Stora Tentan in Bioinformatics

Reading guide for the oral PhD exam at DBB, Stockholm University

Arne Elofsson

2026-10-08

Table of contents

About this guide 8
What the exam is . . . 8
Programming and reproducible research . . . 9
Uncertainty: many numbers, different meanings . . . 11
Information theory in brief . . . 12
How each chapter is organised . . . 13
Topics . . . 14
Earlier versions of the instructions . . . 14
Additional material . . . 15
Companion textbook and contributors . . . 15
Licence . . . 15

I Topics 16

1 Sequence searching 17
1.1 Overview . . . 17
1.2 Homology and sequence similarity . . . 17
1.3 Dynamic programming and sequence alignment . . . 24
1.4 Heuristic search methods . . . 36
1.5 Alignment-free sequence comparison . . . 49
1.6 Profiles and multiple sequence alignments . . . 51
1.7 RNA homology search . . . 74
1.8 Whole-genome alignment and conservation . . . 78
1.9 Databases and domains . . . 81
1.10 Protein language models . . . 90
1.11 Benchmarking search methods . . . 98
1.12 Key concepts . . . 100
1.13 Recommended reading . . . 101
1.14 Background reading (open access) . . . 102
1.15 Student recommendations . . . 103
1.16 Review problems . . . 103

2 Databases 112
2.1 Overview . . . 112
2.2 How biological databases work . . . 112
2.3 Sequence databases . . . 119
2.4 Genome databases and browsers . . . 121
2.5 Structure databases . . . 123
2.6 Function and pathways . . . 124
2.7 Interaction databases . . . 126
2.8 Expression and proteomics repositories . . . 127
2.9 Medical and variant data . . . 128
2.10 Key concepts . . . 129

2.11 Recommended reading . . . 130
2.12 Background reading (open access) . . . 131
2.13 Student recommendations . . . 131
2.14 Review problems . . . 132

3 Evolution **139**
3.1 Overview . . . 139
3.2 The origin of life . . . 139
3.3 Basic evolutionary concepts . . . 142
3.4 Homologues, orthologues and gene duplication . . . 145
3.5 Protein evolution . . . 150
3.6 Detecting selection . . . 153
3.7 Genome evolution . . . 155
3.8 Key concepts . . . 157
3.9 Recommended reading . . . 158
3.10 Background reading (open access) . . . 158
3.11 Student recommendations . . . 160
3.12 Review problems . . . 160

4 Phylogeny **167**
4.1 Overview . . . 167
4.2 Basic definitions . . . 167
4.3 Phylogenetic methods . . . 170
4.4 Alignments, genomes and conflicting trees . . . 177
4.5 The tree of life . . . 182
4.6 Key concepts . . . 185
4.7 Recommended reading . . . 186
4.8 Background reading (open access) . . . 187
4.9 Student recommendations . . . 188
4.10 Review problems . . . 188

5 Genomics **196**
5.1 Overview . . . 196
5.2 Sequencing methods . . . 196
5.3 Genome assembly . . . 200
5.4 Mapping and variant calling . . . 204
5.5 Regulatory and epigenomic sequencing data . . . 211
5.6 Gene prediction . . . 213
5.7 Metagenomics . . . 217
5.8 Human genetics: finding disease genes and variants . . . 219
5.9 Key concepts . . . 223
5.10 Recommended reading . . . 224
5.11 Background reading (open access) . . . 224
5.12 Student recommendations . . . 226
5.13 Review problems . . . 226

6 Genomes **238**
6.1 Overview . . . 238
6.2 Background: genes, genomes and cells . . . 238
6.3 From the first genome projects . . . 240
6.4 Differences across the tree of life . . . 243
6.5 Gene order, synteny and genome rearrangements . . . 247

6.6 Genomes in populations . . . 251
6.7 Repeats and the 3D genome . . . 254
6.8 Pseudogenes, new genes and small proteins . . . 257
6.9 RNA genes and regulatory elements . . . 260
6.10 Key concepts . . . 262
6.11 Recommended reading . . . 263
6.12 Background reading (open access) . . . 264
6.13 Student recommendations . . . 265
6.14 Review problems . . . 265

