently, models may learn to rely on the correlations that these systematic biases underpin, even though they are irrelevant to the scientific context of the study. This can lead to misguided predictions and misleading conclusions [71]. Unsupervised learning and other exploratory analyses can help identify such biases in these datasets before applying a deep learning model.

Overall, practitioners should thoroughly study their data and understand its context and peculiarities before moving on to performing deep learning.

Tip 5: Choose an appropriate data representation and neural network architecture

Neural network architecture refers to the number and types of layers in the network and how they are connected. While certain best practices have been established by the research community [72], architecture design choices remain largely problem-specific and are vastly empirical efforts requiring extensive experimentation. Furthermore, as deep learning is a quickly evolving field, many recommendations are often short-lived and are frequently replaced by newer insights supported by recent empirical results. This is further complicated by the fact that many recommendations do not generalize well across different problems and datasets. Therefore, choosing how to represent data and design an architecture is closer to an art than a science. That said, there are some general principles to follow when experimenting.

First and foremost, knowledge of the available data and scientific question should inform data representation and architectural design choices. For example, if the dataset is an array of measurements with no natural ordering of inputs (such as gene expression data), multilayer perceptrons may be effective. These are the most basic type of neural network. They are able to learn complex nonlinear relationships across the input data despite their relative simplicity. Similarly, if the dataset is comprised of images, convolutional neural networks (CNNs) are a good choice because they emphasize local structures and adjacency within the data. CNNs may also be a good choice for learning on sequences. Recent empirical evidence suggests that they can outperform canonical sequence learning techniques such as recurrent neural networks and the closely related long short-term memory networks in some cases [73]. Transformers are powerful sequence models [74] but require extensive data and computing power to train from scratch. Accessible high-level overviews of different neural network architectures are provided in [75,76].

Deep learning models typically benefit from increasing the amount of labeled training data. Large amounts of data help to avoid overfitting and increase the likelihood of achieving top performance on a given task. If there is not enough data available to train a well-performing model, transfer learning should be considered. In transfer learning, a model whose weights were generated by training on another dataset is used as the starting point for training [77]. Transfer learning is most useful when the pre training and target datasets are of similar nature [77]. For this reason, it is important to search for similar datasets that are already available. However, even when similar datasets do not exist, transferring features can still improve model performance compared with random feature initialization. For example, Rajkomar and colleagues showed advantages of ImageNet pre training [78] for a model that is applied to grayscale medical image classification [79]. Pre trained models can be obtained from public repositories, such as Kipoi [80] for genomics or Hugging Face [81] for biomedical text [82], protein sequences [29], and chemicals [83]. Moreover, learned features could be helpful even when a pre training task is different from a target task [84].

Recently, the concept of self-supervised learning, which is closely related to pre training and transfer learning, has seen an increase in popularity [85]. Self-supervised learning

leverages large amounts of unlabeled data and uses naturally available information as labels for supervised learning. Thus, self-supervised learning is sometimes also described as autonomous supervised learning. Using self-supervised learning, a model can be pre trained on a related task before it is trained on the target task. Another related approach is multitask learning, which simultaneously trains a network for multiple separate tasks that share features. In fact, multitask learning can be used separately or even in combination with transfer learning [86].

Practitioners should base the neural network's architecture on knowledge of the problem and take advantage of similar existing data or pre trained models.

Tip 6: Tune your hyperparameters extensively and systematically

Given at least one hidden layer, a nonlinear activation function, and a large number of hidden units, multilayer neural networks can approximate arbitrary continuous functions that relate input and output variables [16,87]. Deeper architectures that feature additional hidden layers and an increasing number of overall hidden units and learnable weight parameters (the so-called increasing "capacity" of neural networks) allow for solving increasingly complex problems. However, this increased capacity results in many more parameters to fit and hyperparameters to tune, which can pose additional challenges during model training. In general, one should expect to systematically evaluate the impact of numerous hyperparameters when applying deep neural networks to new data or challenges. Hyperparameters typically manifest as choices of optimization algorithms, loss function, learning rate, activation functions, number of hidden layers and hidden units, size of the training batches, and weight initialization schemes. Moreover, additional hyperparameters are introduced by common techniques that facilitate training deeper architectures. These include regularization penalties, dropout [88], and batch normalization [89], which can reduce the effect of the so-called vanishing or exploding gradient problem when working with deep neural networks.

This wide array of potential parameters can make it difficult to evaluate the extent to which neural network methods are well suited to solving a task. For example, it can be unclear to practitioners whether previously successful deep learning applications were the result of general model suitability for the data at hand or interactions between unique data attributes and specific hyperparameter settings. As a result, a lack of clarity about how extensive arrays of hyperparameters were tested or chosen can hamper method developers as they attempt to compare techniques. This effect also has implications for those seeking to use existing deep learning methods, as performance estimates from deep neural networks are often provided after tuning. The implication is that attaining performance numbers that match those reported in publications is likely to require significant effort toward temporally expensive hyperparameter optimization. Strategies for tuning hyperparameters include exhaustive grid search, random search, or Bayesian optimization and other specialized techniques. Tools such as Keras Tuner (https://keras-team.github.io/keras-tuner/) and Ray Tune (https://docs.ray.io/en/latest/tune/index.html) support best practices for hyperparameter optimization.

To get the best performance from your model, researchers should be sure to systematically optimize their hyperparameters on the training dataset and report both the selected hyperparameters and the hyperparameter optimization strategy.

Tip 7: Address deep neural networks' increased tendency to overfit the dataset

Overfitting is a challenge inherent to machine learning in general and is one of the most significant challenges you will face when applying deep learning specifically. Overfitting occurs when a model fits patterns in the training data so closely that it includes nongeneralizable

noise or nonscientifically relevant perturbations in the relationships it learns. In other words, the model fits patterns that are overly specific to the data it is training on rather than learning general relationships that hold across similar datasets. This subtle distinction is made clearer by seeing what happens when a model is tested on data to which it was not exposed during training: Just as a student who memorizes exam materials struggles to correctly answer questions for which they have not studied, a machine learning model that has overfit to its training data will perform poorly on unseen test data. Deep learning models are particularly susceptible to overfitting due to their relatively large number of parameters and associated representational capacity. Just as some students may have greater potential for memorization, deep learning models seem more prone to overfitting than machine learning models with fewer parameters. However, having a large number of parameters does not always imply that a neural network will overfit [90].

In general, one of the most effective ways to combat overfitting is to detect it in the first place. One way to do this is to split the main dataset being worked on into 3 independent parts: a training set, a tuning set (also commonly called a validation set in the machine learning literature), and a test set. These 3 partitions allow you to optimize models by iterating between model learning on the training set and hyperparameter evaluation on the tuning set without affecting the final model assessment on the test set. A researcher can compare the model's performance on the training and tuning data to assess how overfit (that is, nongeneralizable) the model is. The data used for testing should be "locked away" and used only once to evaluate the final model after all training and tuning steps are completed. This type of approach is necessary for evaluating the generalizability of models without the biases that can arise from learning and testing on the same data [91,92]. While a slight drop in performance from the training set to the test set is normal, a significant drop is a clear sign of overfitting. See Fig 2 for a visual demonstration of an overfit model that performs poorly on test data.

There are a variety of techniques to reduce overfitting, including data augmentation and regularization techniques [93,94]. Another way to reduce overfitting, as described by Chuang and Keiser, is to identify the baseline level of memorization that is occurring by training on data that has its labels randomly shuffled [95]. By comparing the model performance with the shuffled data to that achieved with the actual data [95], a practitioner can identify overfitting as a model that performs no better on real data. This suggests that any predictive capacity is not due to data-driven signal. One important caveat when working with partitioned data is the need to apply transformation and normalization procedures equally to all datasets. The parameters required for such procedures (for example, quantile normalization, a common standardization method when analyzing gene-expression data) should only be derived from the training data, and not from the tuning or test data.

Additionally, many conventional metrics for classification (for example, area under the receiver operating characteristic curve) have limited utility in cases of extreme class imbalance [96]. Consider an example of a dataset of mammograms in which 99% of the samples do not have breast cancer. A model could achieve 99% accuracy by classifying every sample as negative. Therefore, model performance should be evaluated with a carefully picked panel of relevant metrics that make minimal assumptions about the composition of the testing data [97]. One alternative approach is to use the precision-recall curve rather than the receiver operating characteristic since the former is more robust to class imbalance [98].

When working with biological and medical data, one must also carefully consider potential sources of bias and/or nonindependence when defining training and test sets. For example, a deep learning model for pneumonia detection in chest X-rays appeared to perform well within the hospitals providing the training data, but then failed to generalize to other hospitals [99]. This resulted from the deep learning model picking up on signals related to which hospital the

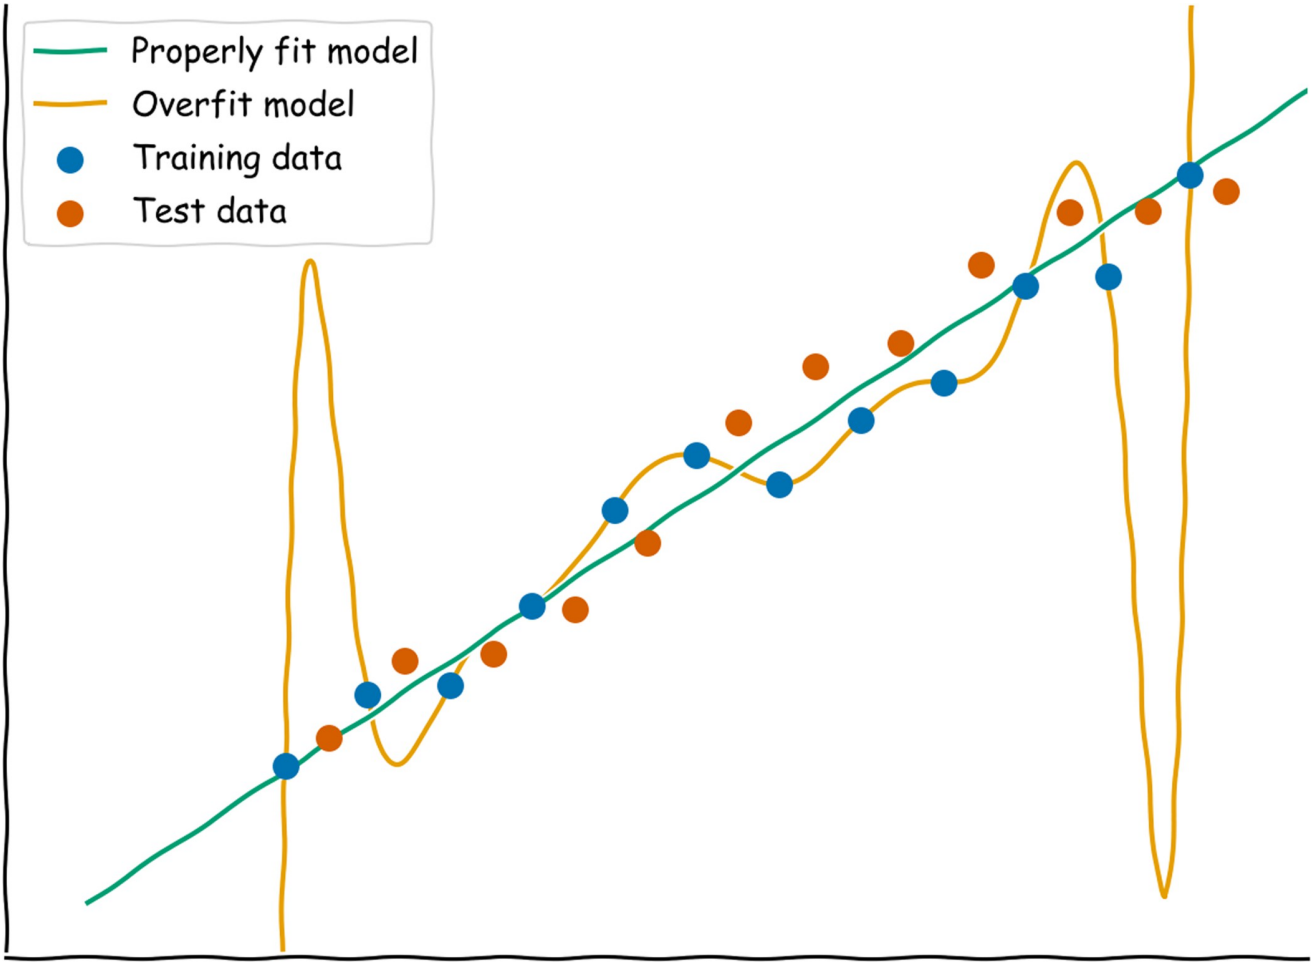

Fig 2. A visual example of overfitting and failure to generalize. While a high-degree polynomial achieves high accuracy on its training data, it performs poorly on the test data that have not been seen before. That is, the model has memorized the training dataset specifically rather than learning a generalizable pattern that represents data of this type. In contrast, a simple linear regression works equally well on both datasets.

https://doi.org/10.1371/journal.pcbi.1009803.g002

images were from and represents a type of artifact or batch effect that practitioners must be vigilant towards. When dealing with sequence data, holding out test data that are evolutionarily related or that share structural homology to the training data can result in overfitting that is hard to detect due to the inherent relatedness of the partitioned data [100]. In such situations, simply holding out test data selected from a random partition of the training data can be insufficient. The best remedy for identifying confounding variables is to know your data and to test models on truly independent data.

In essence, practitioners should split data into training, tuning, and single-use testing sets to assess the performance of the model on data that can provide a reliable estimate of its generalization performance. Furthermore, practitioners should be cognizant of the danger of skewed or biased data artificially inflating performance.

Tip 8: Deep learning models can be made more transparent

While model interpretability is a broad concept, in much of the machine learning literature, it refers to the ability to identify the discriminative features that influence or sway the

predictions. In certain cases, the goal behind interpretation is to understand the underlying data generating processes and biological mechanisms [101]. In other cases, the goal is to understand why a model made the prediction that it did for a specific example or set of examples. Machine learning models vary widely in terms of interpretability: Some are fully transparent while others are considered "black boxes" that make predictions with little ability to examine why. Logistic regression and decision tree models are generally considered interpretable [102]. In contrast, deep neural networks are often considered among the most difficult to interpret naively because they can have many parameters and nonlinear relationships.

Knowing which of the input variables influences a model's predictions, and potentially in what ways, can help with the application or extrapolation of machine learning models. This is particularly important in biomedicine. Subsequent decision-making often requires human input, and models are employed with the hope of better understanding why relationships exist in the first place. Furthermore, while prediction rules can be derived from high-throughput molecular datasets, most affordable clinical tests still rely on lower-dimensional measurements of a limited number of biomarkers. Therefore, it is often unclear how to translate the predictive capacity of deep learning models that encompass nonlinear relationships between countless input variables into clinically digestible terms. As a result, selecting which biomarkers to use for decision-making remains an important modeling and interpretation challenge. In fact, many authors attribute a lower uptake of deep learning tools in healthcare to interpretability challenges [103,104]. Nonetheless, strategies to interpret both machine learning and deep learning models are rapidly emerging, and the literature on the topic is growing quickly [105]. Instead of recommending specific methods for either deep learning–specific or general-purpose model interpretation, we suggest consulting a freely available and continually updated textbook [106].

Tip 9: Don't over interpret predictions

After training an accurate deep learning model, it is natural to want to use it to deduce relationships and inform scientific findings. However, be careful to interpret the model's predictions correctly. Given that deep learning models can be difficult to interpret intuitively, there is often a temptation to over interpret the predictions in indulgent or inaccurate ways. In accordance with the classic statistical saying "correlation doesn't imply causation," predictions by deep learning models rarely provide causal relationships. Accurately predicting an outcome does not mean that a causal mechanism has been learned, even when predictions are extremely accurate. In a poignant example, authors evaluated the capacities of several models to predict the probability of death for patients with pneumonia admitted to an intensive care unit [107,108]. The neural network model achieved the best predictive accuracy. However, after fitting a rule-based model to understand the relationships inherent to their data better, the authors discovered that the hospital data implied the rule "HasAsthma (x)⇒LowerRisk(x)." This rule contradicts medical understanding, as having asthma does not make pneumonia better! Nonetheless, the data supported this rule, as pneumonia patients with a history of asthma tended to receive more aggressive care. The neural network had, therefore, also learned to make predictions according to this rule despite the fact that it has nothing to do with causality or mechanism. Therefore, it would have been disastrous to guide treatment decisions according to the predictions of the neural network, even though the neural network had high predictive accuracy.

It is critical to avoid over interpreting deep learning models by viewing them for what they are: complex statistical models trained on high dimensional data. If causal inference is desired, special techniques for causal inference are required [109].

Tip 10: Actively consider the ethical implications of your work

While deep learning continues to be a powerful, transformative tool within life sciences research—spanning from basic biology and preclinical science to varied translational approaches and clinical studies—it is important to comment on ethical considerations. For instance, despite the fact that deep learning methods are helping to increase medical efficiency through improved diagnostic capability and risk assessment, certain biases may be inadvertently introduced into models related to patient age, race, and gender [110]. Deep learning practitioners may make use of datasets not representative of diverse populations and patient characteristics [111], thereby contributing to these problems.

Therefore, it is important to think thoroughly and cautiously about deep learning applications and their potential impact to persons and society. This includes being mindful of possible harms, injustices, and other types of wrongdoing. At a minimum, practitioners must ensure that, wherever relevant, their life sciences projects are fully compliant with local research governance and approval policies, legal requirements, Institutional Review Board policies, and any other relevant bodies and standards. Moreover, we offer below 3 tangible, action-oriented recommendations to further empower and enrichen deep learning researchers.

First, just as it is a best practice to keep a project-specific or programming-related issue tracker detailing known bugs and other technical issues, practitioners should get into the habit of keeping an active ethics register. In this register, ethical concerns can be raised, recorded, and resolved, exactly as software problems are triaged and fixed. Because projects using deep learning usually rely on writing code, an ethics register can be a part of the issue tracker in the version control system for the software itself. By colocating the two, practitioners can operationalize the concept that ethical problems are "bugs" that must be resolved, not nice-to-haves that can be considered at some indefinite point in the future. For practitioners intending to distribute trained models, having an ethics register can also facilitate creating a model card [112], a short document specifying the domains in which the model's performance was validated (for example, which model organism was used), how the performance was benchmarked, and known limitations and concerns. Second, to help foster a conscious ethics-oriented mindset, researchers should consider expanding journal clubs to include scholarly and popular articles detailing real-world ethics issues relevant to their scientific fields. This will help researchers to think more holistically and judiciously about their work and its implications. Third, we encourage individual- and team-level participation in professional societies [113] and other types of organizations [114] and events [115] related to the domains of artificial intelligence and data ethics as well as bioethics. This will encourage a sense of community and intellectual engagement and will keep practitioners abreast of cutting-edge insights and emerging professional standards.

Furthermore, practitioners may encounter datasets that cannot be shared, such as ones for which there would be significant ethical or legal issues associated with their release [116]. Examples of such data include classified or confidential data, biological data related to trade secrets, medical records, or other personally identifiable information [117]. While deep learning models can capture information-rich abstractions of multiple features of the data during the training process, these features may be more prone to leak the data that they were trained over if the model is shared or allowed to be queried with arbitrary inputs [118,119]. In other words, the complex relationships learned about the input data can potentially be used to infer characteristics about the original dataset, which reflects the facts that the strengths that imbue deep learning with its great predictive capacity may also raise the level of risk surrounding data privacy. Therefore, while there is tremendous promise for deep learning techniques to extract information that cannot readily be captured by traditional methods [120], it is imperative not

to share models trained on sensitive data. This also holds true for certain traditional machine learning methods that learn by capturing specific details of the full training data (for example, *k*-nearest neighbors models).

Techniques to train deep neural networks without sharing unencrypted access to data are being advanced through implementations of homomorphic encryption, which serves to enable equivalent prediction on data that is encrypted end-to-end [121,122]. Privacy-preserving techniques [123], such as differential privacy [124–126], can help to mitigate risks as long as the assumptions underlying these techniques are met. Other methods, such a distributed learning, in which small subsets of the data are processed independently in silos (possibly by different agents), are also promising but require careful investigation before applying to protected information [127]. While these methods provide a path toward a future where trained models and their predictions can be shared, more software development and theoretical advances will be required to make these techniques easy to apply correctly in many settings. Unless using these techniques, researchers must not share the weights or provide arbitrary access to the predictions of models trained on sensitive data.

Conclusions

Collectively, we have presented practical tips that emphasize cutting-edge insights and describe evolving professional standards. In addition, a number of our points are focused on safeguarding against the risks inherent to data science and deep learning. These risks include the over interpretation and misinterpretation of models, poor generalizability, and the potential to harm others. However, we want to strongly emphasize that when used ethically and responsibly, deep learning techniques have the potential to add tremendous value across a diverse range of contexts. After all, these techniques have already shown a remarkable capacity to meet or exceed the performance of both humans and traditional algorithms and have the potential to uncover biomedical insights that drive discovery and innovation. By taking a comprehensive and careful approach to deep learning based on critical thinking about research questions, planning to maintain rigor, and discerning how work might have far-reaching consequences with ethical dimensions, the life science community can advance reproducible, interpretable, and high-quality science that is enriching and beneficial for both scientists and society.

Acknowledgments

The authors would like the thank Daniel Himmelstein and the developers of Manubot for creating the software that enabled the collaborative composition of this manuscript. We would also like to thank Fábio Madeira (0000-0001-8728-9449), Victor Greiff (0000-0003-2622-5032), Shyam Saladi (0000-0001-9701-3059), Anshul Kundaje (0000-0003-3084-2287), Brett K. Beaulieu-Jones (0000-0002-6700-1468), Paul Brodersen (0000-0001-5216-7863), Michael M. Hoffman (0000-0002-4517-1562), and Isaac Lazzeri for their contributions to the discussions that comprised the initial stage of the drafting process.

D.13 Image analysis and models of cells

Further explanations for Chapter 13.

D.13.1 Images as data

- Bankhead (2022) — An open textbook on what digital images are, how they are processed and measured, and how to avoid common mistakes; the best starting point for the classical part of image analysis. *(book chapter; CC BY 4.0)*

  Introduction to Bioimage Analysis. Bankhead (2022). *Online book*. https://bioimagebook.github.io/

- Moore et al. (2023) — Explains why large image data need new file formats and metadata standards, and how OME-Zarr is used to share them. *(review; CC BY 4.0)*

  OME-Zarr: a cloud-optimized bioimaging file format with international community support. Moore et al. (2023). *Histochemistry and Cell Biology*. doi:10.1007/s00418-023-02209-1

  > A growing community is constructing a next-generation file format (NGFF) for bioimaging to overcome problems of scalability and heterogeneity. Organized by the Open Microscopy Environment (OME), individuals and institutes across diverse modalities facing these problems have designed a format specification process (OME-NGFF) to address these needs. This paper brings together a wide range of those community members to describe the cloud-optimized format itself-OME-Zarr-along with tools and data resources available today to increase FAIR access and remove barriers in the scientific process. The current momentum offers an opportunity to unify a key component of the bioimaging domain-the file format that underlies so many personal, institutional, and global data management and analysis tasks.

D.13.2 Deep learning for images

- Hallou et al. (2021) — A clear introduction to classification, segmentation, tracking and restoration with deep learning, written for biologists, with practical advice on training data and validation. *(review; CC BY 4.0)*

  Deep learning for bioimage analysis in developmental biology. Hallou et al. (2021). *Development*. doi:10.1242/dev.199616

  > Deep learning has transformed the way large and complex image datasets can be processed, reshaping what is possible in bioimage analysis. As the complexity and size of bioimage data continues to grow, this new analysis paradigm is becoming increasingly ubiquitous. In this Review, we begin by introducing the concepts needed for beginners to understand deep learning. We then review how deep learning has impacted bioimage analysis and explore the open-source resources available to integrate it into a research project. Finally, we discuss the future of deep learning applied to cell and developmental biology. We analyze how state-of-the-art methodologies have the potential to transform our understanding of biological systems through new image-based analysis and modelling that integrate multimodal inputs in space and time.

- Chamier et al. (2021) — Describes notebooks for training common networks (U-Net, StarDist, CARE and others) without installing software; useful for trying the methods yourself. *(tutorial; CC BY 4.0)*

  Democratising deep learning for microscopy with ZeroCostDL4Mic. von Chamier et al. (2021). *Nature Communications*. doi:10.1038/s41467-021-22518-0

> Deep Learning (DL) methods are powerful analytical tools for microscopy and can outperform conventional image processing pipelines. Despite the enthusiasm and innovations fuelled by DL technology, the need to access powerful and compatible resources to train DL networks leads to an accessibility barrier that novice users often find difficult to overcome. Here, we present ZeroCostDL4Mic, an entry-level platform simplifying DL access by leveraging the free, cloud-based computational resources of Google Colab. ZeroCostDL4Mic allows researchers with no coding expertise to train and apply key DL networks to perform tasks including segmentation (using U-Net and StarDist), object detection (using YOLOv2), denoising (using CARE and Noise2Void), super-resolution microscopy (using Deep-STORM), and image-to-image translation (using Label-free prediction - fnet, pix2pix and CycleGAN). Importantly, we provide suitable quantitative tools for each network to evaluate model performance, allowing model optimisation. We demonstrate the application of the platform to study multiple biological processes.