7 Expression analysis **273**
7.1 Overview . . . 273
7.2 The first genome-wide methods: microarrays . . . 273
7.3 RNA sequencing . . . 275
7.4 Testing and statistics . . . 279
7.5 From gene lists to biology . . . 286
7.6 Single-cell genomics . . . 288
7.7 Single-cell sequencing and cancer evolution . . . 292
7.8 Key concepts . . . 294
7.9 Recommended reading . . . 295
7.10 Background reading (open access) . . . 296
7.11 Student recommendations . . . 297
7.12 Review problems . . . 297

8 Proteomics **306**
8.1 Overview . . . 306
8.2 Mass spectrometry methods . . . 306
8.3 Algorithms for peptide identification . . . 311
8.4 Statistics and error control . . . 314
8.5 Proteomics beyond protein abundance . . . 318
8.6 Proteomics without mass spectrometry . . . 320
8.7 Repositories and standards . . . 323
8.8 Key concepts . . . 323
8.9 Recommended reading . . . 324
8.10 Background reading (open access) . . . 325
8.11 Student recommendations . . . 326
8.12 Review problems . . . 326

9 Protein structure **334**
9.1 Overview . . . 334
9.2 CASP: a blind test of structure prediction . . . 334
9.3 Background: amino acids, energetics and enzymes . . . 336
9.4 Protein structure and how it is determined . . . 338
9.5 Protein folding . . . 341
9.6 Structure comparison and evolution . . . 344
9.7 Protein structure databases . . . 345
9.8 Protein structure prediction . . . 346
9.9 Protein language models and structure . . . 353
9.10 Membrane proteins . . . 355
9.11 Dynamics and docking . . . 356
9.12 Protein design . . . 360
9.13 Key concepts . . . 361

9.14 Recommended reading . . . 363
9.15 Background reading (open access) . . . 363
9.16 Student recommendations . . . 365
9.17 Review problems . . . 365

10 Protein function **374**
10.1 Overview . . . 374
10.2 Definitions of function . . . 374
10.3 Experimental determination of function . . . 377
10.4 Function prediction . . . 380
10.5 Subcellular localisation . . . 384
10.6 Predicting the effects of mutations . . . 386
10.7 Benchmarking function prediction . . . 388
10.8 Key concepts . . . 390
10.9 Recommended reading . . . 391
10.10 Background reading (open access) . . . 392
10.11 Student recommendations . . . 392
10.12 Review problems . . . 392

11 Protein–protein interactions **401**
11.1 Overview . . . 401
11.2 Experimental methods . . . 401
11.3 Networks . . . 406
11.4 Prediction methods . . . 412
11.5 Key concepts . . . 414
11.6 Recommended reading . . . 416
11.7 Background reading (open access) . . . 416
11.8 Student recommendations . . . 417
11.9 Review problems . . . 417

12 Machine learning **425**
12.1 Overview . . . 425
12.2 Basics . . . 425
12.3 A short history of machine learning in bioinformatics . . . 431
12.4 Deep learning . . . 433
12.5 Generative models . . . 437
12.6 Foundation models . . . 438
12.7 AI in research practice . . . 440
12.8 Integrating data . . . 441
12.9 Key concepts . . . 444
12.10 Recommended reading . . . 446
12.11 Background reading (open access) . . . 446
12.12 Student recommendations . . . 447
12.13 Review problems . . . 447

13 Image analysis and models of cells **456**
13.1 Overview . . . 456
13.2 Images as data . . . 456
13.3 Deep learning for images . . . 458
13.4 Image-based profiling . . . 459
13.5 Protein localisation from images . . . 461
13.6 Tissues: multiplexed imaging and computational pathology . . . 462

13.7 Cell atlases and virtual cells . . . 463
13.8 Whole-cell models and cryo-electron tomography . . . 464
13.9 Key concepts . . . 465
13.10 Recommended reading . . . 466
13.11 Background reading (open access) . . . 466
13.12 Student recommendations . . . 468
13.13 Review problems . . . 468

About this guide

> ⚠ Disclaimer
>
> This book is **not complete**. It is a study aid, meant to help you organise your preparation for the exam. We do not guarantee that it covers everything you need to know to pass Stora Tentan, and the exam is not limited to what is written here. Use it as a map of the field and a starting point for your own reading, together with the papers, textbooks and lectures it points to, and discussions with other students and your supervisor.

> ❗ Version 0.6.1 (October 2026)
>
> This is an early version of the book. Version 0.6.1 lists the classical papers in bioinformatics under Appendix C. Version 0.6 filled gaps found by a comparison with two classic textbooks (Pevsner; Zvelebil & Baum): new sections on human genetics (linkage disequilibrium, GWAS, fine-mapping, polygenic scores, diagnosing rare disease), regulatory and epigenomic sequencing, whole-genome alignment and conservation scores, pseudogenes, new genes and small proteins, and the experimental determination of function, a short introduction to information theory, and new subsections in most chapters. Version 0.5 integrated Matteo Tadiello's companion textbook (review problems, figures and new text), and version 0.4 added a chapter on image analysis and models of cells (Chapter 13), which is not part of the 2025 exam description. The chapters and reading lists are open for comments from teachers and students: use the suggestion form (SU login).

This book collects reading material for **Stora Tentan**, the 15 hp oral exam in bioinformatics for PhD students at the Department of Biochemistry and Biophysics (DBB), Stockholm University. It is built on the current exam description (2025) and on the more detailed reading lists that were used in earlier years. It is not a course book: everything in it is chosen for one purpose, to help PhD students at DBB prepare for this exam.

What the exam is

Stora Tentan should show that a student awarded a PhD from DBB has a good basic knowledge of bioinformatics, *wider than their own thesis area.* The exam assumes the knowledge needed to pass the department's advanced-level courses in bioinformatics and comparative genomics, but it is primarily a test of the ability to explain how bioinformatics methods are used to answer fundamental biological questions. Students are also expected to follow seminars and dissertations at DBB and SciLifeLab and to be aware of current international research.

- Two examiners, about two hours.
- No single required textbook. Zvelebil & Baum (Zvelebil and Baum 2008) or Pevsner (Pevsner 2015) cover most areas, but they are not up to date — you need to update your knowledge to the current state of the art (the proceedings of the last few ISMB and ECCB meetings are a good start).

- The exam is **not** about knowing every detail. You should be able to discuss and reason about methods: how they work (algorithms), their advantages and limitations, and when to use them.
- Fundamental knowledge of the algorithms and limitations of established methods for **sequence searching, protein structure prediction, phylogeny and function annotation** is required.
- Every exam is unique. Depending on how the first topic goes, other topics may be covered in more or less depth, or not at all.

Experience shows that discussing the exam with other PhD students is a very efficient way to prepare, and that online lectures often explain things better than textbooks.

Programming and reproducible research

Programming and reproducibility are **general professional background**, not a separate exam topic. You will not be asked to write code, and the topic chapters do not return to these practices in detail. But you are expected to know how computational research is done and to be able to discuss the tools and practices you use: examiners may ask how you would implement or scale an algorithm, or how someone else could reproduce one of your results.