D.13.3 Image-based profiling

- Caicedo et al. (2017) — The standard description of the profiling workflow, from illumination correction and feature extraction to normalisation, batch correction and similarity measures. *(review; CC BY 4.0)*

  Data-analysis strategies for image-based cell profiling. Caicedo et al. (2017). *Nature Methods*. doi:10.1038/nmeth.4397

  > Image-based cell profiling is a high-throughput strategy for the quantification of phenotypic differences among a variety of cell populations. It paves the way to studying biological systems on a large scale by using chemical and genetic perturbations. The general workflow for this technology involves image acquisition with high-throughput microscopy systems and subsequent image processing and analysis. Here, we introduce the steps required to create high-quality image-based (i.e., morphological) profiles from a collection of microscopy images. We recommend techniques that have proven useful in each stage of the data analysis process, on the basis of the experience of 20 laboratories worldwide that are refining their image-based cell-profiling methodologies in pursuit of biological discovery. The recommended techniques cover alternatives that may suit various biological goals, experimental designs, and laboratories' preferences.

- Stirling et al. (2021) — Describes the most widely used software for extracting features from Cell Painting and other screens. *(tutorial; CC BY 4.0)*

  CellProfiler 4: improvements in speed, utility and usability. Stirling et al. (2021). *BMC Bioinformatics*. doi:10.1186/s12859-021-04344-9

  > Background Imaging data contains a substantial amount of information which can be difficult to evaluate by eye. With the expansion of high throughput microscopy methodologies producing increasingly large datasets, automated and objective analysis of the resulting images is essential to effectively extract biological information from this data. CellProfiler is a free, open source image analysis program which enables researchers to generate modular pipelines with which to process microscopy images into interpretable measurements. Results Herein we describe CellProfiler 4, a new version of this software with expanded functionality. Based on user feedback, we have made several user interface refinements to improve the usability of the software. We introduced new modules to expand the capabilities of the software. We also evaluated performance and made targeted optimizations to reduce the time and cost associated with running common large-scale analysis pipelines. Conclusions CellProfiler 4 provides significantly improved performance in complex workflows compared to previous versions. This release will ensure that researchers will have continued access to CellProfiler's powerful computational tools in the coming years.

D.13.4 Protein localisation from images

- Xiao et al. (2024) — Reviews both sequence-based and image-based prediction of localisation, and so connects this section with the sequence-based methods of chapter 10. *(review; CC BY 4.0)*

  A Review for Artificial Intelligence Based Protein Subcellular Localization. Xiao et al. (2024). *Biomolecules*. doi:10.3390/biom14040409

> Proteins need to be located in appropriate spatiotemporal contexts to carry out their diverse biological functions. Mislocalized proteins may lead to a broad range of diseases, such as cancer and Alzheimer's disease. Knowing where a target protein resides within a cell will give insights into tailored drug design for a disease. As the gold validation standard, the conventional wet lab uses fluorescent microscopy imaging, immunoelectron microscopy, and fluorescent biomarker tags for protein subcellular location identification. However, the booming era of proteomics and high-throughput sequencing generates tons of newly discovered proteins, making protein subcellular localization by wet-lab experiments a mission impossible. To tackle this concern, in the past decades, artificial intelligence (AI) and machine learning (ML), especially deep learning methods, have made significant progress in this research area. In this article, we review the latest advances in AI-based method development in three typical types of approaches, including sequence-based, knowledge-based, and image-based methods. We also elaborately discuss existing challenges and future directions in AI-based method development in this research field.

- Kobayashi et al. (2022) — A readable example of how self-supervised learning on images groups proteins by localisation without labels (cytoself). *(primary study; CC BY 4.0)*

  Self-supervised deep learning encodes high-resolution features of protein subcellular localization. Kobayashi et al. (2022). *Nature Methods*. doi:10.1038/s41592-022-01541-z

  > Explaining the diversity and complexity of protein localization is essential to fully understand cellular architecture. Here we present cytoself, a deep-learning approach for fully self-supervised protein localization profiling and clustering. Cytoself leverages a self-supervised training scheme that does not require preexisting knowledge, categories or annotations. Training cytoself on images of 1,311 endogenously labeled proteins from the OpenCell database reveals a highly resolved protein localization atlas that recapitulates major scales of cellular organization, from coarse classes, such as nuclear and cytoplasmic, to the subtle localization signatures of individual protein complexes. We quantitatively validate cytoself's ability to cluster proteins into organelles and protein complexes, showing that cytoself outperforms previous self-supervised approaches. Moreover, to better understand the inner workings of our model, we dissect the emergent features from which our clustering is derived, interpret them in the context of the fluorescence images, and analyze the performance contributions of each component of our approach.

D.13.5 Tissues: multiplexed imaging and computational pathology

- Park et al. (2022) — An overview of imaging- and sequencing-based spatial methods for RNA, proteins and other molecules, and how they are combined. *(review; CC BY 4.0)*

  Spatial omics technologies at multimodal and single cell/subcellular level. Park et al. (2022). *Genome Biology*. doi:10.1186/s13059-022-02824-6

  > Spatial omics technologies enable a deeper understanding of cellular organizations and interactions within a tissue of interest. These assays can identify specific compartments or regions in a tissue with differential transcript or protein abundance, delineate their interactions, and complement other methods in defining cellular phenotypes. A variety of spatial methodologies are being developed and commercialized; however, these techniques differ in spatial resolution, multiplexing capability, scale/throughput, and coverage. Here, we review the current and prospective landscape of single cell to subcellular resolution spatial omics technologies and analysis tools to provide a comprehensive picture for both research and clinical applications.

- Howard et al. (2021) — Shows how hidden differences between hospitals inflate the apparent accuracy of pathology models; a good case study of data leakage. *(primary study; CC BY 4.0)*

  The impact of site-specific digital histology signatures on deep learning model accuracy and bias. Howard et al. (2021). *Nature Communications*. doi:10.1038/s41467-021-24698-1

  > The Cancer Genome Atlas (TCGA) is one of the largest biorepositories of digital histology. Deep learning (DL) models have been trained on TCGA to predict numerous features directly from histology, including survival, gene expression patterns, and driver mutations. However, we demonstrate that these features vary substantially across tissue submitting sites in TCGA for over 3,000 patients with six cancer subtypes. Additionally, we show that histologic image differences between submitting sites can easily be identified with DL. Site detection remains possible despite commonly used color normalization and augmentation

methods, and we quantify the image characteristics constituting this site-specific digital histology signature. We demonstrate that these site-specific signatures lead to biased accuracy for prediction of features including survival, genomic mutations, and tumor stage. Furthermore, ethnicity can also be inferred from site-specific signatures, which must be accounted for to ensure equitable application of DL. These site-specific signatures can lead to overoptimistic estimates of model performance, and we propose a quadratic programming method that abrogates this bias by ensuring models are not trained and validated on samples from the same site.

D.13.6 Cell atlases and virtual cells

- Regev et al. (2017) — The white paper that defined the aims of the Human Cell Atlas, including what is meant by a cell type and why images and locations are part of it. *(perspective; CC BY 4.0)*

  The Human Cell Atlas. Regev et al. (2017). *eLife*. doi:10.7554/elife.27041

  > The recent advent of methods for high-throughput single-cell molecular profiling has catalyzed a growing sense in the scientific community that the time is ripe to complete the 150-year-old effort to identify all cell types in the human body. The Human Cell Atlas Project is an international collaborative effort that aims to define all human cell types in terms of distinctive molecular profiles (such as gene expression profiles) and to connect this information with classical cellular descriptions (such as location and morphology). An open comprehensive reference map of the molecular state of cells in healthy human tissues would propel the systematic study of physiological states, developmental trajectories, regulatory circuitry and interactions of cells, and also provide a framework for understanding cellular dysregulation in human disease. Here we describe the idea, its potential utility, early proofs-of-concept, and some design considerations for the Human Cell Atlas, including a commitment to open data, code, and community.

- Kedzierska et al. (2025) — A careful evaluation of single-cell foundation models against simple baselines; useful for discussing what virtual cell models can and cannot yet do. *(primary study; CC BY 4.0)*

  Zero-shot evaluation reveals limitations of single-cell foundation models. Kedzierska et al. (2025). *Genome Biology*. doi:10.1186/s13059-025-03574-x

  > Foundation models such as scGPT and Geneformer have not been rigorously evaluated in a setting where they are used without any further training (i.e., zero-shot). Understanding the performance of models in zero-shot settings is critical to applications that exclude the ability to fine-tune, such as discovery settings where labels are unknown. Our evaluation of the zero-shot performance of Geneformer and scGPT suggests that, in some cases, these models may face reliability challenges and could be outperformed by simpler methods. Our findings underscore the importance of zero-shot evaluations in development and deployment of foundation models in single-cell research.

Abstract

Recent advances in cryo-electron microscopy have marked only the beginning of the potential of this technique. To bring structure into cell biology, the modality of cryo-electron tomography has fast developed into a bona fide in situ structural biology technique where structures are determined in their native environment, the cell. Nearly every step of the cryo-focused ion beam-assisted electron tomography (cryo-FIB-ET) workflow has been improved upon in the past decade, since the first windows were carved into cells, unveiling macromolecular networks in near-native conditions. By bridging structural and cell biology, cryo-FIB-ET is advancing our understanding of structure–function relationships in their native environment and becoming a tool for discovering new biology.

Keywords

cryo-electron tomography; in situ structural biology; quantitative cell biology; biophysical modeling; molecular architecture

INTRODUCTION

Since the 1940s, direct visualization into the inner working of a cell by conventional transmission electron microscopy (TEM) has facilitated discoveries and generated both new hypotheses and awe as researchers peered directly into the complex and heterogeneous cellular environment for the first time (154). TEM experiments on cells that were fixed, permeabilized, and stained, a process referred to as conventional TEM, gave way to high-pressure freezing (HPF) methods and freeze-substitution, which allowed researchers to inch closer to native conditions and better visualize a cell's interior. Separately, the development of direct electron detector devices (DDDs) and new image processing algorithms precipitated the resolution revolution in single-particle cryo-electron microscopy (cryo-EM) (81). These technical developments further facilitated high-resolution 3D reconstructions of in vitro samples determined, not by combining thousands of 2D

projections of different particles of the same kind (single-particle cryo-EM), but from projections acquired at multiple orientations or tilts of the same sample (tomography) (101, 127). The next hurdle was to visualize these macromolecules directly in cells (in situ or in cellulo), without any fixation, sectioning, or other perturbations. How could one achieve this? By borrowing techniques from materials science and by operating under cryogenic temperatures, researchers carved out a whole new field in which they could open windows directly into the complex cellular environment using focused ion beam (FIB) milling (94). The preservation of high-resolution information created a new field of structural cell biology studies in which subtomogram analysis, combined with other methods such as integrative modeling, has expanded how structure–function relationships can be explored and investigated (8, 94).

BACKGROUND

Investigating how individual macromolecules organize to perform all functions in the cell, e.g., cellular growth, division, and migration, requires understanding how individual small players act in concert, resulting in emergent properties that accomplish larger tasks. Macromolecular complexes are roughly tens of nanometers across (102), and their interactions are governed by chemical bonds, electrostatic interactions, hydrogen bonds, and van der Waals forces. These proteins and macromolecular complexes then assemble to form structures that are micrometers in size (e.g., organelles, filaments). Investigating structure–function relationships in situ requires the ability to image across multiple length scales. Investigating how these distinct structures function in their native environment requires the ability to visualize macromolecules that are minimally perturbed. By imaging across multiple length scales (from angstroms to microns), an electron microscopist can investigate assemblies at the molecular level and also define relevant spatial relationships—all within a single cell. Furthermore, new discoveries can be made via electron microscopy (EM) because the interaction between the electron beam and the sample occurs for all atoms in the sample that are subsequently captured in the resulting image. This is in contrast to fluorescence microscopy, in which prior knowledge and labeling of key macromolecules are required for further investigation of their molecular function, and only labeled molecules are captured in the image. Essentially, an electron beam sees all.

Cryo-electron tomography (cryo-ET) is a modality of TEM in which a flash-frozen sample is imaged at multiple orientations by tilting the sample. The resulting collection of images, or tilt series, is aligned to reconstruct the sample in three dimensions into a tomogram, where the intensities in a sample are roughly proportional to the mass of the underlying atoms (159). From the tomogram, one can extract specific regions containing macromolecules of interest. These subtomograms can then be extracted, aligned, averaged, and further analyzed to obtain 3D structures of molecular complexes, a technique called subtomogram analysis (STA). In a proof of the principle that high-resolution information can be recovered from in situ data, a recent cryo-ET reconstruction of a ribosome stalled during protein translation was resolved to 3.4 Å (137). However, as only transmitted electrons are detected, there is a strict thickness limitation to this methodology. The mean free path of 300 keV electrons was determined to be 280 nm for free vesicles in cryogenic conditions (66, 97, 119, 162). Larger thicknesses result in multiple interactions

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

of the electrons with the sample, dramatically reducing the signal-to-noise ratio (SNR) in the images. As most cells are thicker than 500 nm, samples need to be thinned. In the past decade, this limitation was overcome by cryo-FIB milling (141, 144). This technique ablates away most of the cellular material, leaving behind a window of several to tens of microns in *x* and *y*, with a thickness of approximately 80–300 nm. Cryo-FIB-ET is the highest-resolution technique available to image macromolecules inside cells, and an ever increasing number of landmark discoveries have been made in the past decade using this technology (1, 3, 47, 48). In this review, we describe the cryo-FIB-ET workflow, the recent advances in the field (sample preparation, data acquisition, and analysis),the integration with other methods, considerations for designing a successful project, and an outlook for the field.

THE CRYO-FOCUSED ION BEAM MILLING AND ELECTRON TOMOGRAPHY WORKFLOW

Most commonly, cultured cells are grown or deposited onto an EM grid, and the sample is then rapidly frozen into a noncrystalline, glass-like vitrified state by plunging it into liquid ethane cooled to liquid nitrogen temperature. The result is preservation of macromolecular structures in their cellular networks in near-native conditions (40, 72). The sample is then transferred under cryogenic conditions (liquid nitrogen temperature) to a dual beam microscope equipped with an FIB and a scanning electron microscope (SEM); the FIB-SEM is routinely used within materials science for microstructural analysis, chip editing, nanomachining, and sample preparation for TEM (61). For vitrified cells, regions above and below the region of interest are selectively ablated as the FIB rasters across, removing cellular material via the interaction between an ion source, typically of gallium, and the sample in a process referred to as milling (94, 145). The resulting lamella is milled to a thickness of 80–300 nm (94, 145). The sample is transferred to a TEM, and regions of interest within the lamellae are imaged at different tilt angles to collect a tilt series that is later aligned and reconstructed computationally to generate a 3D volume or tomogram. The resulting tomogram shows the interior of the cell in three dimensions at the highest achievable resolution without fixation or perturbation (see Figure 1). Detailed workflows for cryo-FIB milling and electron tomography (cryo-FIB-ET) are available (82, 123, 143).

ADVANCES IN THE CRYO-FOCUSED ION BEAM WORKFLOW

Recent improvements in the cryo-FIB-ET workflow have dramatically increased sample throughput, experimental handling, and improved data collection. For adherent cells, the first step in this workflow is seeding cells on an EM grid. Adaptation of micropatterning to EM grids enabled the control of the position, size, and shape of adherent cells on the EM grid (138). Added to this, 3D-printed holders for EM grids can minimize grid handling mishaps (49). It is unfortunate, after preparing a lamella, to discover that it is not suitable for high-resolution TEM data acquisition. This unsuitability could be due to lamellae being too thick, broken, badly vitrified, or contaminated during transfers, among others. Recent advances in the FIB milling process have resulted in more optimal lamellae that are more stable, have reduced ice contamination, and notably can be generated through automation.

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

The stability of the lamella has been made more robust through stress-reducing expansion joints, or trenches, around the lamella site (157). A cryo-glove box was developed to reduce contamination during sample transfer (136). Incubating samples in 10% glycerol improved the vitrification of large samples, i.e., the peripheral nervous system tissues from *Drosophila* (7). Another challenge is that milling can result in curtains due to differential sputtering rates in cellular compositions, ice contamination, or milling at high currents for an extensive period of time (82, 123). Platinum deposition and sputtering alleviate some curtaining effects, as described below. To alleviate persistent curtaining and improve visual interpretability, curtain artifacts can be removed in silico, with regions of interest targeted on the postprocessed image (7). Finally, through FIB milling automation, sample throughput has improved, and a user is now able to generate up to 20 lamellae in a session through software automation (79, 80, 136, 163).

Newer methods for dealing with a diverse set of samples have expanded what can be imaged by this technique. Tissues, or other thick specimens, cannot be fully vitrified by plunge freezing due to inadequate heat transfer (133) but can be vitrified through HPF. After HPF, a section of the specimen is carved using the FIB, lifted out from the sample, transferred to a new grid placed in the same shuttle within the FIB-SEM instrument, and then further thinned down to generate a 100–300 nm lamella through a method referred to as lift out (93). A recent study used in situ sputtering from the micromanipulator to enable cryogenic preparation of specimens for atom probe tomography by FIB, enabling the analysis of silicon content within a sample (39).

As an alternative to lift out, the inventive waffle method makes cryo-FIB-ET more amenable to thick specimens; specimens that orient preferably on an EM grid, e.g., bacteria that lie along their long axis; and specimens that require a high local concentration, e.g., cells that need to grow to confluency (75). In this method, the sample is applied to the backside of an EM grid and is then high-pressure frozen, thereby achieving high uniform density, which facilitates cells orienting in multiple directions (75).

Recently, the types of ion sources used during the cryo-FIB milling process have been expanded to include plasma from gases including oxygen, nitrogen, argon, and xenon. Initial studies suggest that these gases may induce less damage from the ion beam and lead to higher-resolution data (12, 129).

Data Collection

After producing a beautiful (or at least usable) lamella, the user must decide on a data collection scheme (Figure 2). A tilt series is a collection of images of a sample at different tilt angles. Each of these images is called a projection, as it collapses the 3D information of the sample along the optical path of the microscope into two dimensions (58). Because biological macromolecules are low atomic weight, they are considered to be weak-phase objects, as the generated contrast is weak. Image contrast is achieved by shifting the focal plane via defocusing the objective lens (62). This image defocus, along with other factors, introduces variations in the image described by the contrast transfer function (CTF) that can be corrected to retrieve a more accurate representation of the sample (51). Tilt series acquisition that produces a high-accuracy reconstruction in three dimensions relies

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

on several factors, including stage and sample stability; lamella thickness; location of the feature of interest within the lamella; and, once the data are acquired, the ability to align each projection in the tilt series and CTF correct it. During data collection, additional images are typically acquired to ensure that the field of view remains centered in the area of interest (*XY* tracking) and at the same defocus (*Z*). Subsequently, to align the tilt series accurately for 3D reconstruction, features in the images of the tilt series must be followed from one image to the next (fiducials). Gold beads are electron dense and are utilized extensively for in vitro cryo-ET; these fiducials enable accurate focus and tracking during collection and tilt series alignment post-collection (147). In most cases, membranes and other features present in the cells can be used as fiducials for tilt series alignment. In one attempt to improve alignments for in situ studies, researchers added gold beads to the cell culture media; these gold beads were endocytosed, becoming fiducials within the lamella (13).

How the tilt series should be collected depends on several factors, including the scientific question, how the data will be analyzed, and sample quality. Software packages offer flexibility in tilt series acquisition; these include the academic packages SerialEM and Leginon (98, 134) and the commercial packages Tomography 5 (Thermo Fisher Scientific), Latitude (Gatan), and Recorder (JEOL). These packages allow the user to control parameters such as acquisition scheme, tilt range, tilt increment, dose, magnification, and target defocus. SerialEM is a broadly used and reliable package that is ideal to test new schemes while offering out-of-the box solutions, including automated tomography data collection (98). National Institutes of Health funding and user-contributed support of SerialEM facilitates such innovation by providing a platform on which users can develop and disseminate their own schemes for data collection.

A major consideration when acquiring data is the accumulated radiation damage to target areas of acquisition (65). When collecting 2D data [as in single-particle analysis (SPA) and 2D template matching, introduced below)], a single movie is acquired with a total fluence (commonly referred to as dose) of 60–120 e^{-}/A^{2}. In tomography, the total dose that a sample experiences has to be distributed among many images in the tilt series. The choice of how to distribute the dose determines how well the individual images can be aligned to others in the tilt series and which images have the most information: The projections generated from early stages in data collection will contain the least amount of radiation damage and the best-quality high-resolution information. A variety of tilt series acquisition schemes are available depending on such considerations.

Collection schemes include continuous collection, in which the sample is tilted to the maximum tilt angle on one side (e.g., –70°) and then toward the maximum tilt angle on the other side (e.g., +70°). The benefits of this scheme are speed of data acquisition and minimal stage perturbations. However, when acquiring a tilt series, the effective thickness of the sample increases as the sample tilts from 0° to 70° because there is more material for the beam to pass through at high tilts (the thickness increases as 1/cos of the tilt angle). Thus, the detriment of continuous collection is that the initial dose, when the sample is most undisturbed by radiation, is spent on high-tilt images, where the sample will be the thickest, resulting in a lower-contrast image. A commonly used bidirectional collection scheme starts at 0° (or at the angle where the lamella is thinnest, compensating for its pretilt), moves

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

toward the highest angle in one direction, and then returns to the initial position, collecting until it reaches the maximum tilt angle in the other direction. A bidirectional tilt series will result in two halves, and since the adjacent projection images at the lower tilts will have experienced different amounts of accumulated dose, there is often a problem aligning the tilt series. Additionally, since the sample is thinnest at the low tilt angles, it is at these angles that the images can be attained at high resolution; however, in the bidirectional scheme, at low tilt angles on one side, the sample has received significant electron dose, and thus high-resolution information is lost (139). To maximize initial dose at lower tilts while still producing a smooth reconstruction, Hagen et al. (67) developed the dose-symmetric (DS) scheme, also known as the Hagen scheme, in which acquisition begins at 0° (or the lamella pretilt) and alternates between positive or negative tilt angles along the tilt range. A thorough comparison among these schemes via STA of in vitro data concluded that the DS scheme resulted in the highest attainable resolution (139).

Beyond optimizing for individual tilt series, new collection schemes have been described that can (*a*) decrease the amount of time for sets of tilt series to be acquired and further boost the throughput of data collection, (*b*) improve the CTF estimation and correction, and/or (*c*) collect data in a way that allows better utilization of high-resolution information (Figure 2).

Single versus dual tilt and continuous acquisition.—Tomography data typically suffer from a missing wedge, since samples cannot be tilted to obtain tilt projections in the full range (–90 to 90°) (124). Multi-tilt axis tomography can reduce this missing information from a wedge to a pyramid or cone (112). The Titan Krios (Thermo Fisher Scientific) was designed initially to tilt along two orthogonal tilt axes. However, it was determined that, due to radiation damage, dual-axis tilt series collection did not offer an advantage over single-axis tilt series collection (28, 41). Thus, new-generation microscopes have a single-tilt holder with improved mechanical stability. Using a single-tilt holder, researchers demonstrated that one could dramatically reduce data collection time to minutes by setting the camera to acquire one continuous movie during the tilt scheme (28, 41), with the electron beam blanked when the stage moves between tilt angles and for a preset amount of time afterward to allow the stage to settle; this is referred to as the fast-incremental method (28, 41).

Beam shifts reduce acquisition time.—The rate-limiting step for TEM data collection is waiting for minimal stage drift following stage movements due to stage motor vibrations (27). In SPA, it is routine to use beam shifts rather than stage shifts, obviating the need for settling times and thus increasing the number of attainable targets, as a central focus and tracking area is employed and the beam is then tilted to desired target sites for data collection (27). Data collection is >720 micrographs per hour for a K3 using image shift, a roughly 10-fold increase compared to stage shift (111). Post-collection, the beam tilt is estimated and corrected during CTF estimation (167).

The challenge to implementing this method for tomography is that the distance between a central focus and tracking area and the target point changes during the tilt series acquisition. Beam-image shift electron cryo-tomography (BISECT) was able to adapt this beam-image shift for in vitro tomography by determining relevant geometric constraints (16). BISECT

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

reduced tilt series acquisition time to mere minutes, without compromising data quality, when comparing STA results to collection by the DS method (16). In multishot tomography, researchers implemented beam-tilt image shift by acquiring a multishot tilt series along the tilt axis (77). Unfortunately, cellular features of interest within a lamella are not likely to be arranged neatly along the tilt axis. To overcome this problem, a third group developed the parallel cryo-electron tomography (Pace-Tomo) acquisition scheme, which utilizes a geometric model of the lamella that accounts for the lamella pretilt and sample geometry, and also developed an empirically determined defocus ramp that reduces errors in the tilt axis offset (42). With both Pace-Tomo and multishot tomography, researchers achieved 8 Å reconstructions of an in situ ribosome (16, 42).

The best of both worlds? Hybrid subtomogram analysis and single-particle analysis.—In tilt series collection, a total electron dose of 80–200 e^{-}/A^{2} is divided along the entire tilt range. This results in a low SNR for each tilt image, since 1–3 e^{-}/A^{2} is spent on a tilt image, depending on total dose, tilt increment, and tilt range. A few hybrid STA-SPA (hSTA) workflows have been described wherein a higher-electron-dose image is acquired at the 0° tilt angle, followed by a DS tilt series for the remaining projections (121). The initial high-dose image at 0° has a higher SNR, resulting in a better defocus estimation and CTF correction. Using hSTA, Sanchez et al. (121) improved the resolution of the Tobacco Mosaic Virus (TMV) from 7.2 Å to 4.4 Å compared to a DS tilt series. Similarly, TYGRESS implemented a hybrid workflow: At 0°, the specimen is exposed to an initial high dose (30 e^{-}/A^{2}), followed by a regular low dose; a DS tilt series is collected afterward (131). In subsequent STA, the high-dose image is used for CTF estimation.