What you should know

- **Languages and their roles.** Python and R for analysis, statistics and visualisation; the Unix shell for handling files and running programs; compiled languages (C, C++, Rust) for performance-critical tools such as aligners. Know why most heavy bioinformatics tools are written in compiled languages, while analyses are written in scripting languages.
- **Algorithms and complexity.** Big-O notation, and why an $O(n^2)$ algorithm becomes unusable on a million sequences while an $O(n \log n)$ one does not. Basic data structures (arrays, hash tables, trees, graphs) and the algorithmic ideas that recur in this book: dynamic programming (Section 1.3), hashing and indexing (Section 1.4), and graph algorithms (Chapter 5).
- **Computing environments.** Working on a Unix system and on a computer cluster with a job scheduler such as Slurm; when to use GPUs (mainly for deep learning); cloud computing and its cost.
- **Version control.** Using git for code and analyses, and platforms such as GitHub or GitLab for collaboration (Perez-Riverol et al. 2016).
- **Reproducibility.** Recording software versions and parameters; managing software environments (conda, containers such as Docker or Apptainer); using workflow managers such as Snakemake or Nextflow (Köster and Rahmann 2012; Di Tommaso et al. 2017); documenting analyses, for example in notebooks or Quarto/R Markdown documents. Sandve et al. (2013) and Wilson et al. (2017) give short, practical rules.
- **Reproducible is not the same as correct.** An analysis is *reproducible* if the same data and code give the same result, *replicable* if new data give the same conclusion, and *robust* if the conclusion survives other reasonable analysis choices. A perfectly reproducible analysis can still be wrong, for example because of data leakage or confounding (4). Containers record the software, but not the input data, the reference files or sources of randomness, which must be recorded separately.
- **Data management.** The FAIR principles (findable, accessible, interoperable, reusable) (Wilkinson et al. 2016); depositing data in public repositories (Chapter 2); standard file formats (FASTA, FASTQ, SAM/BAM, VCF, PDB/mmCIF; see Table 1); handling sensitive human data in line with GDPR and ethical approvals.
- **Testing and correctness.** Checking code on small examples with known answers, and being sceptical of results that look too good. Many published errors come from simple bugs such as off-by-one errors, swapped sample labels or spreadsheet conversions of gene names to dates.

Common file formats

Most bioinformatics data are exchanged in a small number of community formats. You should know what each contains and what it is used for.

Table 1: Common bioinformatics file formats.

Format	What it contains
FASTA	Sequences (nucleotide or protein), each with a header line starting with >; no quality information
FASTQ	Sequencing reads with a quality score for every base (Phred scale, encoded as characters), four lines per read
SAM / BAM / CRAM	Reads aligned to a reference: position, mapping quality, flags and a CIGAR string describing the alignment. SAM is text, BAM its compressed binary form, CRAM a smaller, reference-based compression
VCF (and binary BCF)	Variants: position, reference and alternative alleles, quality, filters, and the genotype of each sample
BED	Genomic intervals (chromosome, start, end, and optionally name, score and strand), for example peaks or target regions
GFF3 / GTF	Genome annotation: genes, transcripts, exons and coding sequences, with parent–child relations in an attribute column. GTF is an older variant used by Ensembl and GENCODE
PDB / mmCIF	Atomic coordinates of macromolecular structures. The legacy fixed-column PDB format cannot hold very large structures; PDBx/mmCIF is the archive standard
HDF5, AnnData (`.h5ad`)	HDF5 is a hierarchical binary container for large arrays. AnnData, built on it, stores a single-cell count matrix together with cell and gene annotations and embeddings
OME-Zarr	Chunked, cloud-friendly storage of large multidimensional images, for example microscopy and spatial omics, with standard metadata

Coordinates differ between formats: BED (and BAM internally) counts from 0 with half-open intervals, whereas SAM, VCF and GFF count from 1 with closed intervals, so conversions are a classic source of off-by-one errors (Chapter 2).

A provenance checklist

A computational result can only be reproduced if everything that produced it is recorded. For any analysis, you should be able to state:

- the **data**: accession numbers, and the **release or date of every database** used (a UniProt or Pfam release changes search results; see Chapter 2);
- the **reference genome and annotation versions**, for example GRCh38 with a specific GENCODE release, or the T2T or pangenome reference (Chapter 5);
- the **software versions and all parameters**, including thresholds and defaults that were left unchanged;
- **random seeds**, for anything stochastic: MCMC, clustering, UMAP, training of machine-learning models, structure prediction with several seeds;
- the **computing environment**: a conda environment file or a container image;

- the **models**: the versions or weights of trained models, and for AI tools the tool, model version, date and prompts (Section 12.7);
- the **workflow**: the scripts or workflow-manager pipeline that link these steps, under version control;
- where the **code and data are deposited**, so that others can rerun the analysis.

Reading

- Sandve et al. (2013) — ten simple rules for reproducible computational research.
- Wilson et al. (2017) — good enough practices in scientific computing.
- Software Carpentry lessons, for example the Unix shell, version control with git, and programming in Python or R.

Uncertainty: many numbers, different meanings

Almost every method in this book reports a number that expresses confidence in a result. They answer different questions and must not be confused, which is a frequent source of mistakes in oral exams. The table summarises the most important ones.