Capturing the full picture (montage data collection).—The choice of magnification, and thus field of view, is a compromise between the area that needs to be included in the tilt series and the pixel size, which determines the limit to resolution (151). Another consideration is that higher magnification also results in higher total doses: The dose in an individual image increases as $1/r^{2}$, where r is the pixel size. For research inquiries that would benefit from a large field of view without decreasing magnification or resolution, it would be advantageous to obtain one exhaustive tomogram of the entire lamella. This idea was initially developed for tomography of data collected from resin-embedded samples (113). By collecting cryo-ET data composed of overlapping fields of view, two studies tiled multiple images to create one massive montaged tomogram with a large field of view (110, 161).

2D template matching.—For in situ STA, the ability to obtain high-resolution structures, or to unveil multiple conformational and compositional states, can be limited by the number of particles that can be extracted from the data. This limitation can be due to abundance of the macromolecule of interest in cells, the number of in situ conformational or compositional states (e.g., transient interactions), or other factors. Even more challenging is how to find these particles in the crowded environment of the cell, where most proteins have similar shapes and molecular weights. How can we identify our particles of interest and generate high-resolution reconstructions? One powerful idea is to avoid tilt series acquisition and instead acquire a low-defocus and low-dose (approximately $30e^{-}/A^{2}$) 2D projection (120). Using the high-resolution information, users search for particles by template matching

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

in two dimensions, determining the position in X-Y and orientation within the sample as defocus estimation is used to determine the localization along the optical axis (Z). Once these parameters are determined, the particles in two dimensions can be used for averaging to obtain high-resolution 3D reconstructions (89). In a follow-up study, Lucas et al. (90) used this method to locate ribosomal subunits in the nucleus of a yeast cell and found that homolog templates were enough to find relevant particles, with which they could identify and resolve 60S maturation intermediates in situ. Expanding this idea to the entire lamella, in the defocus correction large area cryo-EM (DeCo-LACE) method, a large field of view was collected at low defocus values, enabling the identification of ribosomes at low defocus within the cell by 2D template matching (44). This powerful technique promises to be the key to locating proteins in crowded environments and using high-resolution information to determine their structures, provided that there are templates to search for and that enough particles can be found within the data (see Figure 3).

Phase plate.—In TEM, contrast is generated by defocusing the objective lens, and spatial information is recovered by estimating and correcting the CTF. The Volta phase plate (VPP) generates phase contrast by introducing a phase shift between the scattered and unscattered electron waves (35). Since the VPP is a physical material that is exposed to the EM beam, the phase shift evolves over time and needs to be monitored (35). Examples of VPP use for enhancing contrast for tomographic studies include initial work visualizing the nuclear periphery by cryo-FIB-ET (92) and structural analysis on in situ chromatin (23, 50). The VPP does not reliably outcompete standard methods for high-resolution data determination (139). However, it has excited the field due to the possibilities of phase contrast imaging in TEM. It was recently demonstrated that the laser phase plate, a high-intensity continuous-wave laser beam, is capable of generating phase contrast imaging in TEM (128). Because the phase shift is generated by a laser and not a material, continuous exposure to the TEM beam would not affect data acquisition over time.

Scanning transmission electron microscopy.—What if we were able to acquire more than just projection images, i.e., more than just a series of gray values from our biological samples? Pioneering work using cryo-scanning TEM (STEM) has demonstrated that it is feasible to obtain spectroscopic information from biological samples (156). STEM uses a weakly convergent beam at high energy and generates an electron diffraction pattern that is then detected by bright field, annular dark field, or high-angle annular dark field detectors (43). As a proof of principle, STEM with integrated differential phase contrast mode resolved TMV to 3.5 Å but imaged with only 30 $e^{-}/Å^{2}$ (85). Such low doses would be ideal for in situ tomography.

Data Reconstruction and Analysis

Interpreting a tomogram is challenging because of the low SNR; recall that biomolecules are weak-phase objects, composed of elements of similar atomic masses, and are radiation sensitive. Additionally, biomolecules exist in a very crowded medium, and many of them have very similar overall shapes. Unequivocally identifying individual proteins or biomolecular complexes is challenging, and the type of analysis that must be performed depends on the focus of the study. Cryo-ET can be used as an imaging method or driven by

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

structure determination, whereas STA is used to determine the architecture of biomolecular complexes in situ. Computational algorithms improve the interpretability of a reconstructed 3D tomogram, facilitating data annotation (segmentation) and particle identification for STA.

Reconstruction methods.—After tilt series acquisition, tilt images are aligned and then reconstructed to generate a 3D volume or tomogram; typical methods include weighted back project (WBP) (118), simultaneous iterative reconstruction technique (SIRT), or simultaneous algebraic reconstruction technique (SART) in Image Modeler (IMOD) (100). In WBP, the 2D projection images are back-projected with a weighting function that preserves the high-frequency information that is necessary for further structure determination from the resulting 3D tomogram (57).

The quality of the reconstruction will depend on the accuracy of the tilt series alignment and the accurate correction of local motion. In situ cryo-FIB-ET cannot easily utilize fiducials to solve the tilt series alignment, as with in vitro tomography; thus, recent solutions for image misalignment work computationally. Warp and AreTomo (Alignment and Reconstruction for Electron Tomography) (165) solve for and correct for in-plane rotations, translations, and local motion. While Warp utilizes individual particles averaged from a tomogram to improve the tilt series geometry, AreTomo solves these parameters and applies those solutions to the whole tomogram.

Denoising filters, deconvolution, machine learning (ML), and deep learning (DL) algorithms improve the interpretability of noisy cryo-EM data by acting on either the input 2D projections, during the reconstruction process, or the 3D reconstruction. Denoising filters enhance the SNR and visual interpretability of whole tomograms; these filters include the non-local means filter, median filter, Sigma filter, and Gaussian filters (55). SIRT and SART filters enhance low-frequency information that is suitable for visual interpretation (147). Additional post-reconstruction filters include the non-linear anisotropic diffusion filter, which smooths and enhances edges (56).

ML and DL algorithms, which were developed for restoration of any type of image, have been adopted by denoising programs specifically for EM data. ML strategies such as Noise2Noise, Noise2Void, and Noise2Self are particularly useful when the ground truth is unknown—as it is for cryo-EM data (11, 18, 86, 137). Programs that denoise TEM projection images or tomographic volumes through DL include Warp, CryoCARE, Topaz-Denoise, and IsoNet (11, 19, 87).

Deconvolution for missing wedge mitigation.—Due to the inherent geometry of a lamella slab and data acquisition, there is a missing wedge of information in the *Z*-direction, and data collection is limited to +/–60° due to the sample holder tilt range (124). The inability to correct for this missing information, or to account for its absence, can cause artifacts in downstream analysis. Deconvolution is regularly applied to fluorescence microscopy images (122) and, more recently, STEM cryotomography (150). Croxford et al. (31) found that applying an entropy-regularized deconvolution algorithm to cryo-ET data improved the reconstruction by modeling the point spread function (PSF) of the TEM beam

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

in three dimensions, then deconvolving the back-projected 3D image with the 3D PSF to fill the missing wedge, resulting in a less isotropic reconstruction. Using experimental and synthetic data, they demonstrated that their deconvolution method fills in information in the missing wedge lost during either tilt series acquisition or WBP.

Missing wedge mitigation is also performed via isotropic reconstruction of electron tomograms with DL by IsoNet (88). IsoNet adds Gaussian noise to a training set and then iteratively improves the SNR by attempting to eliminate the added noise through DL (88). The information learned during training is then used to fill the missing wedge (88). Standards for denoising tomograms by DL would be helpful as this field progresses, as would guidelines for appropriate user implementation during data analysis. Conservative uses of a tomogram denoised through ML include visual interpretation and particle picking, always referring to the original data for further STA.

Data annotation.—After improving the contrast and SNR of a tomogram, annotation enhances the interpretability by defining the relevant features. The process of annotating features in a tomogram is referred to as segmentation. Membranes and filaments are continuous 2D and 1D objects that are readily identifiable in tomograms. Manual membrane segmentation of cellular organelles was initially traced by hand, a time-consuming process. Algorithms that automate at least part of this process include TomosegmemTV (95), Membranorama (153), and the Surface Morphometrics toolkit (5). A growing number of programs identify and annotate cellular features through artificial intelligence: DeepFinder identifies macromolecules (104), and MemBrain identifies membranes (83), as well as programs for filament identification (37).Template-free detection and classification of membrane-bound complexes in a tomogram is another useful tool (96). Complete annotation of a tomogram (membranes, filaments, and macromolecules) can be performed in EMAN2 (26). Software to visualize these annotations and utilize embedded analysis tools include Amira and DragonFly (114, 132).

Subtomogram Analysis

There are several situations in which in situ tomography is an ideally suited technique, including when the goal is to determine the structure of macromolecular assemblies as they exist in their native environment; when the proteins are deeply embedded in their environments and cannot be faithfully reconstituted outside of cells (9, 108, 130, 158); when the assemblies are transient, or multiple compositional or conformational states exist (1, 2); and when contextual information will never be faithfully recapitulated in vitro (e.g., chromatin topology). The molecular architecture of in situ complexes can be resolved by STA and combined with integrative modeling, facilitating the proposal of new structures and models. STA typically entails multiparticle refinement and its predecessor, subtomogram averaging.

Subtomogram averaging.—Following tomogram generation and the visual enhancement of choice, if your molecule of interest is present, then you would explore STA methods. We refer readers to more detailed reviews that describe current STA methodology in theory and in practice (116, 117, 147, 164). First, frames are aligned to account for

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

beam-induced motion (BIM). Then, the CTFs of the tilt images are estimated and corrected; however, because tilted images have a defocus gradient, CTF estimation correction must occur in three dimensions in its local position to accurately determine the CTF for a given particle (140). The tilt series are aligned, and a tomogram is reconstructed (99). The next step is particle picking or template matching for molecules of interest, after which subtomograms around that particle are extracted, and those subtomograms are then aligned to a reference (17). Software packages for subtomogram averaging include Dynamo, EMAN2, emClarity, RELION, and StopGap (10, 14, 24, 148). Structures determined using STA on in situ data are being published at an ever increasing pace. Often, the structures obtained test or generate existing hypotheses that can only be addressed in their natural environment. Examples include the nuclear pore complex (1, 9, 105, 166), bacterial and eukaryotic ribosomes (42, 47, 84, 107, 137), microtubules (54, 64, 135), proteasomes (2, 4), LRRK2 bound to microtubules (149), the Arp2/3 complex (48), the COPI coat (22), nucleosomes (23), a bacterial chemosensory array (20), and a bacterial gap junction (152).

Multiparticle refinement.—In situ structure determination improved significantly with the implementation of a framework in which relationships between particles within the same tomogram are solved as part of a larger system. Due to BIM and radiation damage, particles appear to move in different trajectories through a tilt series. By determining the trajectories of one set of particles, one can facilitate the alignment and translation of neighboring particles within that system (6, 137). Implementation of multiparticle refinement yielded a 3.4 Å reconstruction of an in situ stalled ribosome (137). Initially referred to and described as constrained single-particle tomography, multiparticle refinement was fully realized when it was implemented through emClarity and Warp/M (6, 69, 137). By solving the particle trajectories of one species, one can improve the trajectories of another; for example, researchers performed STA on bacterial ribosomes and then used the optimized tilt series to improve the trajectories of the target, a jumbo phage nuclear shell, chimallin, thereby improving the final reconstruction (84).

A major source of difficulty in implementing STA is migrating data between software programs. It is nontrivial to properly convert particle coordinates, metadata, etc. (21). It is not uncommon to jump among Dynamo, Warp/M, and RELION; for instance, the in-cell structure of Arp2/3 relied on all of these software packages (48). A collection of scripts that makes the move among Dynamo, Warp/M, and RELION seamless was recently published, a win for all Team Tomo members (21). Additional scripts for converting RELION-v4 starfiles are available via the RELION-4 Github.

Making the most out of angular information.—A very powerful algorithm, NEMO-TOC (NEighboring MOlecule TOpology Clustering), utilizes the coordinates and the Euler angles determined from STA to facilitate the clustering and interpretation of neighboring macromolecules such as polysomes along the same messenger RNA chain (74). There is tremendous potential to apply fully utilized refined particle coordinates to map structures and orientations in their native environment. For instance, future applications using the coordinates and refined Euler angles of in situ nucleosomes would advance our understanding of chromatin chain topology directly inside the cell.

QUANTITATIVE CELL BIOLOGY AND BIOPHYSICAL MODELING

A cellular tomogram, not unlike a painting by a Dutch master, is rich in both detail and contextual information, with diverse equally mesmerizing vignettes (T. Laughlin, personal communication). Where should one begin the analysis? One could solve the ratio of active to inactive proteasomes within a neuron (2) or measure exactly the differences in dimensions and curvature between two organelles (5, 91). Additionally, since bacteria are comparable in size to the light diffraction limit (76), their internal structure and modeling are challenging for traditional light microscopy methods, and thus many unexpected discoveries and molecular mechanisms have been resolved using cryo-FIB-ET (25).

This section highlights a few examples in which in situ tomography data have been used to better model the characters in a cell and how they interact in a quantitative and biophysical manner. This list is by no means exhaustive, but it serves as an illustration of the power of the technology as a quantitative imaging tool. The earliest work performing in situ cryo-ET studies was on the thin cellular regions, which are easily vitrified and thin enough (<300 nm) that the TEM beam could penetrate (9). Later,visualization of actin comet tails in cells infected by the bacterium *Listeria monocytogenes* facilitated biophysical models for actin branching based on X, Y, and Z coordinates determined in their native state (73).Recent work that beautifully captured actin-mediated endocytosis directly provided the basis for biophysical modeling of this fundamental event (130).

Moving further into the cell, cryo-FIB-ET studies have illuminated junctions between organelles where membrane contact sites communicate and exchange contents. Membrane contact sites are sites of lipid transfer, approximately 20 nm structures, and are difficult to resolve by other techniques. The endoplasmic reticulum (ER) contacts many other organelles, as it is the lipid factory responsible for synthesizing structural phospholipids, sterols, and storage lipids (115). What is the molecular basis for lipid exchange? Direct visualization of the molecules between the plasma membrane and the cortical ER (cER), followed by correlative light microscopy EM (CLEM), made it clear that extended synaptotagmins (tricalbins in yeast) form 16–24 nm bridges between these two organelles at regions of high cER curvature and that these bridges are Ca^{2+} dependent (30, 71).

Through STA and integrative modeling, Wozny et al. (158) recently proposed a model for lipid transport for the ER–mitochondrial encounter structure (ERMES) in which three ERMES synaptotagmin-like mitochondrial lipid-binding protein (SMP) domains stack to form a continuous structure or supramolecular organization that facilitates lipid transport between the ER and mitochondria (158).

Cryo-FIB-ET preserves membrane features extremely well and allows researchers to better visualize membrane remodeling events that occur during stress, starvation, and apoptotic conditions. Stress and starvation elicit the de novo formation of an entirely new organelle, the autophagosome. How the autophagosome is nucleated, which membranes supply lipids to the growing autophagosome, and how subsequent fusion with the lysosome or vacuole occurs are open questions. Visualizing and quantifying the entire process in nitrogen-deprived yeast via cryo-FIB-ET led to a few striking conclusions. It was revealed

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

that general macroautophagy does not require cargo targeting. Through nearest-neighbor analysis, it was determined that the phagophore comes in very close contact with many membranes—lipid droplets, the ER, the nucleus, mitochondria, and the vacuole—potentially explaining conflicting reports about which organelles supply the lipids (15). Finally, it was found that the curvature of the phagophore rim changes shape during phagophore growth, which is perhaps related to how the phagophore rim expands (15).

Observations that Yield More Questions

Cryo-FIB-ET has discovered new biology (25) and likely will continue to do so, as it is currently the highest-resolution imaging method for cell biology capable of capturing intact molecular networks, and because the imaging source is agnostic to the sample, all molecules are observed. In this section, we highlight a few unexpected observations made by cryo-FIB-ET that have raised additional questions.

While investigating the *Plasmodium* life cycle, researchers discovered microtubule protofilament diversity: 13–18 protofilament microtubules, as well as doublets, triplets, and quadruplets in the gametocyte (52). They found a pseudohelical protein within the microtubule lumen of the sporozite, the *Plasmodium* motile spore-like stage; its identity remains unknown (52). De novo structure determination or AlphaFold mining of the *Plasmodium* genome with structural constraints could perhaps yield its identity, thus realizing visual proteomics.

Models of vesicular transport through the Golgi (from *cis*-Golgi, to Golgi stacks, to *trans*-Golgi) have consolidated around the vesicle maturation model. A rather striking STA result determined that there is an array of proteins in the narrow *trans*-Golgi lumen of *Chlamydomonas* (46). These structures show high periodicity, with interactions between *cis*- and *trans*-facing arrays arranged in a zipper-like fashion, and potentially unidentified glycosyltransferases (46). As these proteins occupy the central portion of the Golgi, it suggests that modified cargo is forced into the Golgi periphery by locally narrowing the *trans*-Golgi lumen (46).

Cell biology studies on how the mitochondria undergoes fission implicated the ER in this process, as it appeared from live-cell confocal fluorescent microscopy that the ER encircled the mitochondria (60). However, in situ cryo-FIB-ET showed that mitochondrial fission directly involved actin and septin right before fission (91). Whether the ER could become involved, after actin and septin, and encircle a mitochondria is currently an open question.

How to Find Your Favorite Macromolecule

Unequivocally identifying a molecule of interest within in situ cryo-ET data remains one of the largest challenges in using this method. When peering at your tomogram, your eyes are drawn to recognizable features: large macromolecular assemblies, lipid bilayers, filaments. Thus, we have a problem—smaller, less recognizable macromolecules are hiding in plain sight, as it is hard to unequivocally identify a molecule only by a tomogram. Tools to identify your molecule of interest include cryo-fluorescence microscopy (cryo-FM), metal-based tags, and molecular tags. This section covers these technologies and what caveats and challenges exist for each.

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

CLEM

There are two steps in which fluorescence microscopy is extremely useful in targeting and identifying molecules of interest. CLEM is a well-established tool for correlating fluorescence images and EM data. Fluorescence images taken under cryogenic conditions (cryo-FM) can be used to identify which cells among the ones in the grid contain the feature of interest to generate a lamella, for instance, when thereis heterogenous protein expression, as with a transient transfection; stochastic expression due to lentiviral integration; or a rare cellular event. The resolution of a cryo-FM image is roughly 250 nm in X-Y and 500 nm in Z (36). As the desired lamella thickness is 100–300 nm, it is possible to mill through your target if you are relying on fluorescence images limited to 500 nm. The second CLEM step overlays the fluorescence image on a low-magnification TEM image of the lamella to identify molecules or features of interest. Unfortunately, correlating protein localizing between fluorescence microscopy and the TEM image is challenging, as it requires correlation between features in both, and is thus best applied to membrane-bound targets, microtubule-bound targets, or discrete assemblies rather than dispersed cytosolic targets. Nevertheless, many studies have been made possible only through CLEM. The recent development of CLEM systems installed inside the dual beam FIB-SEM microscope (63) promises a higher yield and throughput of lamellae containing the features of interest, and commercial devices using these systems are now available, including Meteor (Delmic) and iFLM (Thermo Fisher Scientific).

What about superresolution microscopy? Ideally, we would want to locate proteins of interest within a tomogram with single-molecule precision. The challenges with adopting superresolution microscopy methods for cryogenic conditions include sample devitrification from the laser source, the poor numerical aperture of an air objective lens (36), the difficulty of photoactivating a fluorophore at cryogenic conditions, and correlating the TEM and fluorescence data to high precision (125). A proof-of-principle superresolution experiment using single-molecule active control microscopy (SMACM) utilized a photoactivable protein (PAmKate) to perform correlative cryogenic SMACM and cryo-ET (CIASM, pronounced like chasm) to identify the localization of caulobacter proteins (34). One of the main challenges in this work involves heating (and devitrifying) the sample with the laser, which limits the number of fluorophores that can be detected. Using different substrates, Dahlberg et al. (33) managed to increase the density of localizations and improve correlative imaging. Use of this imaging modality in lamellae remains to be implemented, as thermal conductivity in frozen cellular samples is low. Another exciting development in the attempt to fully leverage superresolution capabilities was achieved through a custom-built liquid helium–cooled microscope, which images samples under vacuum conditions. These high-pressure frozen specimens were imaged by cryo-superresolution microscopy, thereby facilitating the study of ultrastructure relationships in intranuclear vesicles, the ER, and chromatin transcriptional domains between two imaging states: superresolution fluorescence and electron microscopy (70).

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

Other Molecular Tags

Besides tagging proteins of interest with fluorescent proteins, use of other types of tags that can be visualized directly in the TEM would dramatically expand the amount of the proteome that is accessible to cryo-ET. One possibility is to use signpost origami tags (SPOTs), which recognize and bind green fluorescent protein (GFP) through an aptamer composed of DNA origami (68). The effective distance from the target to the SPOT is roughly 70 nm, which may or may not be achievable and may disrupt the molecular networks, depending on the query.

Using nanoparticles composed of atoms with high atomic numbers to find your molecule of interest would be ideal, as biological material is mostly made of the lighter elements—carbon, nitrogen, oxygen, phosphorus, trace metals, etc. Heavy elements such as gold or iron would appear as a darker contrasting object, as the atom's nucleus is more dense by comparison to the biological sample and would scatter more electrons from the imaging source. An example of this is the FerriTag system, in which the molecule of interest is expressed as a fusion construct to GFP-FKBP, and dimerization occurs when rapamycin is supplied and FKBP binds to a coexpressed fusion of an FRB-mCherry-ferritin cage (29).The large ferritin cage is roughly 40 nm away from the molecule of interest (29).Another ferritin-based labeling strategy expressed a ferritin cage within *Escherichia coli* and was used to target specific proteins of interest (146). Additionally, a 2.2 nm nanogold particle was conjugated to designed-ankyrin repeat proteins (DARPins), which were engineered to recognize extracellular integrins on a mammalian cell and visualized by cryo-ET (32).

CRYO-ELECTRON TOMOGRAPHY BY THE NUMBERS

Above, we describe technical hurdles in cryo-ET and relevant solutions that allow us to capture macromolecules in near-native conditions; however, a greater challenge is selecting or designing the right model system. The scientific questions driving a project will determine how the data are acquired, what kind of analysis is performed, and what amount of data is required. If structure determination is the goal, then what is the resolution required? How abundant is the complex or event of interest in the cell, and thus, what is the likelihood of capturing it in a tomogram? If it is present, can it be unequivocally identified? What is the potential conformational and compositional variability of the protein or complex? The bottom-line question is how many instances of an event must be captured to better understand its structure–function relationship in situ? From this question follows another: Is in situ absolutely required?

Let us consider the fact that a typical mammalian cell is roughly 2,000 μm^3 (103) (BioNumber Identification 108244). A typical lamella is a 3D slab that is ideally approximately 100–200 nm in thickness and covers an area of approximately 10–20 μm per side (approximately 100–400 μm^2); thus, the lamella volume is approximately 10–80 μm^3, covering 0.5–4% of the cell. With the magnifications typically used for cryo-ET, which result in an imaging area of 0.4 to 2 μm per side, a tomogram covers significantly less than a percentage of the total cell volume. Knowing the total copy number (or the local concentration) of your protein of interest is necessary to obtain an estimation of how many lamellae, tomograms, and particles will be necessary to observe your chosen macromolecule

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

and perform relevant analysis. To answer the question of how many lamellae and tomograms are needed to answer your question or solve a structure, estimate how many copies one could reasonably achieve per tomogram, how heterogeneous these instances are expected to be, and what resolution is necessary to answer the question. The size and cellular abundance of a given macromolecule (or its local concentration) are relevant when estimating how many lamellae, tomograms, and particles you will need to perform STA. Not surprisingly, the more abundant protein complexes (ribosomes, nucleosomes) will have a greater ratio of particles per tomogram compared to less abundant complexes (the nuclear pore complex). However, since the nuclear pore complex and the ribosome are megadalton-sized complexes, they can be easily identified in a crowded tomogram, and their large size also facilitates particle alignment during STA. Such back-of-the-envelope calculations are useful when estimating how much data (roughly) are required to answer a given question (see Figure 3).

THE STRUCTURAL REVOLUTION

Before the resolution revolution in SPA (81), integrative modeling was used to bring together data from various sources (X-ray, cryo-EM, mass spectroscopy, cross-linking, proteomics, and others) to model the architecture of macromolecular complexes. This tradition has continued as cryo-ET has begun to produce maps of challenging complexes in situ (1, 149). More recently, the advent of AlphaFold has potentialized this methodology: Models from AlphaFold can be used to interpret the cryo-ET data, e.g., using template matching, and to assist in building molecular models from in situ maps obtained through STA (53, 106).

OUTLOOK

Cryo-ET has rapidly established itself as a powerful technology to bring structure to cell biology. Although lacking in temporal resolution, this technique is currently the highest-spatial-resolution imaging tool available for cell biology, and it can be used to make new discoveries or to generate new hypotheses that can be further tested with other methods such as live cell imaging and proteomics. It can also produce novel structures of macromolecular complexes embedded in their environment or perform censuses on the number and composition or conformation of molecular complexes in cells, as well as other quantitative analysis. Future advances and automation will democratize this technology and allow it to become a widely available and powerful tool for the cell biologist.

ACKNOWLEDGMENTS

We thank Dorotea Fracchiolla and Tara Bensen for illustrating the cryo-FIB-ET workflow in Figure 1. We thank members of the Villa lab for their helpful comments on the manuscript. L.N.Y. is supported by a National Institutes of Health NCI K00 award (5K00CA223029-05). E.V. is a Howard Hughes Medical Institute Investigator.