Table 2: Measures of confidence used in this book.

Measure	What it is	Common misreading	See
E-value	Expected number of hits with at least this score by chance, for one query against this database	A probability; it grows with database size	Section 1.4
p-value	Probability of data at least as extreme as observed, *if* the null hypothesis is true	The probability that the null hypothesis is true	Section 7.4.1
FDR	Expected *proportion* of false positives among the set of results called significant	The probability that one particular hit is false	Section 7.4
q-value	For one result, the smallest FDR threshold at which it would be called significant	The FDR of that single result	Section 7.4
Local FDR, posterior error probability	Probability that one particular result is false, under the model	Model-free; it is only as good as the model	Section 8.4
Bootstrap support	Percentage of resampled data sets in which a clade is recovered	The probability that the clade is true	Section 4.3.9
Posterior probability (Bayesian)	Probability of a clade or parameter given the data, the model and the priors	Independent of the model; it can be close to 1 for wrong clades if the model is wrong	Section 4.3.9
pLDDT, PAE, ipTM	AlphaFold's predicted error of local structure, relative positions and interfaces	Measured accuracy; confident predictions can still be wrong	Section 9.8
Classifier score	A model's output for one example	A probability: it is one only if the model is calibrated, and it depends on how common positives are	4

All of them are conditional on assumptions: the null model, the substitution model, the training data. A small number is not evidence by itself. It is evidence only together with the assumptions behind it.

Information theory in brief

Several quantities in this book come from information theory, founded by Shannon (Shannon 1948). With logarithms to base 2 they are measured in **bits**; with natural logarithms, as in most machine learning, in *nats*.

Entropy measures the uncertainty of a distribution p over symbols a, or the average surprise $-\log_2 p_a$ of an observation:

$$H(p) = -\sum_a p_a \log_2 p_a.$$

It is the average number of yes/no questions needed to identify a symbol. A uniform distribution over the four nucleotides has 2 bits, over the 20 amino acids $\log_2 20 \approx 4.3$ bits, and a fully conserved alignment column has 0 bits. A related quantity, the information content $-\log_2 P(t)$ of a single event, weights rare, specific GO terms more than general ones in the evaluation of function prediction (Section 10.6).

Relative entropy, or the **Kullback–Leibler divergence** (Kullback and Leibler 1951), measures how different a distribution p is from a reference q:

$$D(p \,\|\, q) = \sum_a p_a \log_2 \frac{p_a}{q_a}.$$

It is the average log-odds score $\log_2(p_a/q_a)$ when the data really come from p. It is never negative, and zero only if $p = q$, but it is not symmetric, so it is not a true distance. It appears twice in Chapter 1. The relative entropy of a substitution matrix is the average score per aligned pair in true alignments, about 0.7 bits for BLOSUM62, and tells how long an alignment must be to stand out from chance (Section 1.3). The information content of a motif position is the relative entropy of the column with respect to the background, and is the height of a stack in a sequence logo (Section 1.6).

Mutual information measures how much knowing one variable reduces the uncertainty about another. It is the relative entropy between the joint distribution and the product of the marginals:

$$I(X;Y) = \sum_{x,y} p(x,y) \log_2 \frac{p(x,y)}{p(x)\,p(y)}.$$

It is zero only if X and Y are independent, and unlike correlation it also detects non-linear dependence. Between two columns of an alignment it reveals covariation: base pairs in RNA (Section 1.7) and residue contacts in proteins (Section 3.5, Section 9.8), where global models are needed to separate direct from indirect couplings. It is also used to infer gene regulatory networks from expression data (Section 11.2). The relative entropy of a substitution matrix is itself the mutual information between the two residues of a true aligned pair.

Cross-entropy compares the true distribution p with a model's predicted distribution q:

$$H(p, q) = -\sum_a p_a \log q_a = H(p) + D(p \,\|\, q).$$

For a classifier, p puts all its weight on the true class y, and the loss for one example is $-\log q_y$, the negative log-likelihood of the correct answer. Minimising the average cross-entropy loss is therefore maximum likelihood, and since $H(p)$ is fixed by the data, it also minimises the divergence of the model from the data (4).

Perplexity is the exponential of the cross-entropy, 2^H in bits or e^H in nats. It is the effective number of equally likely choices the model is choosing between at each position: a uniform guess over the amino acids gives 20, and a perfect prediction gives 1. It is the usual measure of how well a protein language model predicts sequences (Section 1.10).

> **Sources**
>
> Written for this book. For background, see the Wikipedia articles Entropy (information theory), Kullback–Leibler divergence, Mutual information, Cross-entropy and Perplexity.

How each chapter is organised

The thirteen topic chapters share the same structure:

1. **Overview** — what the chapter covers and how it connects to the others.
2. **Sections** — a full text on each part of the topic, written mainly from Wikipedia and other open sources (credited at the end of each section), with references to the key papers. Background that every student is expected to know, such as statistics, basic biochemistry and the use of AI tools, is included where it is needed: statistics in Chapter 7, nucleic acids and cells in Chapter 6, amino acids, energetics and enzymes in Chapter 9, and AI in research practice in Chapter 12.
3. **Key concepts** — a checklist of things you should be able to explain.
4. **Recommended reading** — about six papers to read in full, mostly from the reading lists of earlier years, each with a one-line note on why it matters.
5. **Background reading (open access)** — overviews to get started, mostly Wikipedia articles and tutorials, each with a short description.
6. **Student recommendations** — papers, online lectures, tutorials and exam experiences recommended by students. Students can send suggestions, including corrections and exam questions, through the suggestion form (SU login); the teachers review them and add the good ones in the next version.
7. **Review problems** — problems that test understanding rather than recall, each with extensions, a solution outline and common errors (click to show them in the HTML version). They are adapted from the companion textbook by Matteo Tadiello (see below).

The papers are collected in appendices, so that the chapters stay readable:

- **Appendix A, Recommended reading** (A.1–A.13, one section per chapter): the recommended papers with titles, abstracts, DOI and library links. In the PDF version the open-access papers follow in full.
- **Appendix B, Further papers** (B.1–B.13): for each chapter, a longer list of papers grouped by theme, with titles, DOI links and abstracts (click *Abstract* in the HTML version). Papers marked ⋆ were mandatory in earlier reading lists.
- **Appendix D, Further explanations** (D.1–D.13): for each section of a chapter, one to three open-access reviews, tutorials or textbook chapters that explain the topic in more detail than the book does, each with a short comment. In the PDF version one or two of them per chapter follow in full. Each section of the chapters points to its part of appendix D.
- **Appendix E, Wikipedia index** (E.1–E.13): the main Wikipedia articles for each section, with a one-line description. They are a quick way to look up a term, not a source to cite.
- **Appendix F, Cross-topic problems and case studies**: problems that combine several chapters, as questions in the oral exam often do, and two longer case studies.

Appendix C lists textbooks and general resources. Full references are collected in References; hover over a citation to see it.

Topics

Topic	What is covered
Sequence searching	Alignment algorithms, substitution matrices, BLAST, profile HMMs, significance, MSA, motifs
Databases	Primary and derived databases, their hierarchy and relations
Evolution	Homology, orthology/paralogy and orthology databases, gene duplication, selection, drift
Phylogeny	Distance, parsimony, likelihood and Bayesian methods; models; support
Genomics	Sequencing technologies, assembly, read mapping, variant calling, gene prediction
Genomes	Prokaryotic vs. eukaryotic genome organisation, viral genomes, gene order and synteny, genome size and complexity
Expression analysis	Microarrays, RNA-seq, single-cell, normalisation, multiple testing
Proteomics	Mass spectrometry, peptide identification, quantification, FDR
Protein structure	Structure, domains, secondary/tertiary prediction, AlphaFold, design, docking
Protein function	Function definitions (GO), annotation transfer, localisation, variant effects
Protein–protein interactions	Experimental and computational PPI methods, networks, pathway and network enrichment
Machine learning	HMMs, neural networks, evaluation and overfitting, deep learning, language models, integrating data
Image analysis and models of cells	Bioimage analysis, segmentation and classification, Cell Painting, protein localisation, pathology, cell atlases, virtual and whole-cell models (not in the 2025 exam description)

Earlier versions of the instructions

The reading lists from earlier years (in `data/`) contained a list of mandatory articles and a much longer list of background papers. These have been distributed over the topic chapters. A 2021 variant of the exam was instead based on Pevsner's textbook (Pevsner 2015) together with the review by Sapoval et al. (2022); both remain excellent starting points.