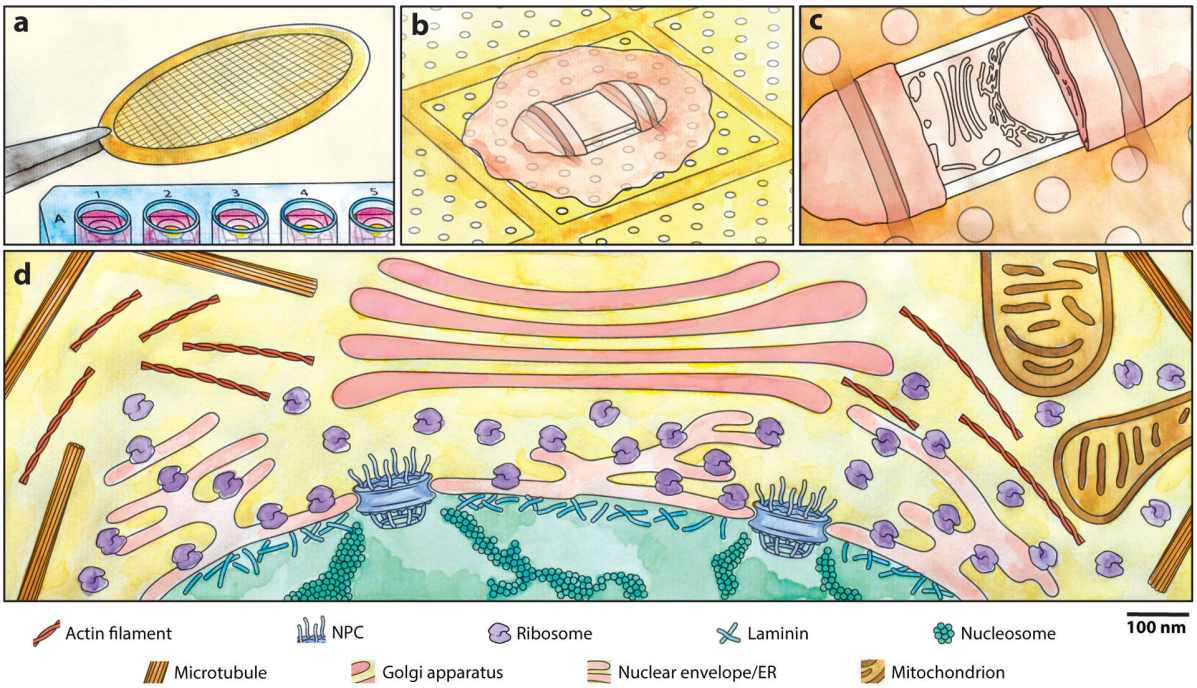

Figure 1.

Cryo-FIB-ET workflow. (*a*) Adherent cells can be cultured on EM grids, allowing unique lab-on-a-grid experiments. (*b*) A thin window or lamella is carved into an adherent grid grown on an EM grid via an FIB under cryogenic conditions. Expansion joints (trenches) on either side of the lamella are made to improve mechanical stability by offering points to allow flexing. (*c*) The lamella is imaged by TEM under cryogenic conditions at multiple tilt angles to facilitate a 3D reconstruction of the molecules within the lamella. (*d*) The complex and heterogeneous interior of a cell can be imaged at the highest achievable spatial resolution, resolving individual macromolecules (ribosomes, the NPC, nucleosomes), filaments (microtubules, actin, lamin), and organelles (mitochondria, ER, nucleus, Golgi). Abbreviations: cryo-FIB-ET, cryo-focused ion beam milling and electron tomography; EM, electron microscopy; ER, endoplasmic reticulum; FIB, focused ion beam; NPC, nuclear pore complex; TEM, transmission electron microscopy. Figure copyright 2023 Dorotea Fracchiolla, adapted with permission.

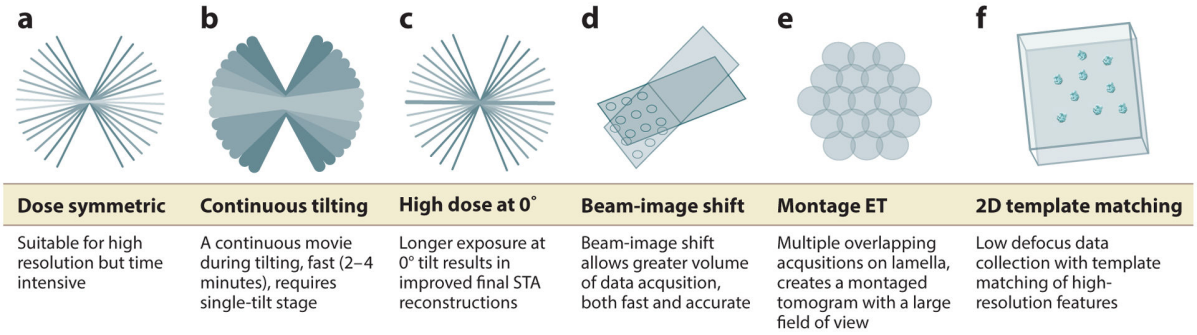

Figure 2.

Data collection methods. What data collection method is best for your data? It depends. (*a*) In the dose-symmetric tilt series, data collection alternates between positive and negative tilts. (*b*) In continuous fast tilting, data are continuously acquired. (*c*) In hybrid STA-SPA, a high-dose image is collected at 0°, followed by implementation of the dose-symmetric method. (*d*) In beam-image shift, the beam is shifted from a central focus and tracking to targeted areas of acquisition, facilitating the collection of multiple tilt series simultaneously. (*e*) In a montage collection series, the entire lamella is imaged to create one large tomogram. (*f*) In 2D template matching, one single projection image is acquired at 0°, and high-resolution features of a target are matched to the data. Abbreviations: ET, electron tomography; SPA, single-particle analysis; STA, subtomogram analysis.

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

Macromolecule	Abundance	Size	Sample datasets for solved structures			
			Lamella(e)	Tomograms	Particles	Resolution
Nuclear pore complex						
Mammalian	10^4	125 MDa	153 lamellae	54 tomograms	194 particles	~34 Å
S. pombe WT condition	10^2	66 MDa	~3.9 NPCs per tomograms	78 tomograms	2,237 particles	22 Å
Ribosome						
Mammalian (80S)	6×10^6	4.5 MDa	17 lamellae	180 tomograms	15,628 particles	4.9 Å
Bacterial (70S)	2.6×10^4	2.5 MDa	---	65 tomograms	17,890 particles	3.5 Å
Nucleosomes						
Mammalian	3×10^7/nucleus	200 kDa	1 lamella	1 tomogram	1,141 particles	24 Å
COPII		600 kDa	60 lamellae	60 tomograms	1,866 particles	9 Å
Arp2/3		224 kDa	---	131 tomograms	14,296 particles	9 Å

Figure 3.

Cryo-ET by the numbers. The size and cellular abundance of a given macromolecule (or its local concentration) are relevant when estimating how many lamellae, tomograms, and particles you will need to perform STA. Not surprisingly, the more abundant protein complexes (e.g., ribosomes, nucleosomes) will have a greater ratio of particles to tomograms compared to less abundant complexes (e.g., the NPC). For the number of NPCs in yeast, see Reference 155; particle numbers and estimated resolution from EMDB 11373 (166). For the number of NPCs in mammals, see Reference 109; particle numbers and estimated resolution from EMDB 12814 (126). For the number of nucleosomes in the mammalian nucleus, see Reference 45; particle numbers and estimated resolution from EMDB 6949 (23). For the number of bacterial ribosomes, see References 59 and 142; BioID 106861; particle numbers and estimated resolution from EMDB 11650 (137). For the number of mammalian ribosomes, see Reference 160; BioID 106861; particle numbers and estimated resolution from Reference 78 and EMDB XXXX (yet to be released). COPII particle numbers and estimated resolution from EMDB 3720 (38). Arp2/3 particle numbers and estimated resolution from EMDB 11869 (48). Abbreviations: ET, electron tomography; NPC, nuclear pore complex; *S. pombe*, *Saccharomyces pombe*; STA, subtomogram analysis; WT, wild type.

E Wikipedia index

Wikipedia is often the most up-to-date overview of a topic, and much of the text of this book is adapted from it. For each main section, this index lists the most relevant articles with the opening sentences of each article (CC BY-SA 4.0). Wikipedia articles change; check the date and the references of an article before relying on it.

E.1 Sequence searching

Wikipedia articles for Chapter 1.

E.1.1 Homology and sequence similarity

- **Homology (biology)** — In biology, homology is similarity in anatomical structures or genes between organisms of different taxa due to shared ancestry, regardless of current functional differences.
- **Sequence homology** — Sequence homology is the biological homology between DNA, RNA, or protein sequences, defined in terms of shared ancestry in the evolutionary history of life.
- **Gene** — In biology, the word gene has two meanings. The Mendelian gene is a basic unit of heredity. The molecular gene is a sequence of nucleotides in DNA that is transcribed to produce RNA.
- **Protein** — Proteins are large biomolecules and macromolecules that comprise one or more long chains of amino acid residues.
- **Convergent evolution** — Convergent evolution is the independent evolution of similar features in species of different lineages. Convergent evolution creates analogous structures that have similar form or function but were not present in the last common ancestor of those groups.
- **Gene duplication** — Gene duplication is a mechanism through which new genetic material is generated during molecular evolution. It can be defined as any duplication of a region of DNA that contains a gene.
- **Horizontal gene transfer** — Horizontal gene transfer (HGT) or lateral gene transfer (LGT) is the movement of genetic material between organisms other than by the ("vertical") transmission of DNA from parent to offspring (reproduction).

E.1.2 Dynamic programming and sequence alignment

- **Dynamic programming** — Dynamic programming (DP) is both a mathematical optimization method and an algorithmic paradigm. The method was developed by Richard Bellman in the 1950s and has found applications in numerous fields, such as aerospace engineering and economics.
- **Sequence alignment** — In bioinformatics, a sequence alignment is a way of arranging the sequences of DNA, RNA, or protein to identify regions of similarity that may be a consequence of functional, structural, or evolutionary relationships between the sequences.

- **Needleman–Wunsch algorithm** — The Needleman–Wunsch algorithm is an algorithm used in bioinformatics to align protein or nucleotide sequences. It was one of the first applications of dynamic programming to compare biological sequences. The algorithm was developed by Saul B.
- **Smith–Waterman algorithm** — The Smith–Waterman algorithm performs local sequence alignment; that is, for determining similar regions between two strings of nucleic acid sequences or protein sequences.
- **Gap penalty** — In DNA analysis, gap penalty is a method of scoring alignments of two or more DNA sequences. When aligning sequences, introducing gaps in the sequences can allow an alignment algorithm to match more terms than a gap-less alignment can.
- **Substitution matrix** — In bioinformatics and evolutionary biology, a substitution matrix describes the frequency at which a character in a nucleotide sequence or a protein sequence changes to other character states over evolutionary time.
- **BLOSUM** — In bioinformatics, the BLOSUM matrix is a substitution matrix used for sequence alignment of proteins. BLOSUM matrices are used to score alignments between evolutionarily divergent protein sequences. They are based on local alignments.
- **Point accepted mutation** — A point accepted mutation — also known as a PAM — is the replacement of a single amino acid in the primary structure of a protein with another single amino acid, which is accepted by the processes of natural selection.

E.1.3 Heuristic search methods

- **BLAST (biotechnology)** — In bioinformatics, BLAST is an algorithm and program for comparing primary biological sequence information, such as the amino-acid sequences of proteins, nucleotides of DNA and/or RNA sequences.
- **FASTA** — FASTA is a DNA and protein sequence alignment software package first described by David J. Lipman and William R. Pearson in 1985. Its legacy is the FASTA format which is now ubiquitous in bioinformatics.
- **Gumbel distribution** — In probability theory and statistics, the Gumbel distribution is used to model the distribution of the maximum of a number of samples of various distributions.
- **Suffix array** — In computer science, a suffix array is a sorted array of all suffixes of a string. It is a data structure used in, among others, full-text indices, data-compression algorithms, and the field of bibliometrics.
- **Burrows–Wheeler transform** — The Burrows–Wheeler transform (BWT) rearranges a character string into runs of similar characters, in a manner that can be reversed to recover the original string.
- **FM-index** — In computer science, an FM-index is a compressed full-text substring index based on the Burrows–Wheeler transform, with some similarities to the suffix array.

E.1.4 Alignment-free sequence comparison

- **Alignment-free sequence analysis** — In bioinformatics, alignment-free sequence analysis approaches to molecular sequence and structure data provide alternatives over alignment-based approaches.
- **K-mer** — In bioinformatics, k-mers are substrings of length contained within a biological sequence.
- **MinHash** — In computer science and data mining, MinHash is a technique for quickly estimating how similar two sets are.
- **Jaccard index** — The Jaccard index is a statistic used for gauging the similarity and diversity of sample sets. It is defined in general taking the ratio of two sizes, the intersection size divided by the union size, also called intersection over union (IoU).

E.1.5 Profiles and multiple sequence alignments

- **Multiple sequence alignment** — Multiple sequence alignment (MSA) is the process or the result of sequence alignment of three or more biological sequences, generally protein, DNA, or RNA.
- **Clustal** — Clustal is a computer program used for multiple sequence alignment in bioinformatics. It is one of the most widely cited bioinformatics software with two of its academic publications amongst the top 100 papers cited of all time, according to Nature in 2014.
- **Sequence motif** — In biology, a sequence motif is a nucleotide or amino-acid sequence pattern that is widespread and usually assumed to be related to biological function of the macromolecule.
- **Position weight matrix** — A position weight matrix (PWM), also known as a position-specific weight matrix (PSWM) or position-specific scoring matrix (PSSM), is a commonly used representation of motifs (patterns) in biological sequences.
- **Sequence logo** — In bioinformatics, a sequence logo is a graphical representation of the sequence conservation of nucleotides or amino acids . A sequence logo is created from a collection of aligned sequences and depicts the consensus sequence and diversity of the sequences.
- **Hidden Markov model** — In probability theory, a hidden Markov model (HMM) is a Markov model in which the observations are dependent on a latent Markov process. An HMM requires that there be an observable process whose outcomes depend on the outcomes of in a known way.
- **Viterbi algorithm** — The Viterbi algorithm is a dynamic programming algorithm that finds the most likely sequence of hidden events that would explain a sequence of observed events. The result of the algorithm is often called the Viterbi path.
- **HMMER** — HMMER is a free and commonly used software package for sequence analysis written by Sean Eddy. Its general usage is to identify homologous protein or nucleotide sequences, and to perform sequence alignments.

E.1.6 RNA homology search

- **Non-coding RNA** — A non-coding RNA (ncRNA) is a functional RNA molecule that is not translated into a protein. The DNA sequence from which a functional non-coding RNA is transcribed is often called a non-coding gene or an RNA gene.
- **Nucleic acid secondary structure** — Nucleic acid secondary structure is the basepairing interactions within a single nucleic acid polymer or between two polymers. It can be represented as a list of bases which are paired in a nucleic acid molecule.
- **Nucleic acid structure prediction** — Nucleic acid structure prediction is a computational method to determine secondary and tertiary nucleic acid structure from its sequence. Secondary structure can be predicted from one or several nucleic acid sequences.
- **Probabilistic context-free grammar** — In theoretical linguistics and computational linguistics, probabilistic context free grammars (PCFGs) extend context-free grammars, similar to how hidden Markov models extend regular grammars. Each production is assigned a probability.
- **Rfam** — Rfam is a database containing information about non-coding RNA (ncRNA) families and other structured RNA elements.

E.1.7 Databases and domains

- **Protein domain** — In molecular biology, a protein domain is a region of a protein's polypeptide chain that is self-stabilizing and folds independently from the rest. Each domain forms a compact, folded three-dimensional structure.
- **Protein family** — A protein family is a group of evolutionarily related proteins. In many cases, a protein family has a corresponding gene family, in which each gene encodes a corresponding protein with a 1:1 relationship.

- **Protein superfamily** — A protein superfamily is the largest grouping (clade) of proteins for which common ancestry can be inferred. Usually this common ancestry is inferred from structural alignment and mechanistic similarity, even if no sequence similarity is evident.
- **Pfam** — Pfam is a database of protein families that includes their annotations and multiple sequence alignments generated using hidden Markov models. The latest version of Pfam, 37.0, was released in June 2024 and contains 21,979 families.
- **InterPro** — InterPro is a database of protein families, protein domains and functional sites in which identifiable features found in known proteins can be applied to new protein sequences in order to functionally characterise them.
- **Structural Classification of Proteins database** — The Structural Classification of Proteins (SCOP) database is a largely manual classification of protein structural domains based on similarities of their structures and amino acid sequences.
- **CATH database** — The CATH Protein Structure Classification database is a free, publicly available online resource that provides information on the evolutionary relationships of protein domains.

E.1.8 Protein language models

- **Word embedding** — In natural language processing, a word embedding is a representation of a word. The embedding is used in text analysis.
- **Transformer (deep learning)** — In deep learning, the transformer is a family of artificial neural network architectures based on the multi-head attention mechanism, in which input data such as text, images, or audio is converted to a sequence of numerical representations called tokens, and each token is converted into a vector through an embedding layer.
- **BERT (language model)** — Bidirectional encoder representations from transformers (BERT) is a language model introduced in October 2018 by researchers at Google. It learns to represent text as a sequence of vectors using self-supervised learning.
- **Large language model** — A large language model (LLM) is an AI model trained on a vast amount of text for natural language processing tasks, especially language generation. LLMs can typically generate, summarize, translate, and analyze text in many contexts.

E.1.9 Benchmarking search methods

- **Receiver operating characteristic** — A receiver operating characteristic curve, or ROC curve, is a graphical plot that illustrates the performance of a binary classifier model at varying threshold values.
- **Precision and recall** — In classification, precision and recall are performance metrics that apply to data retrieved from a collection, corpus or sample space.
- **Sensitivity and specificity** — In medicine and statistics, sensitivity and specificity mathematically describe the accuracy of a test that reports the presence or absence of a medical condition.
- **False discovery rate** — In statistics, the false discovery rate (FDR) is a method of conceptualizing the rate of type I errors in null hypothesis testing when conducting multiple comparisons.
- **Structural Classification of Proteins database** — The Structural Classification of Proteins (SCOP) database is a largely manual classification of protein structural domains based on similarities of their structures and amino acid sequences.

E.1.10 Whole-genome alignment and conservation

- **Comparative genomics** — Comparative genomics is a branch of biological research that examines genome sequences across a spectrum of species, spanning from humans and mice to a diverse array of organisms from bacteria to chimpanzees.

- **Conserved sequence** — In evolutionary biology, conserved sequences are identical or similar sequences in nucleic acids or proteins across species, or within a genome, or between donor and receptor taxa.
- **Phylogenetic footprinting** — Phylogenetic footprinting is a technique used to identify transcription factor binding sites (TFBS) within a non-coding region of DNA of interest by comparing it to the orthologous sequence in different species.
- **Human accelerated regions** — Human accelerated regions (HARs), first described in August 2006, are a set of 49 segments of the human genome that are conserved throughout vertebrate evolution but are strikingly different in humans.

E.2 Databases

Wikipedia articles for Chapter 2.

E.2.1 How biological databases work

- **Biological database** — Biological databases are libraries of biological sciences, collected from scientific experiments, published literature, high-throughput experiment technology, and computational analysis.
- **Accession number (bioinformatics)** — An accession number, in bioinformatics, is a unique identifier given to a DNA or protein sequence record to allow for tracking of different versions of that sequence record and the associated sequence over time in a single data repository.
- **Entrez** — The Entrez Global Query Cross-Database Search System is a federated search engine, or web portal that allows users to search many discrete health sciences databases at the National Center for Biotechnology Information (NCBI) website.
- **PubMed** — PubMed is an openly accessible, free database which primarily includes the MEDLINE database of references and abstracts on life sciences and biomedical topics.
- **Biocuration** — Biocuration is the field of life sciences dedicated to organizing biomedical data, information and knowledge into structured formats, such as spreadsheets, tables and knowledge graphs.
- **FAIR data** — FAIR data is data which meets the 2016 FAIR principles of findability, accessibility, interoperability, and reusability, first formally published in 2016.
- **PubMed Central** — PubMed Central (PMC) is a free digital repository that archives open access full-text scholarly articles that have been published in biomedical and life sciences journals.
- **Europe PubMed Central** — Europe PubMed Central is an open-access repository that contains millions of biomedical research works. It was known as UK PubMed Central until 1 November 2012.

E.2.2 Sequence databases

- **International Nucleotide Sequence Database Collaboration** — The International Nucleotide Sequence Database Collaboration (INSDC) consists of a joint effort to collect and disseminate databases containing DNA and RNA sequences.
- **GenBank** — The GenBank sequence database is an open access, annotated collection of publicly available nucleotide sequences and their protein translations.
- **European Nucleotide Archive** — The European Nucleotide Archive (ENA) is a repository providing free and unrestricted access to annotated DNA and RNA sequences.

- **Sequence Read Archive** — The Sequence Read Archive is a bioinformatics database that provides a public repository for DNA sequencing data, especially the "short reads" generated by high-throughput sequencing, which are typically less than 1,000 base pairs in length.
- **RefSeq** — The Reference Sequence (RefSeq) database is an open access, annotated and curated collection of publicly available nucleotide sequences and their protein products. RefSeq was introduced in 2000.
- **UniProt** — UniProt is a freely accessible database of protein sequence and functional information, many entries being derived from genome sequencing projects.
- **Pfam** — Pfam is a database of protein families that includes their annotations and multiple sequence alignments generated using hidden Markov models. The latest version of Pfam, 37.0, was released in June 2024 and contains 21,979 families.
- **InterPro** — InterPro is a database of protein families, protein domains and functional sites in which identifiable features found in known proteins can be applied to new protein sequences in order to functionally characterise them.

E.2.3 Genome databases and browsers

- **Ensembl genome database project** — Ensembl genome database project is a scientific project at the European Bioinformatics Institute, which provides a centralized resource for geneticists, molecular biologists and other researchers studying the genomes of our own species and other vertebrates and model organisms.
- **UCSC Genome Browser** — The UCSC Genome Browser is an online and downloadable genome browser hosted by the University of California, Santa Cruz (UCSC).
- **Model organism database** — Model organism databases (MODs) are biological databases, or knowledgebases, dedicated to the provision of in-depth biological data for intensively studied model organisms.
- **Genome browser** — The completion of the human genome sequencing in the early 2000s was a turning point in genomics research. Scientists have conducted series of research into the activities of genes and the genome as a whole.
- **Reference genome** — A reference genome is a genome assembly that represents the complete genetic sequence of an organism as a continuous string of nucleotides.
- **GENCODE** — GENCODE is a scientific project in genome research and part of the ENCODE scale-up project.
- **FlyBase** — FlyBase is an online bioinformatics database and the primary repository of genetic and molecular data for the insect family Drosophilidae.
- **Genome Taxonomy Database** — The Genome Taxonomy Database (GTDB) is an online database that maintains information on a proposed nomenclature of prokaryotes, following a phylogenomic approach based on a set of conserved single-copy proteins.

E.2.4 Structure databases

- **Protein Data Bank** — The Protein Data Bank (PDB) is a database for the three-dimensional structural data of large biological molecules such as proteins and nucleic acids, which is overseen by the Worldwide Protein Data Bank (wwPDB).
- **Worldwide Protein Data Bank** — The Worldwide Protein Data Bank (wwPDB) is an organization that maintains the archive of macromolecular structure.
- **EM Data Bank** — The EM Data Bank or Electron Microscopy Data Bank (EMDB) collects 3DEM maps and associated experimental data determined using electron microscopy of biological specimens.

- **AlphaFold** — AlphaFold is an artificial intelligence (AI) program developed by DeepMind, a subsidiary of Alphabet, which performs predictions of protein structure. It is designed using deep learning techniques.
- **CATH database** — The CATH Protein Structure Classification database is a free, publicly available online resource that provides information on the evolutionary relationships of protein domains.
- **Structural Classification of Proteins database** — The Structural Classification of Proteins (SCOP) database is a largely manual classification of protein structural domains based on similarities of their structures and amino acid sequences.

E.2.5 Function and pathways

- **Gene Ontology** — The Gene Ontology (GO) is a major bioinformatics initiative to unify the representation of gene and gene product attributes across all species.
- **KEGG** — KEGG is a collection of databases dealing with genomes, biological pathways, diseases, drugs, and chemical substances.
- **Reactome** — Reactome is a free online database of biological pathways. It is manually curated and authored by PhD-level biologists, in collaboration with Reactome editorial staff. The content is cross-referenced to many bioinformatics databases.
- **Ontology (information science)** — In information science, an ontology encompasses a representation, formal naming, and definitions of the categories, properties, and relations between the concepts, data, or entities that pertain to one, many, or all domains of discourse.
- **Biological pathway** — In cell biology, a biological pathway is a series of molecular interactions among molecules within a cell that leads to a specific product or a change in the cell.
- **Gene set enrichment analysis** — Gene set enrichment analysis (GSEA) (also called functional enrichment analysis or pathway enrichment analysis) is a method to identify classes of genes or proteins that are over-represented in a large set of genes or proteins, and may have an association with different phenotypes (e.g. different organism growth patterns or diseases).
- **Critical Assessment of Function Annotation** — The Critical Assessment of Function Annotation (CAFA) is an ongoing community-driven experiment designed to evaluate computational methods for protein function prediction.
- **Knowledge graph** — In knowledge representation and reasoning, a knowledge graph is a knowledge base that uses a graph-structured data model or topology to represent and operate on data.