Additional material

A lot of the material in this book is covered by the two bioinformatics courses given by Arne Elofsson (KB8029) and Erik Sonnhammer (KB8030). The course book for KB8029 can be found at https://course.bioinfo.se. The suggested course litterature for KB8030 is *Zvelebil, M. J., Baum, J.O. (2007) Understanding Bioinformatics, Garland Science*

Companion textbook and contributors

Matteo Tadiello, a student of Arne Elofsson, has written a companion textbook, *Modern Bioinformatics: From Foundations to Frontiers* (<https://bioinfo.se/teaching/modern-bioinformatics/>). It covers the same topics as a general textbook, in more depth and with more mathematics, and is a good next step after the summaries in this book. Each chapter here links to the matching chapters of his book. The review problems at the end of each chapter, the cross-topic problems and case studies in appendix F, many of the figures, and new text in most chapters are adapted from his book with his permission (CC BY 4.0). This includes the sections on orthology databases, gene order and synteny, viral genomes, pathway and network enrichment, and integrating data; every adapted part is credited where it appears.

Licence

This book is licensed under the Creative Commons Attribution-ShareAlike 4.0 International licence (CC BY-SA 4.0). Parts of the text are adapted from Wikipedia and other openly licensed sources, which are credited in each section. Included papers keep their own licences, and only openly licensed papers are reproduced in full. A private edition of the book (rendered with `quarto render --profile private`) also contains copyrighted papers; it is for students at DBB only and must not be distributed.

Part I

Topics

1 Sequence searching

> **From the exam description**
>
> Both historical and state-of-the-art methods are used for speed and accuracy. Understanding the advantages of different algorithms is essential.

1.1 Overview

Finding sequences that are similar to a query is one of the most frequently used operations in bioinformatics. It is the first step in annotating a new gene, building a family alignment, inferring a phylogeny or predicting a structure. This chapter follows the development of the field:

- what homology is, and how it relates to sequence similarity (1);
- exact alignment by dynamic programming and the substitution matrices that score it (Section 1.3);
- the heuristic and indexing methods that make database search fast, and the statistics that tell us which hits to trust (Section 1.4);
- comparing sequences without aligning them, by their k-mers (Section 1.5);
- multiple alignments, motifs, profiles and profile hidden Markov models, which capture whole families and find more distant relationships (Section 1.6);
- how the same ideas are extended to structured RNAs, where secondary structure is often conserved better than sequence (Section 1.7);
- aligning whole genomes, and the conservation scores computed from multiple genome alignments (Section 1.8);
- protein domains and the databases that classify them (Section 1.9);
- protein language models and how they are starting to be used to detect remote homology (Section 1.10);
- how search methods are benchmarked, and what can go wrong (Section 1.11).

1.2 Homology and sequence similarity

Almost everything in this chapter rests on one idea. If two genes or proteins descend from a common ancestor, then what we know about one tells us something about the other. The relationship is called *homology*, and sequence searching is, at bottom, a set of methods for inferring homology from sequence similarity. Before turning to the algorithms, it is worth being precise about what is inferred, from what, and why the inference works.

1.2.1 Evolutionary background

All living organisms descend from a common ancestor, and their genomes have been shaped by the same small set of processes (see Chapter 3 for a fuller treatment):

- **Mutation** creates variation. The simplest mutations are *point substitutions*, the replacement of one nucleotide by another. In DNA these are classified as *transitions* (purine ↔ purine or pyrimidine ↔ pyrimidine), which are more frequent, and *transversions* (purine ↔ pyrimidine). *Insertions and deletions* (indels) add or remove nucleotides. Larger events duplicate, delete, invert or move whole segments of DNA, from a few nucleotides up to entire genomes.
- **Recombination** reshuffles existing variation. In proteins, unequal crossing-over and exon shuffling can join segments that encode separate domains, so that new proteins arise as new combinations of old parts (Section 1.9).
- **Horizontal (lateral) gene transfer** moves genes between organisms other than by descent. It is common in prokaryotes and rarer, but not absent, in eukaryotes.
- **Natural selection** and **genetic drift** determine the fate of each variant. Most mutations that change the structure or function of an important protein are harmful and are removed by *purifying selection*. Mutations with little effect are fixed or lost largely at random by drift, as the neutral theory proposed (Kimura 1968). Occasionally a mutation is beneficial and spreads by *positive selection*.