E.2.6 Interaction databases

- **STRING** — In molecular biology, STRING is a biological database and web resource of known and predicted protein–protein interactions.
- **BioGRID** — The Biological General Repository for Interaction Datasets (BioGRID) is a curated biological database of protein-protein interactions, genetic interactions, chemical interactions, and post-translational modifications created in 2003 (originally referred to as simply the General Repository for Interaction Datasets by Mike Tyers, Bobby-Joe Breitkreutz, and Chris Stark at the Lunenfeld-Tanenbaum Research Institute at Mount Sinai Hospital.
- **Interactome** — In molecular biology, an interactome is the whole set of molecular interactions in a particular cell. The term specifically refers to physical interactions among molecules but can also describe sets of indirect interactions among genes.
- **Protein–protein interaction** — Protein–protein interactions (PPIs) are physical contacts of high specificity established between two or more protein molecules as a result of biochemical events steered by interactions that include electrostatic forces, hydrogen bonding and the hydrophobic effect.

E.2.7 Expression and proteomics repositories

- **Gene Expression Omnibus** — Gene Expression Omnibus (GEO) is a database for gene expression profiling and DNA methylation profiling managed by the National Center for Biotechnology Information (NCBI).
- **Human Protein Atlas** — The Human Protein Atlas (HPA) is a Swedish-based program started in 2003 with the aim to map all the human proteins in cells, tissues and organs using integration of various omics technologies, including antibody-based imaging, mass spectrometry-based proteomics, transcriptomics and systems biology.
- **Gene expression profiling** — In the field of molecular biology, gene expression profiling is the measurement of the activity of thousands of genes at once, to create a global picture of cellular function.
- **RNA-Seq** — RNA-Seq is a next-generation sequencing (NGS) technique used to quantify and identify RNA molecules in a biological sample, providing a snapshot of the transcriptome at a specific time.
- **Proteomics** — Proteomics is the large-scale study of proteins. The proteome is the entire set of proteins produced or modified by an organism or system.

E.2.8 Medical and variant data

- **DbSNP** — The Single Nucleotide Polymorphism Database (dbSNP) is a free public archive for genetic variation within and across different species developed and hosted by the National Center for Biotechnology Information (NCBI) in collaboration with the National Human Genome Research Institute (NHGRI).
- **ClinVar** — ClinVar is a public archive with free access to reports on the relationships between human genetic variations and phenotypes, with supporting evidence. The database includes germline and somatic variants of any size, type or genomic location.
- **Online Mendelian Inheritance in Man** — Online Mendelian Inheritance in Man (OMIM) is a continuously updated catalog of human genes and genetic disorders and traits, with a particular focus on the gene-phenotype relationship.
- **GWAS catalog** — The GWAS Catalog is a free online database that compiles data of genome-wide association studies (GWAS), summarizing unstructured data from different literature sources into accessible high quality data.
- **The Cancer Genome Atlas** — The Cancer Genome Atlas (TCGA) is a project to catalogue the genomic alterations responsible for cancer using genome sequencing and bioinformatics.
- **COSMIC cancer database** — COSMIC is an online database of somatically acquired mutations found in human cancer. Somatic mutations are those that occur in non-germline cells that are not inherited by children.
- **European Genome-phenome Archive** — European Genome-phenome Archive (EGA) is a repository for human biomolecular and phenotypic data in the United Kingdom and Spain.
- **Variant of uncertain significance** — A variant of uncertain significance (VUS) is a genetic variant that has been identified through genetic testing but whose significance to the function or health of an organism is not known.

E.3 Evolution

Wikipedia articles for Chapter 3.

E.3.1 The origin of life

- **Abiogenesis** — Abiogenesis or the origin of life is the natural process by which life arises from non-living matter, such as simple organic compounds.
- **Miller–Urey experiment** — The Miller–Urey experiment, or Miller experiment, was an experiment in chemical synthesis carried out in 1952 that simulated the conditions thought at the time to be present in the atmosphere of the early, prebiotic Earth.
- **RNA world** — The RNA world is a hypothetical stage in the evolutionary history of life on Earth in which self-replicating RNA molecules proliferated before the evolution of DNA and proteins. The term also refers to the hypothesis that posits the existence of this stage.
- **Ribozyme** — Ribozymes are RNA molecules that have the ability to catalyze specific biochemical reactions, including RNA splicing in gene expression, similar to the action of protein enzymes.
- **Iron–sulfur world hypothesis** — The iron–sulfur world hypothesis is a set of proposals for the origin of life and the early evolution of life advanced in a series of articles between 1988 and 1992 by Günter Wächtershäuser, a Munich patent lawyer with a degree in chemistry, who had been encouraged and supported by philosopher Karl R.
- **Protocell** — A protocell is a self-organized, membrane-bound or membraneless compartment that concentrates biomolecules, proposed as a rudimentary precursor to cells during the origin of life. It is a minimal unit that can undergo Darwinian evolution.
- **Earliest known life forms** — The earliest known life forms on Earth may be as old as 4.1 billion years according to biologically fractionated graphite inside a single zircon grain in the Jack Hills range of Australia.
- **Astrobiology** — Astrobiology is a scientific field within the life and environmental sciences that studies the origins, early evolution, distribution, and future of life in the universe by investigating its deterministic conditions and contingent events.

E.3.2 Basic evolutionary concepts

- **Mutation** — In biology, a mutation is an alteration in the nucleic acid sequence of the genome of an organism, virus, or extrachromosomal DNA.
- **Natural selection** — Natural selection is the differential survival and reproduction of individuals due to differences in the relative fitness endowed on them by their own particular complement of observable characteristics.
- **Genetic drift** — Genetic drift is the change in the frequency of an existing allele in a population due to chance.
- **Effective population size** — The effective population size (Ne) is the size of an idealised population that would experience the same rate of genetic drift as the real population.
- **Genetic hitchhiking** — Genetic hitchhiking, also called genetic draft or the hitchhiking effect, is when an allele changes frequency not because it itself is under natural selection, but because it is near another gene that is undergoing a selective sweep and that is on the same DNA chain.
- **Neutral theory of molecular evolution** — The neutral theory of evolution holds that most of the genetic variation within and between species is due to random genetic drift of mutant alleles that are selectively neutral.
- **Nearly neutral theory of molecular evolution** — The nearly neutral theory of molecular evolution is a modification of the neutral theory of molecular evolution that accounts for the fact that not all mutations are either so deleterious such that they can be ignored, or else neutral.
- **Molecular clock** — The molecular clock is a figurative term for a technique that uses the mutation rate of biomolecules to deduce the time in prehistory when two or more life forms diverged.

E.3.3 Homologues, orthologues and gene duplication

- **Homology (biology)** — In biology, homology is similarity in anatomical structures or genes between organisms of different taxa due to shared ancestry, regardless of current functional differences.
- **Sequence homology** — Sequence homology is the biological homology between DNA, RNA, or protein sequences, defined in terms of shared ancestry in the evolutionary history of life.
- **Gene duplication** — Gene duplication is a mechanism through which new genetic material is generated during molecular evolution. It can be defined as any duplication of a region of DNA that contains a gene.
- **Subfunctionalization** — Subfunctionalization was proposed by Stoltzfus (1999) and Force et al.
- **Neofunctionalization** — Neofunctionalization, one of the possible outcomes of functional divergence, occurs when one gene copy, or paralog, takes on a totally new function after a gene duplication event.
- **Gene conversion** — Gene conversion is the process by which one DNA sequence replaces a homologous sequence such that the sequences become identical after the conversion.
- **Concerted evolution** — Concerted evolution is the phenomenon where paralogous genes within one species are more closely related to one another than to members of the same gene family in closely related species.
- **Paleopolyploidy** — Paleopolyploidy is the result of genome duplications which occurred at least several million years ago (MYA). Such an event could either double the genome of a single species (autopolyploidy) or combine those of two species (allopolyploidy).

E.3.4 Protein evolution

- **Protein domain** — In molecular biology, a protein domain is a region of a protein's polypeptide chain that is self-stabilizing and folds independently from the rest. Each domain forms a compact, folded three-dimensional structure.
- **Tandem repeat** — In genetics, tandem repeats occur in DNA when a pattern of one or more nucleotides is repeated and the repetitions are directly adjacent to each other, e.g. ATTCG ATTCG ATTCG, in which the sequence ATTCG is repeated three times.
- **Intrinsically disordered proteins** — In molecular biology, an intrinsically disordered protein (IDP) is a protein that lacks a fixed or ordered three-dimensional structure, typically in the absence of its macromolecular interaction partners, such as other proteins or RNA.
- **Short linear motif** — In molecular biology short linear motifs (SLiMs), linear motifs or minimotifs are short stretches of protein sequence that mediate protein–protein interaction.
- **Direct coupling analysis** — Direct coupling analysis or DCA is an umbrella term comprising several methods for analyzing sequence data in computational biology.
- **Alternative splicing** — Alternative splicing, alternative RNA splicing, or differential splicing is an alternative splicing process during gene expression that allows a single gene to produce different splice variants.
- **Ancestral reconstruction** — Ancestral reconstruction is the extrapolation back in time from measured characteristics of individuals, populations, or species to their common ancestors.

E.3.5 Detecting selection

- **Ka/Ks ratio** — In genetics, the Ka/Ks ratio, also known as ω or dN/dS ratio, is used to estimate the balance between neutral mutations, purifying selection and beneficial mutations acting on a set of homologous protein-coding genes.

- **Models of DNA evolution** — A number of different Markov models of DNA sequence evolution have been proposed. These substitution models differ in terms of the parameters used to describe the rates at which one nucleotide replaces another during evolution.
- **Negative selection (natural selection)** — In natural selection, negative selection or purifying selection is the selective removal of alleles that are deleterious. This can result in stabilising selection through the purging of deleterious genetic polymorphisms that arise through random mutations.
- **Directional selection** — In population genetics, directional selection is a mode of natural selection in which individuals with a trait at one extreme of a phenotypic distribution have better fitness than individuals with intermediate or opposite extreme phenotypes.
- **McDonald–Kreitman test** — The McDonald–Kreitman test is a statistical test often used by evolutionary and population biologists to detect and measure the amount of adaptive evolution within a species by determining whether adaptive evolution has occurred, and the proportion of substitutions that resulted from positive selection.
- **Tajima's D** — Tajima's D is a population genetic test statistic created by and named after the Japanese researcher Fumio Tajima.
- **Selective sweep** — In genetics, a selective sweep is the process through which a new beneficial mutation that increases its frequency and becomes fixed in a population leads to the reduction or elimination of genetic variation among nucleotide sequences that are near the mutation site.

E.3.6 Genome evolution

- **Horizontal gene transfer** — Horizontal gene transfer (HGT) or lateral gene transfer (LGT) is the movement of genetic material between organisms other than by the ("vertical") transmission of DNA from parent to offspring (reproduction).
- **Bacterial conjugation** — Bacterial conjugation is the transfer of genetic material between bacterial cells by direct cell-to-cell contact or by a bridge-like connection between two cells. This typically takes place through a type IV secretion system, a type of pilus.
- **Transduction (genetics)** — Transduction is the process by which foreign DNA is introduced into a cell by a virus or viral vector. An example is the viral transfer of DNA from one bacterium to another and hence an example of horizontal gene transfer.
- **Genetic transformation** — In molecular biology and genetics, transformation is the genetic alteration of a bacterial cell resulting from the direct uptake and incorporation of exogenous genetic material from its surroundings through the cell membrane(s).
- **Pan-genome** — In the fields of molecular biology and genetics, a pan-genome is the entire set of genes from all strains within a clade. More generally, it is the union of all the genomes of a clade.
- **Gene family** — A gene family is a set of several similar genes, formed by duplication of a single original gene, and generally with similar biochemical functions.
- **Power law** — In mathematics and science, a power law is a functional relationship between two quantities, where a relative change in one quantity results in a relative change in the other quantity proportional to the change raised to a constant exponent: one quantity varies as a power of another.
- **Preferential attachment** — A preferential attachment process is any of a class of processes in which some quantity, typically some form of wealth or credit, is distributed among a number of individuals or objects according to how much they already have, so that those who are already wealthy receive more than those who are not.

E.4 Phylogeny

Wikipedia articles for Chapter 4.

E.4.1 Basic definitions

- **Phylogenetics** — In biology, phylogenetics is the study of the evolutionary history of life using observable characteristics of organisms, which is known as phylogenetic inference.
- **Phylogenetic tree** — A phylogenetic tree or phylogeny is a graphical representation which shows the evolutionary history between a set of species or taxa during a specific time.
- **Cladistics** — Cladistics is an approach to biological classification in which organisms are categorized in groups ("clades") based on hypotheses of most recent common ancestry.
- **Monophyly** — In biological cladistics for the classification of organisms, monophyly is the condition of a taxonomic grouping being a clade – that is, a grouping of organisms which meets these criteria:the grouping contains its own most recent common ancestor, i.e. excludes non-descendants of that common ancestor the grouping contains all the descendants of that common ancestor, without exception
- **Paraphyly** — In taxonomy, a paraphyly is a grouping that consists of the grouping's last common ancestor and some but not all of its descendant lineages. The grouping is said to be paraphyletic with respect to the excluded subgroups.
- **Homology (biology)** — In biology, homology is similarity in anatomical structures or genes between organisms of different taxa due to shared ancestry, regardless of current functional differences.
- **Molecular clock** — The molecular clock is a figurative term for a technique that uses the mutation rate of biomolecules to deduce the time in prehistory when two or more life forms diverged.
- **Newick format** — In mathematics and phylogenetics, Newick tree format is a way of representing graph-theoretical trees with edge lengths using parentheses and commas. It was adopted by James Archie, William H. E. Day, Joseph Felsenstein, Wayne Maddison, Christopher Meacham, F.

E.4.2 Phylogenetic methods

- **Computational phylogenetics** — Computational phylogenetics, phylogeny inference, or phylogenetic inference focuses on computational and optimization algorithms, heuristics, and approaches involved in phylogenetic analyses.
- **UPGMA** — UPGMA is a simple agglomerative (bottom-up) hierarchical clustering method. It also has a weighted variant, WPGMA, and they are generally attributed to Sokal and Michener.
- **Neighbor joining** — In bioinformatics, neighbor joining is a bottom-up (agglomerative) clustering method for the creation of phylogenetic trees, created by Naruya Saitou and Masatoshi Nei in 1987.
- **Maximum parsimony** — In evolutionary biology, maximum parsimony is a method used to build phylogenetic trees based on the principle of simplicity. Under the maximum-parsimony criterion, the best tree will minimize the amount of homoplasy.
- **Long branch attraction** — In phylogenetics, long branch attraction (LBA) is a form of systematic error whereby distantly related lineages are incorrectly inferred to be closely related.
- **Felsenstein's tree-pruning algorithm** — In statistical genetics, Felsenstein's tree-pruning algorithm, attributed to Joseph Felsenstein, is an algorithm for efficiently computing the likelihood of an evolutionary tree from nucleic acid sequence data.
- **Bayesian inference in phylogeny** — Bayesian inference of phylogeny combines the information in the prior and in the data likelihood to create the so-called posterior probability of trees, which is the probability that the tree is correct given the data, the prior and the likelihood model.
- **Models of DNA evolution** — A number of different Markov models of DNA sequence evolution have been proposed. These substitution models differ in terms of the parameters used to describe the rates at which one nucleotide replaces another during evolution.

E.4.3 Alignments, genomes and conflicting trees

- **Phylogenomics** — Phylogenomics is the intersection of the fields of evolution and genomics. The term has been used in multiple ways to refer to analysis that involves genome data and evolutionary reconstructions.
- **Multiple sequence alignment** — Multiple sequence alignment (MSA) is the process or the result of sequence alignment of three or more biological sequences, generally protein, DNA, or RNA.
- **Incomplete lineage sorting** — Incomplete lineage sorting (ILS) (also referred to as hemiplasy, deep coalescence, retention of ancestral polymorphism, or trans-species polymorphism) is a phenomenon in evolutionary biology and population genetics that results in discordance between species and gene trees.
- **Multispecies coalescent process** — Multispecies Coalescent Process is a stochastic process model that describes the genealogical relationships for a sample of DNA sequences taken from several species. It represents the application of coalescent theory to the case of multiple species.
- **Coalescent theory** — Coalescent theory is a model of how alleles sampled from a population may have originated from a common ancestor.
- **Phylogenetic reconciliation** — In phylogenetics, reconciliation is an approach to connect the history of two or more coevolving biological entities.
- **Phylogenetic network** — A phylogenetic network is any graph used to visualize evolutionary relationships between nucleotide sequences, genes, chromosomes, genomes, or species.
- **Horizontal gene transfer** — Horizontal gene transfer (HGT) or lateral gene transfer (LGT) is the movement of genetic material between organisms other than by the ("vertical") transmission of DNA from parent to offspring (reproduction).

E.4.4 The tree of life

- **Tree of life (biology)** — The tree of life or universal tree of life is a metaphor, conceptual model, and research tool used to explore the evolution of life and describe the relationships between organisms, both living and extinct, as described in a famous passage in Charles Darwin's On the Origin of Species (1859).The affinities of all the beings of the same class have sometimes been represented by a great tree.
- **Three-domain system** — The three-domain system is a taxonomic classification system that groups all cellular life into three domains, namely Archaea, Bacteria and Eukarya, introduced by Carl Woese, Otto Kandler and Mark Wheelis in 1990.
- **Two-domain system** — The two-domain system is a biological classification system that groups all cellular organisms in the tree of life into two domains: Archaea and Bacteria, while eukaryotes are considered a specialized clade under Archaea.
- **Last universal common ancestor** — The last universal common ancestor (LUCA) is the hypothesized latest common ancestral population of single-celled organisms from which all subsequent life forms descend under the three-domain system of Bacteria, Archaea, and Eukarya.
- **Asgard (archaea)** — Asgard archaea, or Promethearchaeati, are a kingdom belonging to the domain Archaea that contain eukaryotic signature proteins.
- **Eukaryogenesis** — Eukaryogenesis, the process which created the eukaryotic cell and lineage, is a milestone in the evolution of life, since eukaryotes include all complex cells and almost all multicellular organisms.
- **Hominidae** — The Hominidae, whose members are known as the great apes, are a taxonomic family of primates that includes eight extant species in four genera: Pongo ; Gorilla ; Pan ; and Homo, of which only modern humans remain.
- **Human evolution** — Homo sapiens is a distinct species of the hominid family of primates, which includes all the great apes. Over their evolutionary history, humans gradually developed traits such as bipedalism, dexterity, and complex language.

E.5 Genomics

Wikipedia articles for Chapter 5.

E.5.1 Sequencing methods

- **DNA sequencing** — DNA sequencing is the process of determining the nucleic acid sequence – the order of nucleotides in DNA. It includes any method or technology that is used to determine the order of the four bases: adenine, thymine, cytosine, and guanine.
- **Sanger sequencing** — Sanger sequencing is a method of DNA sequencing that involves electrophoresis and is based on the random incorporation of chain-terminating dideoxynucleotides by DNA polymerase during in vitro DNA replication.
- **Massive parallel sequencing** — Massively parallel sequencing (MPS) is any of several high-throughput approaches to DNA sequencing using the concept of massively parallel processing; it is also called next-generation sequencing (NGS) or second-generation sequencing.
- **Illumina dye sequencing** — Illumina dye sequencing is a technique used to determine the series of base pairs in DNA, also known as DNA sequencing. The reversible terminated chemistry concept was invented by Bruno Canard and Simon Sarfati at the Pasteur Institute in Paris.
- **Single-molecule real-time sequencing** — Single-molecule real-time (SMRT) sequencing is a parallelized single molecule DNA sequencing method. Single-molecule real-time sequencing utilizes a zero-mode waveguide (ZMW).
- **Nanopore sequencing** — Nanopore sequencing is a third generation approach used in the sequencing of biopolymers — specifically, polynucleotides in the form of DNA or RNA.
- **Phred quality score** — A Phred quality score is a measure of the quality of the identification of the nucleobases generated by automated DNA sequencing.
- **Coverage (genetics)** — In genetics, coverage is one of several measures of the depth or completeness of DNA sequencing, and is more specifically expressed in any of the following terms:Sequence coverage is the number of unique reads that include a given nucleotide in the reconstructed sequence.

E.5.2 Genome assembly

- **Sequence assembly** — In bioinformatics, sequence assembly refers to aligning and merging fragments from a longer DNA sequence in order to reconstruct the original sequence.
- **De novo sequence assemblers** — De novo sequence assemblers are a type of program that assembles short nucleotide sequences into longer ones without the use of a reference genome. These are most commonly used in bioinformatic studies to assemble genomes or transcriptomes.
- **De Bruijn graph** — In graph theory, an n-dimensional De Bruijn graph of m symbols is a directed graph representing overlaps between sequences of symbols.
- **Eulerian path** — In graph theory, an Eulerian trail is a trail in a finite graph that visits every edge exactly once. Similarly, an Eulerian circuit or Eulerian cycle is an Eulerian trail that starts and ends on the same vertex.
- **N50, L50, and related statistics** — In computational biology, N50 and L50 are statistics of a set of contig or scaffold lengths. The N50 is similar to a mean or median of lengths, but has greater weight given to the longer contigs.
- **Scaffolding (bioinformatics)** — Scaffolding is a technique used in bioinformatics. It is defined as follows: Link together a non-contiguous series of genomic sequences into a scaffold, consisting of sequences separated by gaps of known length.

- **Hybrid genome assembly** — In bioinformatics, hybrid genome assembly refers to utilizing various sequencing technologies to achieve the task of assembling a genome from fragmented, sequenced DNA resulting from shotgun sequencing.
- **Whole genome sequencing** — Whole genome sequencing (WGS), also known as full genome sequencing or just genome sequencing, is the process of determining the entirety of the DNA sequence of an organism's genome at a single time.

E.5.3 Mapping and variant calling

- **Sequence alignment** — In bioinformatics, a sequence alignment is a way of arranging the sequences of DNA, RNA, or protein to identify regions of similarity that may be a consequence of functional, structural, or evolutionary relationships between the sequences.
- **Burrows–Wheeler transform** — The Burrows–Wheeler transform (BWT) rearranges a character string into runs of similar characters, in a manner that can be reversed to recover the original string.
- **FASTQ format** — FASTQ format is a text-based format for storing both a biological sequence and its corresponding quality scores. Both the sequence letter and quality score are each encoded with a single ASCII character for brevity.
- **SAM (file format)** — Sequence Alignment Map (SAM) is a text-based format originally for storing biological sequences aligned to a reference sequence developed by Heng Li and Bob Handsaker et al.
- **SNV calling from NGS data** — SNV calling from NGS data is any of a range of methods for identifying the existence of single nucleotide variants (SNVs) from the results of next generation sequencing (NGS) experiments.
- **Variant Call Format** — The Variant Call Format or VCF is a standard text file format used in bioinformatics for storing gene sequence or DNA sequence variations.
- **Structural variation** — Genomic structural variation is the variation in structure of an organism's chromosome, such as deletions, duplications, copy-number variants, insertions, inversions and translocations.

E.5.4 Gene prediction

- **Gene prediction** — In computational biology, gene prediction or gene finding refers to the process of identifying the regions of genomic DNA that encode genes.
- **Open reading frame** — In molecular biology and genetics, reading frames are defined as spans of DNA sequence between the start and stop codons.
- **Hidden Markov model** — In probability theory, a hidden Markov model (HMM) is a Markov model in which the observations are dependent on a latent Markov process. An HMM requires that there be an observable process whose outcomes depend on the outcomes of in a known way.
- **RNA splicing** — RNA splicing is a process in molecular biology where a newly-made precursor messenger RNA (pre-mRNA) transcript is transformed into a mature messenger RNA (mRNA). It works by removing all the introns and splicing back together exons.
- **GENSCAN** — In bioinformatics, GENSCAN is a program to identify complete gene structures in genomic DNA. It is a GHMM-based program that can be used to predict the location of genes and their exon-intron boundaries in genomic sequences from a variety of organisms.
- **GeneMark** — GeneMark is a generic name for a family of ab initio gene prediction algorithms and software programs developed at the Georgia Institute of Technology in Atlanta.
- **Genome project** — Genome projects are scientific endeavours that ultimately aim to determine the complete genome sequence of an organism and to annotate protein-coding genes and other important genome-encoded features.

E.5.5 Metagenomics

- **Metagenomics** — Metagenomics is the study of all genetic material from all organisms in a particular environment, providing insights into their composition, diversity, and functional potential.
- **16S ribosomal RNA** — 16S ribosomal RNA is the RNA component of the 30S subunit of a prokaryotic ribosome. It binds to the Shine-Dalgarno sequence and provides most of the SSU structure.
- **Operational taxonomic unit** — An operational taxonomic unit (OTU) is an operational definition used to classify groups of closely related individuals. The term was originally introduced in 1963 by Robert R. Sokal and Peter H. A.
- **Amplicon sequence variant** — An amplicon sequence variant (ASV) is any one of the inferred single DNA sequences recovered from a high-throughput analysis of marker genes.
- **Binning (metagenomics)** — In metagenomics, binning is the computational process of grouping assembled contigs and assigning them to their separate genomes of origin.
- **Metagenome-assembled genome** — Metagenomics is the study of all genetic material from all organisms in a particular environment, providing insights into their composition, diversity, and functional potential.

E.5.6 Regulatory and epigenomic sequencing data

- **ChIP sequencing** — ChIP-sequencing, also known as ChIP-seq, is a method used to analyze protein interactions with DNA. ChIP-seq combines chromatin immunoprecipitation (ChIP) with massively parallel DNA sequencing to identify the binding sites of DNA-associated proteins.
- **ATAC-seq** — ATAC-seq is a laboratory technique used in molecular biology to assess genome-wide chromatin accessibility.
- **Bisulfite sequencing** — Bisulfite sequencing (also known as bisulphite sequencing) is the use of bisulfite treatment of DNA before routine sequencing to determine the pattern of methylation. DNA methylation was the first discovered epigenetic mark, and remains the most studied.
- **DNA methylation** — DNA methylation is a biological process by which methyl groups are added to the DNA molecule. Methylation can change the activity of a DNA segment without changing the sequence.
- **Cross-linking immunoprecipitation** — Cross-linking and immunoprecipitation is a method used in molecular biology that combines UV crosslinking with immunoprecipitation in order to identify RNA binding sites of proteins on a transcriptome-wide scale, thereby increasing our understanding of post-transcriptional regulatory networks.

E.5.7 Human genetics: finding disease genes and variants

- **Genome-wide association study** — In genomics, a genome-wide association study, is an observational study of a genome-wide set of genetic variants in different individuals to see if any variant is associated with a trait.
- **Linkage disequilibrium** — Linkage disequilibrium, often abbreviated to LD, is a term in population genetics referring to the association of genes, usually linked genes, in a population. It has become an important tool in medical genetics and other fields.
- **Polygenic score** — In genetics, a polygenic score (PGS) is a number that summarizes the estimated effect of many genetic variants on an individual's phenotype.
- **Missing heritability problem** — In genetics, the missing heritability problem refers to a difference between heritability estimates obtained from early genome-wide association studies (GWAS)

and heritability estimates from twin and family data across many physical and mental traits, including diseases, behaviors, and other phenotypes.
- **Exome sequencing** — Exome sequencing, also known as whole exome sequencing (WES), is a genomic technique for sequencing all of the protein-coding regions of genes in a genome. It consists of two steps: the first step is to select only the subset of DNA that encodes proteins.
- **Genetic linkage** — Genetic linkage is the tendency of DNA sequences that are close together on a chromosome to be inherited together during the meiosis phase of sexual reproduction.

E.6 Genomes

Wikipedia articles for Chapter 6.

E.6.1 Background: genes, genomes and cells

- **DNA** — Deoxyribonucleic acid is a polymer composed of two polynucleotide chains that coil around each other to form a double helix.
- **RNA** — Ribonucleic acid (RNA) is a polymeric molecule that is essential for most biological functions, either by performing the function itself or by forming a template for the production of proteins. RNA and deoxyribonucleic acid (DNA) are nucleic acids.
- **Gene** — In biology, the word gene has two meanings. The Mendelian gene is a basic unit of heredity. The molecular gene is a sequence of nucleotides in DNA that is transcribed to produce RNA.
- **Central dogma of molecular biology** — The central dogma of molecular biology deals with the flow of genetic information within a biological system. It is often stated as "DNA makes RNA, and RNA makes protein", although this is not its original meaning.
- **Transcription (biology)** — Transcription is the process of duplicating a segment of DNA into RNA for the purpose of gene expression. Some segments of DNA are transcribed into RNA molecules that can encode proteins, called messenger RNA (mRNA).
- **Translation (biology)** — Translation is the process in biological cells in which proteins are produced using RNA molecules as templates. The generated protein is a sequence of amino acids determined by the sequence of nucleotides in the RNA.
- **Genetic code** — Genetic code is a set of rules used by living cells to translate information encoded within genetic material into proteins.
- **Model organism** — A model organism is a non-human species that is extensively studied to understand particular biological phenomena, with the expectation that discoveries made in the model organism will provide insight into the workings of other organisms.

E.6.2 From the first genome projects

- **Genome project** — Genome projects are scientific endeavours that ultimately aim to determine the complete genome sequence of an organism and to annotate protein-coding genes and other important genome-encoded features.
- **Human Genome Project** — The Human Genome Project (HGP) was an international scientific research project with the goal of determining the base pairs that make up human DNA, and of identifying, mapping and sequencing all of the genes of the human genome from both a physical and a functional standpoint.
- **Shotgun sequencing** — In genetics, shotgun sequencing is a method used for sequencing random DNA strands. It is named by analogy with the rapidly expanding, quasi-random shot grouping of a shotgun.

- **Bermuda Principles** — The Bermuda Principles set out rules for the rapid and public release of DNA sequence data.
- **Genome size** — Genome size is the total amount of DNA contained within one copy of a single complete genome. It is typically measured in terms of mass in picograms or less frequently in daltons, or as the total number of nucleotide base pairs, usually in megabases.
- **C-value** — C-value is the amount, in picograms, of DNA contained within a haploid nucleus or one half the amount in a diploid somatic cell of a eukaryotic organism.
- **Polyploidy** — Polyploidy is a condition in which the cells of an organism have more than two paired sets of (homologous) chromosomes.

E.6.3 Differences across the tree of life

- **Prokaryote** — A prokaryote, less commonly spelled procaryote, is a cellular organism that lacks a distinct cell nucleus or other membrane-bound organelles.
- **Bacterial genome** — Bacterial genomes are generally smaller and less varied in size between species when compared with genomes of eukaryotes. Bacterial genomes can range in size anywhere from about 130 kbp to over 14 Mbp.
- **Operon** — In genetics, an operon is a functioning unit of DNA containing a cluster of genes under the control of a single promoter.
- **GC skew** — GC skew is when the nucleotides guanine and cytosine are over- or under-abundant in a particular region of DNA or RNA. GC skew is also a statistical method for measuring strand-specific guanine overrepresentation.
- **Intron** — An intron is any nucleotide sequence within a gene that is not expressed or operative in the final RNA product. The word intron is derived from the term intragenic region, i.e., a region inside a gene.
- **Paleopolyploidy** — Paleopolyploidy is the result of genome duplications which occurred at least several million years ago (MYA). Such an event could either double the genome of a single species (autopolyploidy) or combine those of two species (allopolyploidy).
- **Symbiogenesis** — Symbiogenesis, also known as the endosymbiotic theory or serial endosymbiotic theory,) is the leading scientific theory for the evolutionary origin of eukaryotes from prokaryotic ancestors.
- **Mitochondrial DNA** — Mitochondrial DNA is the DNA located in the mitochondria organelles in a eukaryotic cell that converts chemical energy from organic compounds into adenosine triphosphate (ATP).

E.6.4 Genomes in populations

- **Pan-genome** — In the fields of molecular biology and genetics, a pan-genome is the entire set of genes from all strains within a clade. More generally, it is the union of all the genomes of a clade.
- **Genetic drift** — Genetic drift is the change in the frequency of an existing allele in a population due to chance.
- **Effective population size** — The effective population size (Ne) is the size of an idealised population that would experience the same rate of genetic drift as the real population.
- **Drift-barrier hypothesis** — The drift-barrier hypothesis is an evolutionary hypothesis formulated by Michael Lynch in 2010 as an application of mutation-selection balance to mutation rates.
- **Recent African origin of modern humans** — The recent African origin of modern humans or the "Out of Africa" theory (OOA) holds that present-day humans outside Africa descend mainly from a single expansion of anatomically modern humans from Africa about 70,000–50,000 years ago.

- **Neanderthal genome project** — The Neanderthal genome project is an effort, founded in July 2006, of a group of scientists to sequence the Neanderthal genome.
- **Interbreeding between archaic and modern humans** — Interbreeding between archaic humans and anatomically modern humans took place during the Middle Paleolithic and early Upper Paleolithic.
- **Denisovan** — The Denisovans or Denisova hominins are an extinct species or subspecies of archaic human that ranged across Asia during the Middle to Late Pleistocene, approximately 200,000–32,000 years ago. Most of what is known about Denisovans comes from DNA evidence.

E.6.5 Repeats and the 3D genome

- **Transposable element** — Transposable elements (TEs), also known as transposons, jumping genes, or mobile genetic elements, are DNA sequences that can change their position, or translocate, within a genome.
- **Retrotransposon** — Retrotransposons are mobile elements which move in the host genome by converting their transcribed RNA into DNA through reverse transcription.
- **Alu element** — An Alu element is a short stretch of DNA originally characterized by the action of the Arthrobacter luteus (Alu) restriction endonuclease. Alu elements are the most abundant transposable elements in the human genome, present in excess of one million copies.
- **Selfish genetic element** — Selfish genetic elements are genetic segments that can enhance their own transmission at the expense of other genes in the genome, even if this has no positive or a net negative effect on organismal fitness.
- **Tandem repeat** — In genetics, tandem repeats occur in DNA when a pattern of one or more nucleotides is repeated and the repetitions are directly adjacent to each other, e.g. ATTCG ATTCG ATTCG, in which the sequence ATTCG is repeated three times.
- **Satellite DNA** — Satellite DNA, also known as highly repetitive DNA, consists of very large arrays of tandemly repeating, non-coding DNA. Satellite DNA is the main component of functional centromeres, and form the main structural constituent of heterochromatin.
- **Segmental duplication** — Low copy repeats (LCRs), also known as segmental duplications (SDs), or duplicons, are DNA sequences with high levels of sequence identity, present in multiple locations within a genome.
- **Chromatin** — Chromatin is a complex of DNA and protein responsible for condensing and packaging chromosomal DNA. Chromatin is found in both bacterial and eukaryotic cells.
- **Chromosome conformation capture** — Chromosome conformation capture techniques are a set of molecular biology methods used to analyze the spatial organization of chromatin in a cell.
- **Topologically associating domain** — A topologically associating domain (TAD) is a self-interacting genomic region, meaning that DNA sequences within a TAD physically interact with each other more frequently than with sequences outside the TAD.

E.6.6 RNA genes and regulatory elements

- **Non-coding RNA** — A non-coding RNA (ncRNA) is a functional RNA molecule that is not translated into a protein. The DNA sequence from which a functional non-coding RNA is transcribed is often called a non-coding gene or an RNA gene.
- **MicroRNA** — Micro ribonucleic acid are small, single-stranded, non-coding RNA molecules containing 21–23 nucleotides.
- **Long non-coding RNA** — Long non-coding RNAs are a type of RNA, generally defined as transcripts of more than 200 nucleotides that are not translated into protein.

- **Enhancer (genetics)** — In genetics, an enhancer is a short region of DNA that can be bound by proteins (activators) to increase the likelihood that transcription of a particular gene will occur. These proteins are usually referred to as transcription factors.
- **Non-coding DNA** — Non-coding DNA (ncDNA) sequences are components of an organism's DNA that do not encode protein sequences. Some non-coding DNA is transcribed into functional non-coding RNA molecules.
- **Junk DNA** — Junk DNA is a DNA sequence that has no known biological function.
- **ENCODE** — The Encyclopedia of DNA Elements (ENCODE) is a public research project which aims "to build a comprehensive parts list of functional elements in the human genome."

E.6.7 Gene order, synteny and genome rearrangements

- **Synteny** — In genetics, the term synteny refers to two related concepts:In classical genetics, synteny describes the physical co-localization of genetic loci on the same chromosome within an individual or species.
- **Chromosomal rearrangement** — In genetics, a chromosomal rearrangement is a mutation that is a type of chromosome abnormality involving a change in the structure of the native chromosome.
- **Dot plot (bioinformatics)** — In bioinformatics a dot plot is a graphical method for comparing two biological sequences and identifying regions of close similarity after sequence alignment. It is a type of recurrence plot.
- **Comparative genomics** — Comparative genomics is a branch of biological research that examines genome sequences across a spectrum of species, spanning from humans and mice to a diverse array of organisms from bacteria to chimpanzees.
- **Chromosomal inversion** — An inversion is a chromosome rearrangement in which a segment of a chromosome becomes inverted within its original position.

E.6.8 Pseudogenes, new genes and small proteins

- **Pseudogene** — Pseudogenes are nonfunctional segments of DNA that resemble functional genes. Pseudogenes can be formed from both protein-coding genes and non-coding genes.
- **De novo gene birth** — De novo gene birth is the process by which new genes evolve from non-coding DNA. De novo genes represent a subset of novel genes, and may be protein-coding or instead act as RNA genes.
- **Orphan gene** — Orphan genes, ORFans, or taxonomically restricted genes are genes that lack a detectable homologue outside of a given species or lineage. Most genes have known homologues.
- **Small open reading frame** — In molecular biology and genetics, reading frames are defined as spans of DNA sequence between the start and stop codons.
- **Retrogene** — Gene duplication is a mechanism through which new genetic material is generated during molecular evolution. It can be defined as any duplication of a region of DNA that contains a gene.

E.7 Expression analysis

Wikipedia articles for Chapter 7.

E.7.1 The first genome-wide methods: microarrays

- **DNA microarray** — A DNA microarray is a collection of microscopic DNA spots attached to a solid surface. Scientists use DNA microarrays to measure the expression levels of large numbers of genes simultaneously or to genotype multiple regions of a genome.
- **Gene expression profiling** — In the field of molecular biology, gene expression profiling is the measurement of the activity of thousands of genes at once, to create a global picture of cellular function.
- **Serial analysis of gene expression** — Serial Analysis of Gene Expression (SAGE) is a transcriptomic technique used by molecular biologists to produce a snapshot of the messenger RNA population in a sample of interest in the form of small tags that correspond to fragments of those transcripts.
- **Quantile normalization** — In statistics, quantile normalization is a technique for making two distributions identical in statistical properties.
- **MA plot** — Within computational biology, an MA plot is an application of a Bland–Altman plot for visual representation of genomic data.
- **Affymetrix** — Affymetrix is now Applied Biosystems, a brand of DNA microarray products sold by Thermo Fisher Scientific that originated with an American biotechnology research and development and manufacturing company of the same name.
- **Microarray analysis techniques** — Microarray analysis techniques are used in interpreting the data generated from experiments on DNA, RNA, and protein microarrays, which allow researchers to investigate the expression state of a large number of genes – in many cases, an organism's entire genome – in a single experiment.

E.7.2 RNA sequencing

- **RNA-Seq** — RNA-Seq is a next-generation sequencing (NGS) technique used to quantify and identify RNA molecules in a biological sample, providing a snapshot of the transcriptome at a specific time.
- **Transcriptomics technologies** — Transcriptomics technologies are the techniques used to study an organism's transcriptome, the sum of all of its RNA transcripts. The information content of an organism is recorded in the DNA of its genome and expressed through transcription.
- **Alternative splicing** — Alternative splicing, alternative RNA splicing, or differential splicing is an alternative splicing process during gene expression that allows a single gene to produce different splice variants.
- **Expectation–maximization algorithm** — In statistics, an expectation–maximization (EM) algorithm is an iterative method to find (local) maximum likelihood or maximum a posteriori (MAP) estimates of parameters in statistical models, where the model depends on unobserved latent variables.
- **Batch effect** — In molecular biology, a batch effect occurs when non-biological factors in an experiment cause changes in the data produced by the experiment.

E.7.3 Testing and statistics

- **Negative binomial distribution** — In probability theory and statistics, the negative binomial distribution, also called a Pascal distribution, is a discrete probability distribution that models the number of failures in a sequence of independent and identically distributed Bernoulli trials before a specified/constant/fixed number of successes occur.
- **Generalized linear model** — In statistics, a generalized linear model (GLM) is a flexible generalization of ordinary linear regression.

- **P-value** — In null-hypothesis significance testing, the p-value is the probability of obtaining test results at least as extreme as the result actually observed, under the assumption that the null hypothesis is correct.
- **Multiple comparisons problem** — Multiple comparisons, multiplicity or multiple testing problem occurs when many statistical tests are performed on the same dataset.
- **False discovery rate** — In statistics, the false discovery rate (FDR) is a method of conceptualizing the rate of type I errors in null hypothesis testing when conducting multiple comparisons.
- **Hierarchical clustering** — In data mining and statistics, hierarchical clustering is a method of cluster analysis that seeks to build a hierarchy of clusters.
- **Principal component analysis** — Principal component analysis (PCA) is a linear dimensionality reduction technique with applications in exploratory data analysis, visualization and data preprocessing.
- **T-distributed stochastic neighbor embedding** — t-distributed stochastic neighbor embedding (t-SNE) is a statistical method for visualizing high-dimensional data by giving each datapoint a location in a two or three-dimensional map.

E.7.4 From gene lists to biology

- **Gene set enrichment analysis** — Gene set enrichment analysis (GSEA) (also called functional enrichment analysis or pathway enrichment analysis) is a method to identify classes of genes or proteins that are over-represented in a large set of genes or proteins, and may have an association with different phenotypes (e.g. different organism growth patterns or diseases).
- **Gene Ontology** — The Gene Ontology (GO) is a major bioinformatics initiative to unify the representation of gene and gene product attributes across all species.
- **Hypergeometric distribution** — In probability theory and statistics, the hypergeometric distribution is a discrete probability distribution that describes the probability of successes in draws, without replacement, from a finite population of size that contains exactly objects with that feature, where in each draw is either a success or a failure.
- **Gene co-expression network** — A gene co-expression network (GCN) is an undirected graph, where each node corresponds to a gene, and a pair of nodes is connected with an edge if there is a significant co-expression relationship between them.
- **Weighted correlation network analysis** — Weighted correlation network analysis, also known as weighted gene co-expression network analysis (WGCNA), is a widely used data mining method especially for studying biological networks based on pairwise correlations between variables.
- **Expression quantitative trait loci** — An expression quantitative trait locus (eQTL) is a type of quantitative trait locus (QTL), a genomic locus that is associated with phenotypic variation for a specific, quantifiable trait.
- **Human Protein Atlas** — The Human Protein Atlas (HPA) is a Swedish-based program started in 2003 with the aim to map all the human proteins in cells, tissues and organs using integration of various omics technologies, including antibody-based imaging, mass spectrometry-based proteomics, transcriptomics and systems biology.

E.7.5 Single-cell genomics

- **Single-cell transcriptomics** — Single-cell transcriptomics refers to the quantification and analysis of the transcriptomes of individual cells.
- **Single-cell sequencing** — Single-cell sequencing examines the nucleic acid sequence information from individual cells with optimized next-generation sequencing technologies, providing a higher resolution of cellular differences and a better understanding of the function of an individual cell in the context of its microenvironment.

- **Unique molecular identifier** — Unique molecular identifiers (UMIs), or molecular barcodes (MBC) are short sequences or molecular "tags" added to DNA fragments in some next generation sequencing library preparation protocols to identify the input DNA molecule.
- **CITE-Seq** — CITE-Seq is a method for performing RNA sequencing along with gaining quantitative and qualitative information on surface proteins with available antibodies on a single cell level.
- **RNA velocity** — RNA velocity is a way of measuring the changes in gene expression. It is derived from ratio of spliced to unspliced RNA in the cell over time. Monitoring this value over time allows to see if the gene of interest is induced or repressed.
- **Spatial transcriptomics** — Spatial transcriptomics, or spatially resolved transcriptomics, is a method that captures positional context of transcriptional activity within intact tissue.
- **Foundation model** — In artificial intelligence, a foundation model (FM), also known as large x model, is a machine learning or deep learning model trained on vast datasets so that it can be applied across a wide range of use cases.
- **Human Cell Atlas** — The Human Cell Atlas is a global project to describe all cell types in the human body, to understand human health and for diagnosing, monitoring, and treating disease.

E.7.6 Single-cell sequencing and cancer evolution

- **Somatic evolution in cancer** — Somatic evolution is the accumulation of mutations and epimutations in somatic cells during a lifetime, and the effects of those mutations and epimutations on the fitness of those cells.
- **Tumour heterogeneity** — Tumour heterogeneity describes the observation that different tumour cells can show distinct morphological and phenotypic profiles, including cellular morphology, gene expression, metabolism, motility, proliferation, and metastatic potential.
- **Cancer stem cell** — Cancer stem cells (CSCs) are cancer cells that possess characteristics associated with normal stem cells, specifically the ability to give rise to all cell types found in a particular cancer sample.
- **Single-cell sequencing** — Single-cell sequencing examines the nucleic acid sequence information from individual cells with optimized next-generation sequencing technologies, providing a higher resolution of cellular differences and a better understanding of the function of an individual cell in the context of its microenvironment.
- **Copy number variation** — Copy number variation (CNV) is a phenomenon in which sections of the genome are repeated and the number of repeats in the genome varies between individuals.
- **Phylogenetic tree** — A phylogenetic tree or phylogeny is a graphical representation which shows the evolutionary history between a set of species or taxa during a specific time.
- **Infinite sites model** — The Infinite sites model (ISM) is a mathematical model of molecular evolution first proposed by Motoo Kimura in 1969. Like other mutation models, the ISM provides a basis for understanding how mutation develops new alleles in DNA sequences.

E.8 Proteomics

Wikipedia articles for Chapter 8.

E.8.1 Mass spectrometry methods

- **Proteomics** — Proteomics is the large-scale study of proteins. The proteome is the entire set of proteins produced or modified by an organism or system.

- **Mass spectrometry** — Mass spectrometry (MS) is an analytical technique that is used to measure the mass-to-charge ratio of ions. The results are presented as a mass spectrum, a plot of intensity as a function of the mass-to-charge ratio.
- **Liquid chromatography–mass spectrometry** — Liquid chromatography–mass spectrometry (LC–MS) is an analytical chemistry technique that combines the physical separation capabilities of liquid chromatography with the mass analysis capabilities of mass spectrometry (MS).
- **Electrospray ionization** — Electrospray ionization (ESI) is a technique used in mass spectrometry to produce ions using an electrospray in which a high voltage is applied to a liquid to create an aerosol.
- **Matrix-assisted laser desorption/ionization** — In mass spectrometry, matrix-assisted laser desorption/ionization (MALDI) is an ionization technique that uses a laser energy-absorbing matrix to create ions from large molecules with minimal fragmentation.
- **Orbitrap** — In mass spectrometry, Orbitrap is an ion trap mass analyzer consisting of an outer barrel-like electrode and a coaxial inner spindle-like electrode that traps ions in an orbital motion around the spindle.
- **Tandem mass spectrometry** — Tandem mass spectrometry, also known as MS/MS or MS2, is a technique in instrumental analysis where two or more stages of analysis using one or more mass analyzers are performed with an additional reaction step in between these analyses to increase their abilities to analyse chemical samples.
- **Collision-induced dissociation** — Collision-induced dissociation (CID), also known as collisionally activated dissociation (CAD), is a mass spectrometry technique to induce fragmentation of selected ions in the gas phase.
- **Bottom-up proteomics** — Bottom-up proteomics is a common method to identify proteins and characterize their amino acid sequences and post-translational modifications by proteolytic digestion of proteins prior to analysis by mass spectrometry.
- **Top-down proteomics** — Top-down proteomics is a method of protein identification capable of identifying and quantitating unique proteoforms through the analysis of intact proteins. The name is derived from the similar approach to DNA sequencing.
- **Data-independent acquisition** — In mass spectrometry, data-independent acquisition (DIA) is a method of molecular structure determination in which all ions within a selected m/z range are fragmented and analyzed in a second stage of tandem mass spectrometry.
- **Stable isotope labeling by amino acids in cell culture** — Stable isotope labeling by amino acids in cell culture (SILAC) is a technique based on mass spectrometry that detects differences in protein abundance among samples using non-radioactive isotopic labeling. It is a popular method for quantitative proteomics.
- **Isobaric labeling** — Isobaric labeling is a mass spectrometry strategy used in quantitative proteomics. Peptides or proteins are labeled with chemical groups that have nominally identical mass (isobaric), but vary in terms of distribution of heavy isotopes in their structure.
- **Label-free quantification** — Label-free quantification is a method in mass spectrometry that aims to determine the relative amount of proteins in two or more biological samples.

E.8.2 Algorithms for peptide identification

- **Shotgun proteomics** — Shotgun proteomics refers to the use of bottom-up proteomics techniques in identifying proteins in complex mixtures using a combination of high performance liquid chromatography combined with mass spectrometry.
- **Tandem mass spectrometry** — Tandem mass spectrometry, also known as MS/MS or MS2, is a technique in instrumental analysis where two or more stages of analysis using one or more mass analyzers are performed with an additional reaction step in between these analyses to increase their abilities to analyse chemical samples.

- **Peptide mass fingerprinting** — Peptide mass fingerprinting (PMF), also known as protein fingerprinting, is an analytical technique for protein identification in which the unknown protein of interest is first cleaved into smaller peptides, whose absolute masses can be accurately measured with a mass spectrometer such as MALDI-TOF or ESI-TOF.
- **Mascot (software)** — Mascot is a software search engine that uses mass spectrometry data to identify proteins from peptide sequence databases. Mascot is widely used by research facilities around the world.
- **De novo peptide sequencing** — In mass spectrometry, de novo peptide sequencing is the method in which a peptide amino acid sequence is determined from tandem mass spectrometry.
- **Proteogenomics** — Proteogenomics is a field of biological research that utilizes a combination of proteomics, genomics, and transcriptomics to aid in the discovery and identification of peptides.
- **Edman degradation** — Edman degradation, developed by Pehr Edman, is a method of sequencing amino acids in a peptide. In this method, the amino-terminal residue is labeled and cleaved from the peptide without disrupting the peptide bonds between other amino acid residues.

E.8.3 Statistics and error control

- **False discovery rate** — In statistics, the false discovery rate (FDR) is a method of conceptualizing the rate of type I errors in null hypothesis testing when conducting multiple comparisons.
- **Q-value (statistics)** — In statistical hypothesis testing, specifically multiple hypothesis testing, the q-value in the Storey procedure provides a means to estimate the positive false discovery rate (pFDR).
- **Multiple comparisons problem** — Multiple comparisons, multiplicity or multiple testing problem occurs when many statistical tests are performed on the same dataset.
- **Weak supervision** — Weak supervision is a paradigm in machine learning, the relevance and notability of which increased with the advent of large language models due to the large amount of data required to train them.
- **Support vector machine** — In machine learning, a support vector machine (SVM) or support vector network is a supervised max-margin model with associated learning algorithms that analyze data for classification and regression analysis.
- **Shotgun proteomics** — Shotgun proteomics refers to the use of bottom-up proteomics techniques in identifying proteins in complex mixtures using a combination of high performance liquid chromatography combined with mass spectrometry.
- **Label-free quantification** — Label-free quantification is a method in mass spectrometry that aims to determine the relative amount of proteins in two or more biological samples.

E.8.4 Proteomics beyond protein abundance

- **Post-translational modification** — Post-translational modifications (PTMs) are the covalent processes of changing proteins following their synthesis, and release from ribosomes.
- **Phosphoproteomics** — Phosphoproteomics is a branch of proteomics that identifies, catalogs, and characterizes proteins containing a phosphate group as a posttranslational modification.
- **Protein–protein interaction** — Protein–protein interactions (PPIs) are physical contacts of high specificity established between two or more protein molecules as a result of biochemical events steered by interactions that include electrostatic forces, hydrogen bonding and the hydrophobic effect.
- **Tandem affinity purification** — Tandem affinity purification (TAP) is an immunoprecipitation-based purification technique for studying protein–protein interactions. The goal is to extract from a cell only the protein of interest, in complex with any other proteins it interacted with.

- **Proximity labeling** — Enzyme-catalyzed proximity labeling (PL), also known as proximity-based labeling, is a laboratory technique that labels biomolecules, usually proteins or RNA, proximal to a protein of interest.
- **Hydrogen–deuterium exchange** — Hydrogen–deuterium exchange is a chemical reaction in which a covalently bonded hydrogen atom is replaced by a deuterium atom, or vice versa.
- **Thermal shift assay** — A thermal shift assay (TSA) measures the stability of a protein by the change in its thermal denaturation temperature. This is done under varying conditions, such as variations in drug concentration, buffer formulation, redox potential, or sequence mutation.
- **Mass spectrometry imaging** — Mass spectrometry imaging (MSI) is a technique used in mass spectrometry to visualize the spatial distribution of molecules, as biomarkers, metabolites, peptides or proteins by their molecular masses.

E.8.5 Proteomics without mass spectrometry

- **Human Protein Atlas** — The Human Protein Atlas (HPA) is a Swedish-based program started in 2003 with the aim to map all the human proteins in cells, tissues and organs using integration of various omics technologies, including antibody-based imaging, mass spectrometry-based proteomics, transcriptomics and systems biology.
- **Immunohistochemistry** — Immunohistochemistry is a form of immunostaining. It involves the process of selectively identifying antigens in cells and tissue, by exploiting the principle of antibodies binding specifically to antigens in biological tissues.
- **Antibody** — An antibody (Ab), or immunoglobulin (Ig), is a large protein belonging to the immunoglobulin superfamily which is used by the immune system to identify and neutralize antigens such as those that exist on bacteria and virus cells, including those that cause disease.
- **Proximity extension assay** — The proximity extension assay (PEA) is a method for detecting and quantifying the amount of many specific proteins present in a biological sample such as serum or plasma.
- **Aptamer** — Aptamers are oligomers of artificial ssDNA, RNA, XNA, or peptide that bind a specific target molecule, or family of target molecules.
- **Mass cytometry** — Mass cytometry is a high-dimensional single-cell analysis technique that integrates flow cytometry with time of flight mass spectrometry. It is used for the determination of the properties of cells (cytometry).
- **Protein sequencing** — Protein sequencing is the practical process of determining the amino acid sequence of all or part of a protein or peptide. This may serve to identify the protein or characterize its post-translational modifications.
- **Nanopore sequencing** — Nanopore sequencing is a third generation approach used in the sequencing of biopolymers — specifically, polynucleotides in the form of DNA or RNA.

E.8.6 Repositories and standards

- **Proteomics Identifications Database** — The PRIDE is a public data repository of mass spectrometry-based proteomics data, and is maintained by the European Bioinformatics Institute as part of the Proteomics Team.
- **PeptideAtlas** — PeptideAtlas is a proteomics data resource that gathers tandem mass spectrometry datasets from around the world, reprocesses them with the Trans-Proteomic Pipeline, and makes the combined result freely available to the community.
- **Proteomics Standards Initiative** — The Proteomics Standards Initiative (PSI) is a working group of the Human Proteome Organization. It aims to define data standards for proteomics to facilitate data comparison, exchange and verification.

- **Mass spectrometry data format** — Mass spectrometry is a scientific technique for measuring the mass-to-charge ratio of ions.
- **Human Proteome Organization** — The Human Proteome Organization (HUPO) is an international consortium of national proteomics research associations, government researchers, academic institutions, and industry partners.
- **Human Proteome Project** — The Human Proteome Project (HPP) is a collaborative effort coordinated by the Human Proteome Organization. Its stated goal is to experimentally observe all of the proteins produced by the sequences translated from the human genome.

E.9 Protein structure

Wikipedia articles for Chapter 9.

E.9.1 CASP: a blind test of structure prediction

- **CASP** — Critical Assessment of Structure Prediction (CASP), sometimes called Critical Assessment of Protein Structure Prediction, is a community-wide, worldwide experiment for protein structure prediction taking place every two years since 1994.
- **Global distance test** — The global distance test (GDT), also written as GDT_TS to represent "total score", is a measure of similarity between two protein structures with known amino acid correspondences but different tertiary structures.
- **Template modeling score** — In bioinformatics, the template modeling score or TM-score is a measure of similarity between two protein structures.
- **Root-mean-square deviation of atomic positions** — In bioinformatics, the root mean square deviation of atomic positions, or simply root mean square deviation (RMSD), is the measure of the average distance between the atoms (usually the backbone atoms) of superimposed molecules.
- **Protein structure prediction** — Protein structure prediction is the inference of the three-dimensional structure of a protein from its amino acid sequence—that is, the prediction of its secondary and tertiary structure from primary structure.
- **Critical Assessment of Prediction of Interactions** — Critical Assessment of PRediction of Interactions (CAPRI) is a community-wide experiment in modelling the molecular structure of protein complexes, otherwise known as protein–protein docking.

E.9.2 Background: amino acids, energetics and enzymes

- **Amino acid** — Amino acids are organic compounds that contain both amino and carboxylic acid functional groups. Although over 500 amino acids exist in nature, by far the most important are the 22 α-amino acids incorporated into proteins.
- **Proteinogenic amino acid** — Proteinogenic amino acids are amino acids that are incorporated biosynthetically into proteins during translation from RNA. The word "proteinogenic" means "protein creating".
- **Peptide bond** — In organic chemistry, a peptide bond is an amide type of covalent chemical bond linking two consecutive alpha-amino acids from C1 of one alpha-amino acid and N2 of another, along a peptide or protein chain.
- **Gibbs free energy** — In thermodynamics, the Gibbs free energy is a thermodynamic potential that can be used to calculate the maximum amount of work, other than pressure–volume work, that may be performed by a thermodynamically closed system at constant temperature and pressure.

- **Dissociation constant** — In chemistry, biochemistry, and pharmacology, a dissociation constant (KD) is a specific type of equilibrium constant that measures the propensity of a larger object to separate (dissociate) reversibly into smaller components, as when a complex falls apart into its component molecules, or when a salt splits up into its component ions.
- **Enzyme** — An enzyme is a biological macromolecule, usually a protein, that acts as a biological catalyst, accelerating chemical reactions without being consumed in the process. The molecules on which enzymes act are called substrates, which are converted into products.
- **Enzyme catalysis** — Enzyme catalysis is the increase in the rate of a process by an "enzyme", a biological molecule. Most enzymes are proteins, and most such processes are chemical reactions.
- **Michaelis–Menten kinetics** — In biochemistry, Michaelis–Menten kinetics, named after Leonor Michaelis and Maud Menten, is the simplest case of enzyme kinetics, applied to enzyme-catalysed reactions involving the transformation of one substrate into one product.

E.9.3 Protein structure and how it is determined

- **Protein structure** — Protein structure is the three-dimensional arrangement of atoms in an amino acid-chain molecule. Proteins are polymers – specifically polypeptides – formed from sequences of amino acids, which are the monomers of the polymer.
- **Protein secondary structure** — Protein secondary structure is the local spatial conformation of the polypeptide backbone excluding the side chains. The two most common secondary structural elements are alpha helices and beta sheets, though beta turns and omega loops occur as well.
- **Ramachandran plot** — In biochemistry, a Ramachandran plot, originally developed in 1963 by G. N. Ramachandran, C. Ramakrishnan, and V.
- **X-ray crystallography** — X-ray crystallography is the experimental science of determining the atomic and molecular structure of a crystal, in which the structure causes a beam of incident X-rays to diffract in specific directions.
- **R-factor (crystallography)** — In crystallography, the R-factor is a measure of the disagreement between the crystallographic model and the experimental X-ray diffraction data - lower the R value lower is the disagreement or better is the agreement.
- **Protein nuclear magnetic resonance spectroscopy** — Nuclear magnetic resonance spectroscopy of proteins is a field of structural biology in which NMR spectroscopy is used to obtain information about the structure and dynamics of proteins, and also nucleic acids, and their complexes.
- **Cryogenic electron microscopy** — Cryogenic electron microscopy (cryo-EM) is a transmission electron microscopy technique applied to samples cooled to cryogenic temperatures.
- **Single particle analysis** — Single particle analysis is a group of related computerized image processing techniques used to analyze images from transmission electron microscopy (TEM).

E.9.4 Protein folding

- **Protein folding** — Protein folding is the physical process by which a protein, after synthesis by a ribosome as a linear chain of amino acids, changes from an unstable random coil into a more ordered three-dimensional structure.
- **Anfinsen's dogma** — Anfinsen's dogma, also known as the thermodynamic hypothesis, is a postulate in molecular biology.
- **Levinthal's paradox** — Levinthal's paradox is a thought experiment in the field of computational protein structure prediction that concerns the mechanism through which peptides reach a stable native configuration, given the large amount of folding conformations.

- **Folding funnel** — The folding funnel hypothesis is a specific version of the energy landscape theory of protein folding, which assumes that a protein's native state corresponds to its free energy minimum under the solution conditions usually encountered in cells.
- **Hydrophobic effect** — The hydrophobic effect is the observed tendency of nonpolar substances to aggregate in an aqueous solution and to be excluded by water.
- **Molten globule** — In molecular biology, the term molten globule (MG) refers to protein states that are more or less compact, but are lacking the specific tight packing of amino acid residues which creates the solid state-like tertiary structure of completely folded proteins.
- **Chaperone (protein)** — In molecular biology, molecular chaperones are proteins that assist the conformational folding or unfolding of proteins or macromolecular protein complexes.

E.9.5 Structure comparison and evolution

- **Structural alignment** — Structural alignment attempts to establish homology between two or more polymer structures based on their shape and three-dimensional conformation. This process is usually applied to protein tertiary structures but can also be used for large RNA molecules.
- **Structural alignment software** — This list of structural comparison and alignment software is a compilation of software tools and web portals used in pairwise or multiple structural comparison and structural alignment.
- **Root-mean-square deviation of atomic positions** — In bioinformatics, the root mean square deviation of atomic positions, or simply root mean square deviation (RMSD), is the measure of the average distance between the atoms (usually the backbone atoms) of superimposed molecules.
- **Template modeling score** — In bioinformatics, the template modeling score or TM-score is a measure of similarity between two protein structures.
- **Protein fold** — A protein superfamily is the largest grouping (clade) of proteins for which common ancestry can be inferred. Usually this common ancestry is inferred from structural alignment and mechanistic similarity, even if no sequence similarity is evident.
- **Protein domain** — In molecular biology, a protein domain is a region of a protein's polypeptide chain that is self-stabilizing and folds independently from the rest. Each domain forms a compact, folded three-dimensional structure.
- **Protein superfamily** — A protein superfamily is the largest grouping (clade) of proteins for which common ancestry can be inferred. Usually this common ancestry is inferred from structural alignment and mechanistic similarity, even if no sequence similarity is evident.

E.9.6 Protein structure databases

- **Protein Data Bank** — The Protein Data Bank (PDB) is a database for the three-dimensional structural data of large biological molecules such as proteins and nucleic acids, which is overseen by the Worldwide Protein Data Bank (wwPDB).
- **Structural Classification of Proteins database** — The Structural Classification of Proteins (SCOP) database is a largely manual classification of protein structural domains based on similarities of their structures and amino acid sequences.
- **CATH database** — The CATH Protein Structure Classification database is a free, publicly available online resource that provides information on the evolutionary relationships of protein domains.
- **Evolutionary Classification of Protein Domains** — The Evolutionary Classification of Protein Domains (ECOD) is a biological database that classifies protein domains available from the Protein Data Bank. The ECOD tries to determine the evolutionary relationships between proteins.
- **AlphaFold Protein Structure Database** — AlphaFold is an artificial intelligence (AI) program developed by DeepMind, a subsidiary of Alphabet, which performs predictions of protein structure. It is designed using deep learning techniques.

- **Protein domain** — In molecular biology, a protein domain is a region of a protein's polypeptide chain that is self-stabilizing and folds independently from the rest. Each domain forms a compact, folded three-dimensional structure.

E.9.7 Protein structure prediction

- **Protein structure prediction** — Protein structure prediction is the inference of the three-dimensional structure of a protein from its amino acid sequence—that is, the prediction of its secondary and tertiary structure from primary structure.
- **Homology modeling** — Homology modeling, also known as comparative modeling of protein, refers to constructing an atomic-resolution model of the "target" protein from its amino acid sequence and an experimental three-dimensional structure of a related homologous protein.
- **Threading (protein sequence)** — In molecular biology, protein threading, also known as fold recognition, is a method of protein modeling which is used to model those proteins which have the same fold as proteins of known structures, but do not have homologous proteins with known structure.
- **De novo protein structure prediction** — In computational biology, de novo protein structure prediction refers to an algorithmic process by which protein tertiary structure is predicted from its amino acid primary sequence.
- **Direct coupling analysis** — Direct coupling analysis or DCA is an umbrella term comprising several methods for analyzing sequence data in computational biology.
- **Protein contact map** — A protein contact map represents the distance between all possible amino acid residue pairs of a three-dimensional protein structure using a binary two-dimensional matrix.
- **AlphaFold** — AlphaFold is an artificial intelligence (AI) program developed by DeepMind, a subsidiary of Alphabet, which performs predictions of protein structure. It is designed using deep learning techniques.
- **Intrinsically disordered proteins** — In molecular biology, an intrinsically disordered protein (IDP) is a protein that lacks a fixed or ordered three-dimensional structure, typically in the absence of its macromolecular interaction partners, such as other proteins or RNA.

E.9.8 Protein language models and structure

- **Large language model** — A large language model (LLM) is an AI model trained on a vast amount of text for natural language processing tasks, especially language generation. LLMs can typically generate, summarize, translate, and analyze text in many contexts.
- **Transformer (deep learning architecture)** — In deep learning, the transformer is a family of artificial neural network architectures based on the multi-head attention mechanism, in which input data such as text, images, or audio is converted to a sequence of numerical representations called tokens, and each token is converted into a vector through an embedding layer.
- **BERT (language model)** — Bidirectional encoder representations from transformers (BERT) is a language model introduced in October 2018 by researchers at Google. It learns to represent text as a sequence of vectors using self-supervised learning.
- **Word embedding** — In natural language processing, a word embedding is a representation of a word. The embedding is used in text analysis.
- **Multiple sequence alignment** — Multiple sequence alignment (MSA) is the process or the result of sequence alignment of three or more biological sequences, generally protein, DNA, or RNA.
- **Metagenomics** — Metagenomics is the study of all genetic material from all organisms in a particular environment, providing insights into their composition, diversity, and functional potential.

- **AlphaFold** — AlphaFold is an artificial intelligence (AI) program developed by DeepMind, a subsidiary of Alphabet, which performs predictions of protein structure. It is designed using deep learning techniques.

E.9.9 Membrane proteins

- **Membrane protein** — Membrane proteins are common proteins that are part of, or interact with, biological membranes. Membrane proteins fall into several broad categories depending on their location.
- **Transmembrane protein** — A transmembrane protein is a type of integral membrane protein that spans the entirety of the cell membrane. Many transmembrane proteins function as gateways to permit the transport of specific substances across the membrane.
- **Transmembrane domain** — A transmembrane domain is a membrane-spanning protein domain. TMDs may consist of one or several alpha-helices or a transmembrane beta barrel.
- **Membrane topology** — Topology of a transmembrane protein refers to locations of N- and C-termini of membrane-spanning polypeptide chain with respect to the inner or outer sides of the biological membrane occupied by the protein.
- **Hydrophobicity scales** — Hydrophobicity scales are values that define the relative hydrophobicity or hydrophilicity of amino acid residues. The more positive the value, the more hydrophobic are the amino acids located in that region of the protein.
- **Translocon** — The translocon is a general term for a protein channel in biological membranes that functions to move polypeptides across the membrane or insert them into the lipid bilayer.
- **Beta barrel** — In protein structures, a beta barrel (β barrel) is a beta sheet composed of tandem repeats that twists and coils to form a closed toroidal structure in which the first strand is bonded to the last strand.
- **Bacterial outer membrane** — The bacterial outer membrane is found in gram-negative bacteria. Gram-negative bacteria form two lipid bilayers in their cell envelopes - an inner membrane (IM) that encapsulates the cytoplasm, and an outer membrane (OM) that encapsulates the periplasm.

E.9.10 Dynamics and docking

- **Molecular dynamics** — Molecular dynamics (MD) is a computer simulation method for analyzing the physical movements of atoms and molecules. The atoms and molecules are allowed to interact for a fixed period of time, giving a view of the dynamic "evolution" of the system.
- **Force field (chemistry)** — In the context of chemistry, molecular physics, physical chemistry, and molecular modelling, a force field is a computational model that is used to describe the forces between atoms within molecules or between molecules as well as in crystals.
- **Protein dynamics** — In molecular biology, proteins are generally thought to adopt unique structures determined by their amino acid sequences. However, proteins are not strictly static objects, but rather populate ensembles of conformations.
- **Normal mode** — A normal mode of a dynamical system is a pattern of motion in which all parts of the system move sinusoidally with the same frequency and with a fixed phase relation. The free motion described by the normal modes takes place at fixed frequencies.
- **Anisotropic Network Model** — The Anisotropic Network Model (ANM) is a simple yet powerful tool made for normal mode analysis of proteins, which has been successfully applied for exploring the relation between function and dynamics for many proteins.
- **Gaussian network model** — The Gaussian network model (GNM) is a representation of a biological macromolecule as an elastic mass-and-spring network to study, understand, and characterize the mechanical aspects of its long-time large-scale dynamics.

- **Docking (molecular)** — In the field of molecular modeling, docking is a method which predicts the preferred orientation of one molecule to a second when a ligand and a target are bound to each other to form a stable complex.
- **Scoring functions for docking** — In the fields of computational chemistry and molecular modelling, scoring functions are mathematical functions used to approximately predict the binding affinity between two molecules after they have been docked.

E.9.11 Protein design

- **Protein design** — Protein design is the rational design of new protein molecules to design novel activity, behavior, or purpose, and to advance basic understanding of protein function.
- **Protein engineering** — Protein engineering is the process of developing useful or valuable proteins through the design and production of unnatural polypeptides, often by altering amino acid sequences found in nature.
- **Diffusion model** — In machine learning, diffusion models, also known as diffusion-based generative models or score-based generative models, are a class of latent variable generative models.
- **Rosetta@home** — Rosetta@home is a volunteer computing project researching protein structure prediction on the Berkeley Open Infrastructure for Network Computing (BOINC) platform, run by the Baker lab.
- **Protein folding** — Protein folding is the physical process by which a protein, after synthesis by a ribosome as a linear chain of amino acids, changes from an unstable random coil into a more ordered three-dimensional structure.

E.10 Protein function

Wikipedia articles for Chapter 10.

E.10.1 Definitions of function

- **Gene Ontology** — The Gene Ontology (GO) is a major bioinformatics initiative to unify the representation of gene and gene product attributes across all species.
- **Ontology (information science)** — In information science, an ontology encompasses a representation, formal naming, and definitions of the categories, properties, and relations between the concepts, data, or entities that pertain to one, many, or all domains of discourse.
- **Enzyme Commission number** — The Enzyme Commission number is a numerical classification scheme for enzymes, based on the chemical reactions they catalyze.
- **Enzyme** — An enzyme is a biological macromolecule, usually a protein, that acts as a biological catalyst, accelerating chemical reactions without being consumed in the process. The molecules on which enzymes act are called substrates, which are converted into products.
- **Moonlighting protein** — Protein moonlighting is a phenomenon by which a protein can perform more than one function. It is an example of gene sharing.
- **Protein function prediction** — Protein function prediction methods are techniques that bioinformatics researchers use to assign biological or biochemical roles to proteins. These proteins are usually ones that are poorly studied or predicted based on genomic sequence data.

E.10.2 Function prediction

- **Protein function prediction** — Protein function prediction methods are techniques that bioinformatics researchers use to assign biological or biochemical roles to proteins. These proteins are usually ones that are poorly studied or predicted based on genomic sequence data.
- **Sequence homology** — Sequence homology is the biological homology between DNA, RNA, or protein sequences, defined in terms of shared ancestry in the evolutionary history of life.
- **Homology (biology)** — In biology, homology is similarity in anatomical structures or genes between organisms of different taxa due to shared ancestry, regardless of current functional differences.
- **Protein domain** — In molecular biology, a protein domain is a region of a protein's polypeptide chain that is self-stabilizing and folds independently from the rest. Each domain forms a compact, folded three-dimensional structure.
- **InterPro** — InterPro is a database of protein families, protein domains and functional sites in which identifiable features found in known proteins can be applied to new protein sequences in order to functionally characterise them.
- **Phylogenetic profiling** — Phylogenetic profiling is a bioinformatics technique in which the joint presence or joint absence of two traits across large numbers of species is used to infer a meaningful biological connection, such as involvement of two different proteins in the same biological pathway.
- **Operon** — In genetics, an operon is a functioning unit of DNA containing a cluster of genes under the control of a single promoter.
- **Short linear motif** — In molecular biology short linear motifs (SLiMs), linear motifs or minimotifs are short stretches of protein sequence that mediate protein–protein interaction.

E.10.3 Subcellular localisation

- **Protein targeting** — Protein targeting or protein sorting is the biological mechanism by which proteins are transported to their appropriate destinations within or outside the cell.
- **Signal peptide** — A signal peptide is a short peptide present at the N-terminus of most newly synthesized proteins that are destined toward the secretory pathway.
- **Signal recognition particle** — The signal recognition particle (SRP) is an abundant, cytosolic, universally conserved ribonucleoprotein that recognizes and targets specific proteins to the endoplasmic reticulum in eukaryotes and the plasma membrane in prokaryotes.
- **Transit peptide** — A signal peptide is a short peptide present at the N-terminus of most newly synthesized proteins that are destined toward the secretory pathway.
- **Mitochondrial targeting sequence** — A target peptide is a short peptide consensus sequence that directs the transport of a protein to a specific region in the cell, including the nucleus, mitochondria, endoplasmic reticulum (ER), chloroplast, apoplast, peroxisome and plasma membrane.
- **Nuclear localization sequence** — A nuclear localization sequence, or signal (NLS) is an amino acid sequence motif that 'tags' a protein for import into the cell nucleus by nuclear transport.
- **Protein subcellular localization prediction** — Protein subcellular localization prediction involves the prediction of where a protein resides in a cell, its subcellular localization.

E.10.4 Predicting the effects of mutations

- **Missense mutation** — In genetics, a missense mutation is a point mutation in which a single nucleotide change results in a codon that codes for a different amino acid. It is a type of nonsynonymous substitution.

- **Multiplexed Assays of Variant Effect** — Multiplexed Assays of Variant Effect (MAVE) is a method used to determine sequence-function relationships, identify variants that alter protein structure, stability, or activity, and characterize regulatory elements.
- **ClinVar** — ClinVar is a public archive with free access to reports on the relationships between human genetic variations and phenotypes, with supporting evidence. The database includes germline and somatic variants of any size, type or genomic location.
- **Variant of uncertain significance** — A variant of uncertain significance (VUS) is a genetic variant that has been identified through genetic testing but whose significance to the function or health of an organism is not known.

E.10.5 Benchmarking function prediction

- **Critical Assessment of Function Annotation** — The Critical Assessment of Function Annotation (CAFA) is an ongoing community-driven experiment designed to evaluate computational methods for protein function prediction.
- **Protein function prediction** — Protein function prediction methods are techniques that bioinformatics researchers use to assign biological or biochemical roles to proteins. These proteins are usually ones that are poorly studied or predicted based on genomic sequence data.
- **Precision and recall** — In classification, precision and recall are performance metrics that apply to data retrieved from a collection, corpus or sample space.
- **Open-world assumption** — The closed-world assumption (CWA), in a formal system of logic used for knowledge representation, is the presumption that a statement that is true is also known to be true. Therefore, by the contrapositive, what is not currently known to be true must be false.

E.10.6 Experimental determination of function

- **Forward genetics** — Forward genetics is a molecular genetics approach of determining the genetic basis responsible for a phenotype.
- **Reverse genetics** — Reverse genetics is a method in molecular genetics that is used to help understand the function(s) of a gene by analysing the phenotypic effects caused by genetically engineering specific nucleic acid sequences within the gene.
- **CRISPR gene editing** — CRISPR gene editing is a genetic engineering technique in molecular biology by which the genomes of living organisms may be modified. It is based on a simplified version of the bacterial CRISPR-Cas9 antiviral defense system.
- **Genetic screen** — A genetic screen or mutagenesis screen is an experimental technique used to identify and select individuals who possess a phenotype of interest in a mutagenized population. Hence a genetic screen is a type of phenotypic screen.
- **Gene knockout** — Gene knockouts are a widely used genetic engineering technique that involves the targeted removal or inactivation of a specific gene within an organism's genome.
- **Essential gene** — Essential genes are indispensable genes for organisms to grow and reproduce offspring under certain environment. However, being essential is highly dependent on the circumstances in which an organism lives.

E.11 Protein–protein interactions

Wikipedia articles for Chapter 11.

E.11.1 Experimental methods

- **Protein–protein interaction** — Protein–protein interactions (PPIs) are physical contacts of high specificity established between two or more protein molecules as a result of biochemical events steered by interactions that include electrostatic forces, hydrogen bonding and the hydrophobic effect.
- **Two-hybrid screening** — Two-hybrid screening is a molecular biology technique used to discover protein–protein interactions (PPIs) and protein–DNA interactions by testing for physical interactions between two proteins or a single protein and a DNA molecule, respectively.
- **Tandem affinity purification** — Tandem affinity purification (TAP) is an immunoprecipitation-based purification technique for studying protein–protein interactions. The goal is to extract from a cell only the protein of interest, in complex with any other proteins it interacted with.
- **Co-immunoprecipitation** — Immunoprecipitation (IP) is the technique of precipitating a protein antigen out of solution using an antibody that specifically binds to that particular protein.
- **Protein-fragment complementation assay** — Within the field of molecular biology, a protein-fragment complementation assay, or PCA, is a method for the identification and quantification of protein–protein interactions.
- **Synthetic lethality** — Synthetic lethality is defined as a type of genetic interaction where the combination of two genetic events results in cell death or death of an organism.
- **Epistasis** — Epistasis is a phenomenon in genetics in which the effect of a mutation on a trait is dependent on the presence or absence of mutations at different loci, that may be on the same gene (intragenic) or on different genes, called modifier genes.
- **Gene regulatory network** — A gene regulatory network (GRN) is a collection of molecular regulators that interact with each other and with other substances in the cell to govern the gene expression levels of mRNA and proteins which, in turn, determine the function of the cell.

E.11.2 Networks

- **Interactome** — In molecular biology, an interactome is the whole set of molecular interactions in a particular cell. The term specifically refers to physical interactions among molecules but can also describe sets of indirect interactions among genes.
- **Biological network** — A biological network is a method of representing systems as complex sets of binary interactions or relations between various biological entities. In general, networks or graphs are used to capture relationships between entities or objects.
- **Scale-free network** — A scale-free network is a network whose degree distribution follows a power law, at least asymptotically. That is, the fraction P(k) of nodes in the network having k connections to other nodes goes for large values of k as
- **Small-world network** — A small-world network is a graph characterized by a high clustering coefficient and low distances. In an example of a social network, high clustering implies the high probability that two friends of one person are friends themselves.
- **Clustering coefficient** — In graph theory, a clustering coefficient is a measure of the degree to which nodes in a graph tend to cluster together.
- **Network motif** — Network motifs are recurrent and statistically significant subgraphs or patterns of a larger graph.
- **STRING** — In molecular biology, STRING is a biological database and web resource of known and predicted protein–protein interactions.
- **Network medicine** — Network medicine is the application of network science towards identifying, preventing, and treating diseases. This field focuses on using network topology and network dynamics towards identifying diseases and developing medical drugs.
- **Systems biology** — Systems biology is the computational and mathematical analysis and modeling of complex biological systems.

- **Flux balance analysis** — In biochemistry and systems biology, flux balance analysis (FBA) is a mathematical method for simulating the metabolism of cells or entire unicellular organisms, such as E. coli or yeast, using genome-scale reconstructions of metabolic networks.

E.11.3 Prediction methods

- **Protein–protein interaction prediction** — Protein–protein interaction prediction is a field combining bioinformatics and structural biology in an attempt to identify and catalog physical interactions between pairs or groups of proteins.
- **Phylogenetic profiling** — Phylogenetic profiling is a bioinformatics technique in which the joint presence or joint absence of two traits across large numbers of species is used to infer a meaningful biological connection, such as involvement of two different proteins in the same biological pathway.
- **Direct coupling analysis** — Direct coupling analysis or DCA is an umbrella term comprising several methods for analyzing sequence data in computational biology.
- **Docking (molecular)** — In the field of molecular modeling, docking is a method which predicts the preferred orientation of one molecule to a second when a ligand and a target are bound to each other to form a stable complex.
- **Protein–protein docking** — Macromolecular docking is the computational modelling of the quaternary structure of complexes formed by two or more interacting biological macromolecules.
- **Critical Assessment of Prediction of Interactions** — Critical Assessment of PRediction of Interactions (CAPRI) is a community-wide experiment in modelling the molecular structure of protein complexes, otherwise known as protein–protein docking.
- **AlphaFold** — AlphaFold is an artificial intelligence (AI) program developed by DeepMind, a subsidiary of Alphabet, which performs predictions of protein structure. It is designed using deep learning techniques.
- **Biomolecular condensate** — In biochemistry, biomolecular condensates are a class of membraneless organelles and organelle subdomains, which carry out specialized functions within the cell.

E.12 Machine learning

Wikipedia articles for Chapter 12.

E.12.1 Basics

- **Machine learning** — Machine learning (ML) is a field of study in artificial intelligence concerned with the development and study of statistical algorithms that can learn from data and generalize to unseen data, and thus perform tasks without being explicitly programmed.
- **Overfitting** — In mathematical modeling, overfitting is the production of an analysis that corresponds too closely or exactly to a particular set of data and may therefore fail to fit to additional data or predict future observations reliably.
- **Bias–variance tradeoff** — In statistics and machine learning, the bias–variance tradeoff describes the relationship between a model's complexity, the accuracy of its predictions, and how well it can make predictions on previously unseen data that were not used to train the model.
- **Cross-validation (statistics)** — Cross-validation, sometimes called rotation estimation or out-of-sample testing, is any of various similar model validation techniques for assessing how the results of a statistical analysis will generalize to an independent data set.
- **Leakage (machine learning)** — In statistics and machine learning, leakage refers to the use of information during model training that would not be available at prediction time.

- **Precision and recall** — In classification, precision and recall are performance metrics that apply to data retrieved from a collection, corpus or sample space.
- **Receiver operating characteristic** — A receiver operating characteristic curve, or ROC curve, is a graphical plot that illustrates the performance of a binary classifier model at varying threshold values.
- **Phi coefficient** — In statistics, the phi coefficient, also known as the mean square contingency coefficient or Yule coefficient of correlation and commonly denoted by φ or $r\varphi$, is a measure of association between two binary variables.

E.12.2 A short history of machine learning in bioinformatics

- **Perceptron** — In machine learning, the perceptron is an algorithm for supervised learning of binary classifiers. A binary classifier is a function that can decide whether or not an input, represented by a vector of numbers, belongs to some specific class.
- **Artificial neural network** — In machine learning, a neural network (NN) or artificial neural network (ANN) is a computational model inspired by the structure and functions of biological neural networks.
- **Backpropagation** — In machine learning, backpropagation is a gradient computation method commonly used for training a neural network in computing parameter updates.
- **Hidden Markov model** — In probability theory, a hidden Markov model (HMM) is a Markov model in which the observations are dependent on a latent Markov process. An HMM requires that there be an observable process whose outcomes depend on the outcomes of in a known way.
- **Support vector machine** — In machine learning, a support vector machine (SVM) or support vector network is a supervised max-margin model with associated learning algorithms that analyze data for classification and regression analysis.
- **Kernel method** — In machine learning, kernel machines are a class of algorithms for pattern analysis, whose best known member is the support-vector machine (SVM). These methods involve using linear classifiers to solve nonlinear problems.
- **Random forest** — Random forests or random decision forests is an ensemble learning method for classification, regression and other tasks that works by creating a multitude of decision trees during training.
- **Gradient boosting** — Gradient boosting is a machine learning technique based on boosting in a functional space, where the target is pseudo-residuals instead of residuals as in traditional boosting.

E.12.3 Deep learning

- **Deep learning** — In machine learning, deep learning (DL) focuses on utilizing multilayered neural networks to perform tasks such as classification, regression, and representation learning.
- **Stochastic gradient descent** — Stochastic gradient descent is an iterative method for optimizing an objective function with suitable smoothness properties.
- **Convolutional neural network** — A convolutional neural network (CNN) is a type of feedforward neural network that learns features via filter optimization.
- **Recurrent neural network** — In artificial neural networks, recurrent neural networks (RNNs) are designed for processing sequential data, such as text, speech, and time series, where the order of elements is important.
- **Long short-term memory** — Long short-term memory (LSTM) is a type of recurrent neural network (RNN) aimed at mitigating the vanishing gradient problem commonly encountered by traditional RNNs.

- **Transformer (deep learning architecture)** — In deep learning, the transformer is a family of artificial neural network architectures based on the multi-head attention mechanism, in which input data such as text, images, or audio is converted to a sequence of numerical representations called tokens, and each token is converted into a vector through an embedding layer.
- **Graph neural network** — Graph neural networks (GNNs) are artificial neural networks designed for tasks whose inputs are graphs.
- **Explainable artificial intelligence** — Within artificial intelligence (AI), explainable AI (XAI), generally overlapping with interpretable AI, interpretable machine learning and explainable machine learning (XML), is a field of research that explores methods that provide humans with the ability of intellectual oversight over AI algorithms.

E.12.4 Generative models

- **Generative model** — Generative models are a class of computational models frequently used for classification.
- **Autoregressive model** — In statistics, an autoregressive (AR) model is a modelled representation of a type of random process. It can be used to describe time-varying processes from many natural and artificial sources.
- **Autoencoder** — An autoencoder is a type of artificial neural network used to learn efficient codings of unlabeled data.
- **Variational autoencoder** — In machine learning, a variational autoencoder (VAE) is an artificial neural network architecture introduced by Diederik P. Kingma and Max Welling in 2013. It is part of the families of probabilistic graphical models and variational Bayesian methods.
- **Generative adversarial network** — A generative adversarial network (GAN) is a class of machine learning frameworks and a prominent framework for approaching generative AI. The concept was initially developed by Ian Goodfellow and his colleagues at Université de Montréal in June 2014.
- **Diffusion model** — In machine learning, diffusion models, also known as diffusion-based generative models or score-based generative models, are a class of latent variable generative models.

E.12.5 Foundation models

- **Foundation model** — In artificial intelligence, a foundation model (FM), also known as large x model, is a machine learning or deep learning model trained on vast datasets so that it can be applied across a wide range of use cases.
- **Self-supervised learning** — Self-supervised learning (SSL) is a paradigm in machine learning where a model is trained on a task using the data itself to generate supervisory signals, rather than relying on externally-provided labels.
- **Transfer learning** — Transfer learning (TL) is a technique in machine learning (ML) in which knowledge learned from a task is re-used in order to boost performance on a related task.
- **Fine-tuning (deep learning)** — In deep learning, fine-tuning is the process of adapting a computational model trained for one task to perform a different, usually more specific, task.
- **Neural scaling law** — In machine learning, a neural scaling law is an empirical scaling law that describes how neural network performance changes as key factors are scaled up or down.
- **Retrieval-augmented generation** — Retrieval-augmented generation (RAG) is a technique that enables large language models (LLMs) to retrieve and incorporate new information from external data sources. With RAG, LLMs first refer to a specified set of documents, then respond to user queries.

E.12.6 AI in research practice

- **Artificial intelligence** — Artificial intelligence (AI) is the capability of computational systems to perform tasks typically associated with human intelligence, such as learning, reasoning, problem-solving, perception, and decision-making.
- **Large language model** — A large language model (LLM) is an AI model trained on a vast amount of text for natural language processing tasks, especially language generation. LLMs can typically generate, summarize, translate, and analyze text in many contexts.
- **Generative artificial intelligence** — Generative artificial intelligence (GenAI) is a subfield of artificial intelligence (AI) that uses generative models to generate text, images, videos, audio, computer code or other forms of digital data.
- **Reinforcement learning from human feedback** — In machine learning, reinforcement learning from human feedback (RLHF) is a technique to align an intelligent agent with human preferences.
- **Hallucination (artificial intelligence)** — In the field of artificial intelligence (AI), a hallucination or artificial hallucination is a response generated by AI that contains false or misleading information presented as fact.
- **Ethics of artificial intelligence** — The ethics of artificial intelligence covers a broad range of topics within AI that are considered to have particular ethical stakes.

E.12.7 Integrating data

- **Multiomics** — Multiomics, multi-omics, integrative omics, "panomics" or "pan-omics" is a biological analysis approach in which the data consists of multiple "omes", such as the genome, epigenome, transcriptome, proteome, metabolome, exposome, and microbiome ; in other words, the use of multiple omics technologies to study life in a concerted way.
- **Data integration** — Data integration is the process of combining, sharing, or synchronizing data from multiple sources to provide users with a unified view. There are a wide range of possible applications for data integration, from commercial to scientific.
- **Canonical correlation** — In statistics, canonical-correlation analysis (CCA), also called canonical variates analysis, is a way of inferring information from cross-covariance matrices.
- **Mendelian randomization** — In epidemiology, Mendelian randomization is a method using measured variation in genes to examine the causal effect of an exposure on an outcome.
- **Causal inference** — Causal inference is the process of determining the independent, actual effect of a particular phenomenon that is a component of a larger system.

E.13 Image analysis and models of cells

Wikipedia articles for Chapter 13.

E.13.1 Images as data

- **Microscopy** — Microscopy is the technical field of using microscopes to view subjects too small to be seen with the naked eye.
- **Fluorescence microscope** — A fluorescence microscope is an optical microscope that uses fluorescence instead of, or in addition to scattering, reflection, and attenuation or absorption, to study the properties of organic or inorganic substances.
- **Confocal microscopy** — Confocal microscopy is an optical imaging technique for increasing optical resolution and contrast of a micrograph by means of using a spatial pinhole to block out-of-focus light in image formation.

- **Image segmentation** — In digital image processing and computer vision, image segmentation is the process of partitioning a digital image into multiple image segments, also known as image regions or image objects.
- **Watershed (image processing)** — In the study of image processing, a watershed is a transformation defined on a grayscale image. The name refers metaphorically to a geological watershed, or drainage divide, which separates adjacent drainage basins.
- **Fiji (software)** — Fiji is an open source image processing package based on ImageJ2.
- **CellProfiler** — CellProfiler is free, open-source software designed to enable biologists without training in computer vision or programming to quantitatively measure phenotypes from thousands of images automatically.

E.13.2 Deep learning for images

- **Convolutional neural network** — A convolutional neural network (CNN) is a type of feedforward neural network that learns features via filter optimization.
- **U-Net** — U-Net is a convolutional neural network that was developed for image segmentation.
- **Vision transformer** — A vision transformer (ViT) is a transformer designed for computer vision. A ViT decomposes an input image into a series of patches, serializes each patch into a vector, and maps it to a smaller dimension with a single matrix multiplication.
- **Self-supervised learning** — Self-supervised learning (SSL) is a paradigm in machine learning where a model is trained on a task using the data itself to generate supervisory signals, rather than relying on externally-provided labels.
- **Segment Anything** — Segment Anything is a series of open-source computer vision foundation models developed by Meta AI for image and video segmentation.
- **ImageNet** — The ImageNet project is a large visual database designed for use in visual object recognition software research.

E.13.3 Image-based profiling

- **High-content screening** — High-content screening (HCS), also known as high-content analysis (HCA) or cellomics, is a method that is used in biological research and drug discovery to identify substances such as small molecules, peptides, or RNAi that alter the phenotype of a cell in a desired manner.
- **Cell Painting** — The cell painting assay is a high-content, high-throughput imaging technique used to capture a wide array of cellular phenotypes in response to diverse perturbations.
- **Phenotypic screening** — Phenotypic screening is a type of screening used in biological research and drug discovery to identify substances such as small molecules, peptides, or RNAi that alter the phenotype of a cell or an organism in a desired manner.
- **Mechanism of action** — In pharmacology, the term mechanism of action (MOA) refers to the specific biochemical interaction through which a drug substance produces its pharmacological effect.

E.13.4 Protein localisation from images

- **Human Protein Atlas** — The Human Protein Atlas (HPA) is a Swedish-based program started in 2003 with the aim to map all the human proteins in cells, tissues and organs using integration of various omics technologies, including antibody-based imaging, mass spectrometry-based proteomics, transcriptomics and systems biology.

- **Immunofluorescence** — Immunofluorescence (IF) is a light microscopy-based technique that allows detection and localization of a wide variety of target biomolecules within a cell or tissue at a quantitative level.
- **Subcellular localization** — The cells of eukaryotic organisms are elaborately subdivided into functionally-distinct membrane-bound compartments.
- **Green fluorescent protein** — The green fluorescent protein (GFP) is a protein that exhibits green fluorescence when exposed to light in the blue to ultraviolet range.
- **Protein tag** — Protein tags are peptide sequences genetically grafted onto a recombinant protein. Tags are attached to proteins for various purposes.

E.13.5 Tissues: multiplexed imaging and computational pathology

- **Digital pathology** — Digital pathology is a sub-field of pathology that focuses on managing and analyzing information generated from digitized specimen slides.
- **Spatial transcriptomics** — Spatial transcriptomics, or spatially resolved transcriptomics, is a method that captures positional context of transcriptional activity within intact tissue.
- **Mass cytometry** — Mass cytometry is a high-dimensional single-cell analysis technique that integrates flow cytometry with time of flight mass spectrometry. It is used for the determination of the properties of cells (cytometry).
- **Multiple instance learning** — In machine learning, multiple-instance learning (MIL) is a type of supervised learning. Instead of receiving a set of instances which are individually labeled, the learner receives a set of labeled bags, each containing many instances.
- **Histopathology** — Histopathology is the microscopic examination of tissue in order to study the manifestations of disease.
- **H&E stain** — Hematoxylin and eosin stain is one of the principal tissue stains used in histology. It is the most widely used stain in medical diagnosis and is often the gold standard.

E.13.6 Cell atlases and virtual cells

- **Human Cell Atlas** — The Human Cell Atlas is a global project to describe all cell types in the human body, to understand human health and for diagnosing, monitoring, and treating disease.
- **Virtual cell** — A cellular model or virtual cell is a computational model of aspects of a biological cell, for the purposes of in silico research.
- **Foundation model** — In artificial intelligence, a foundation model (FM), also known as large x model, is a machine learning or deep learning model trained on vast datasets so that it can be applied across a wide range of use cases.
- **Perturb-seq** — Perturb-seq refers to a high-throughput method of performing single cell RNA sequencing (scRNA-seq) on pooled genetic perturbation screens.
- **Chan Zuckerberg Initiative** — The Chan Zuckerberg Initiative (CZI) is an organization established and owned by Facebook founder Mark Zuckerberg and his wife Priscilla Chan with an investment of 99 percent of the couple's wealth from their Facebook shares over their lifetime.

E.13.7 Whole-cell models and cryo-electron tomography

- **Cryogenic electron tomography** — Cryogenic electron tomography (cryoET) is an imaging technique used to reconstruct high-resolution (~1–4 nm) three-dimensional volumes of samples, often biological macromolecules and cells. cryoET is a specialized application of transmission electron cryomicroscopy (CryoTEM) in which samples are imaged as they are tilted, resulting in a series of 2D images that can be combined to produce a 3D reconstruction, similar to a CT scan of the human body.

- **Mycoplasma genitalium** — Mycoplasma genitalium is a sexually transmitted, small pathogenic bacterium that lives on the mucous epithelial cells of the urinary and genital tracts in humans. Medical journals in 2007 and 2015 reported that Mgen had become more common.
- **Minimal genome** — Minimal genome is the theoretical smallest set of genes sufficient for life to exist and propagate under nutrient-rich and stress-free conditions.
- **Molecular dynamics** — Molecular dynamics (MD) is a computer simulation method for analyzing the physical movements of atoms and molecules. The atoms and molecules are allowed to interact for a fixed period of time, giving a view of the dynamic "evolution" of the system.
- **Systems biology** — Systems biology is the computational and mathematical analysis and modeling of complex biological systems.

F Cross-topic problems and case studies

> **Credit**
>
> The problems and case studies in this appendix are adapted from Matteo Tadiello, *Modern Bioinformatics: From Foundations to Frontiers* (CC BY 4.0), used with permission.

The review problems at the end of each chapter test one topic at a time. In the oral exam, questions often move from one topic to another: from a sequence search to evolution, from structure to function, from an experiment to its statistics. The problems in this appendix combine several chapters and have no single correct answer. Use them to practise explaining a complete line of reasoning: what the biological question is, which data and methods would address it, what each result can and cannot show, and how the conclusion would be validated.

F.1 Cross-topic problems

These problems integrate concepts from at least three chapters. For each problem, define the biological claim, identify the data-generating process, justify the computational formulation, state assumptions, compare alternatives, and propose validation.

1. You discover a previously unannotated bacterial gene associated with antibiotic resistance. Design the sequence, structure, evolutionary, expression, and experimental workflow needed before making a functional claim.
2. A profile HMM and a structure search disagree about a remote homolog. Explain possible causes and how you would adjudicate them.
3. A gene is differentially expressed but its protein abundance is unchanged. Give technical and biological explanations and design follow-up tests.
4. A pangenome graph improves variant recall. Explain how you would demonstrate that the gain is real rather than benchmark leakage or truth-set bias.
5. A high-confidence predicted protein complex has no AP-MS support. Reconcile the evidence and propose orthogonal validation.
6. A gene family tree conflicts with the accepted species tree. Compare duplication/loss, incomplete lineage sorting, horizontal transfer, recombination, and artefact explanations.
7. A classifier predicts disease from transcriptomes with AUROC 0.97 but fails prospectively. Diagnose data leakage, batch structure, spectrum effects, calibration, and target shift.
8. An RNA-seq study has three treatment samples processed on one day and three controls on another. Explain what can and cannot be recovered computationally.
9. A protein has 35% sequence identity to a characterised enzyme. Build an evidence hierarchy for transferring catalytic function and substrate specificity.
10. Compare the meaning of an E-value, adjusted p-value, posterior probability, bootstrap proportion, predicted confidence score, and calibrated class probability.
11. Design a database record that distinguishes raw evidence, inferred annotation, version, uncertainty, and provenance.

12. Explain how repeats affect read mapping, genome assembly, gene annotation, expression quantification, and evolutionary inference.
13. A rare cell population appears only after single-cell integration. Explain how to decide whether it is biology or an integration artefact.
14. You need to identify direct interaction partners of a membrane protein in living cells. Compare experimental and computational options.
15. A foundation model produces accurate embeddings. Explain what benchmarks would establish biological utility without circularity.
16. Design a reproducible multi-omics study from sampling through public deposition, including negative controls and validation.

F.2 Case study A: from sequence to mechanism

This case study traces a biological question from comparative genomics through molecular mechanism. The routes can be analysed sequentially or assigned as separate problem sets.

F.2.1 The problem

A conserved protein of unknown function is found in several pathogenic bacteria but is absent from closely related non-pathogens. Design a strategy to determine its origin, molecular function, structure, interaction partners, and contribution to pathogenicity.

F.2.1.1 Route 1: databases and sequence search

- Which databases do you query, and how do you preserve identifier/version provenance?
- When would you choose BLAST, a profile HMM, MMseqs2, or structure search?
- How do E-values change with search space and multiple queries?
- What would make an apparent homolog a false lead?

F.2.1.2 Route 2: evolution and phylogeny

- How would you distinguish vertical inheritance, loss, and horizontal transfer?
- What alignment and substitution-model problems could distort the tree?
- How do you reconcile a gene tree with a species tree?
- What evidence would support selection without overinterpreting dN/dS?

F.2.1.3 Route 3: structure and function

- What does a high-confidence predicted fold establish?
- How would you evaluate a putative active site or ligand-binding pocket?
- When is docking informative, and how would you validate it?
- How would disorder, oligomerisation, or membrane localisation change the plan?

F.2.1.4 Route 4: expression and interactions

- Design a condition-aware expression experiment with biological replication.
- Choose an interaction assay and explain its false-positive/negative profile.
- What would count as orthogonal evidence for a direct interaction?

F.2.1.5 Route 5: integration

- Build the strongest defensible conclusion from mixed evidence.
- Identify which claims remain predictive rather than causal.
- Define the minimum experiments needed before proposing a drug target.

F.2.2 Evaluation criteria

A rigorous analysis connects each biological claim to the evidence generated by the corresponding method, states algorithmic assumptions, distinguishes estimated confidence from correctness, and proposes independent validation. A tool list without an explicit inferential argument is insufficient.

F.3 Case study B: from cohort to biological claim

This case study develops an end-to-end analysis of a heterogeneous clinical cohort, from experimental design and data generation to prediction, causal interpretation, and prospective validation.

F.3.1 The problem

A cohort study collects genomes, bulk RNA-seq, single-cell RNA-seq, and plasma proteomics from patients and controls across three hospitals. The goal is to discover a disease mechanism and a predictive biomarker. Design the analysis and justify each inferential step.

F.3.1.1 Route 1: design and data generation

- What replication and randomisation are required?
- Which variables must be balanced or recorded?
- How do sequencing and mass-spectrometry error processes differ?
- What quality controls detect sample swaps and contamination?

F.3.1.2 Route 2: genomic analysis

- Choose mapping/reference representations and variant-calling strategies.
- Explain reference bias, population structure, phasing, and structural variants.
- How would you validate a candidate regulatory variant?

F.3.1.3 Route 3: expression and proteomics

- Specify the bulk RNA-seq design matrix and contrasts.
- Explain single-cell pseudoreplication and a defensible differential-expression unit.
- Describe peptide-spectrum matching, FDR, protein inference, and missing values.
- How would you interpret RNA–protein disagreement?

F.3.1.4 Route 4: machine learning

- Define the unit of splitting and prevent patient/site leakage.
- Choose metrics for a rare disease and assess calibration.
- Compare L1, L2, tree-based, and representation-learning approaches.
- How would you perform nested model selection and external validation?

F.3.1.5 Route 5: integration and causality

- Compare early, intermediate, and late multi-omics integration.
- Separate a predictive biomarker from a causal mechanism.
- Explain how site, ancestry, treatment, and cell composition could confound the result.
- Specify an orthogonal experiment and a prospective validation study.

F.3.2 Evaluation criteria

The answer must preserve the experimental unit, connect data-generating processes to statistical models, prevent leakage, control multiplicity, distinguish prediction from causation, and specify independent validation.