For sequence analysis, the key consequence is that sequences diverge gradually and unevenly. Positions that matter for structure or function (the hydrophobic core, catalytic residues, binding sites) change slowly. Surface loops and positions that tolerate many amino acids change quickly. When substitutions do occur at constrained positions, they tend to be *conservative*, replacing an amino acid by one with similar properties (isoleucine by leucine or valine, aspartate by glutamate). These patterns are exactly what substitution matrices capture (Section 1.3) and what profiles capture position by position (Section 1.6).

Because divergence is gradual, the similarity between two homologous sequences decays with the time since they shared an ancestor. Eventually so many substitutions have occurred, often several at the same site, that the remaining similarity is no longer distinguishable from chance. The limits of sequence searching are set by this decay.

1.2.2 Genes and proteins

In classical genetics, a *gene* is a unit of heredity, a factor that determines a trait. The molecular definition, used in this book, is a segment of DNA that is transcribed to produce a functional RNA. Most of the genes analysed in this chapter are *protein-coding*: the RNA is a messenger RNA (mRNA) that is translated into a protein. *Non-coding genes* produce functional RNAs such as ribosomal and transfer RNAs, spliceosomal RNAs and microRNAs. The flow of information from DNA to RNA to protein is the *central dogma* of molecular biology.

In eukaryotes a protein-coding gene is usually split. Coding *exons* alternate with non-coding *introns*, which are removed by splicing. Alternative splicing allows one gene to produce several protein *isoforms*. In prokaryotes genes are mostly continuous and are often organised in operons (see Chapter 6).

A *protein* is one or more chains of amino acid residues joined by peptide bonds. The sequence of the chain is specified by the gene through the genetic code. Each of the 64 codons (nucleotide triplets) codes for one of 20 standard amino acids or for a stop signal. Two non-standard amino acids, selenocysteine and pyrrolysine, are used in some organisms. The code is *degenerate*: most amino acids are encoded by several codons that usually differ in the third position. As a result, many DNA substitutions are *synonymous* and leave the protein unchanged. The amino-acid sequence determines how the chain folds into a three-dimensional structure, and the structure determines the function (Anfinsen 1973). Proteins are typically 100–1,000 residues long and many consist of several *domains*: compact units that fold, function and evolve semi-independently (Section 1.9). Short chains of fewer than 20–30 residues are usually called peptides.

Two properties of proteins matter particularly for sequence comparison. First, the 20-letter alphabet carries much more information per position than the 4-letter nucleotide alphabet. Second, among homologous proteins the three-dimensional structure tends to be conserved much longer during evolution than the sequence that encodes it (an empirical tendency, not a law). We return to both points below.

1.2.3 Homology: a statement about ancestry

The word *homology* comes from the Greek *homologos*, "agreeing". It was introduced into biology by the anatomist Richard Owen in 1843. He used it for "the same organ in different animals under every variety of form and function", and contrasted it with *analogy*, different structures that perform the same function. Owen's definition was not evolutionary. In 1859 Darwin explained homologous structures as inheritance from a common ancestor, and that is how the term has been used ever since. The classical example is the vertebrate forelimb. The wing of a bat, the flipper of a whale, the foreleg of a horse and the human arm are built from the same bones (humerus, radius, ulna) inherited from an ancestral tetrapod limb, even though they now serve very different purposes.

The molecular definition is the same. Two genes, proteins or parts of them are **homologous if they descend from a common ancestral sequence**. Homology is therefore a statement about history, not about the sequences as we observe them today. It has three consequences that are often misunderstood:

1. **Homology is qualitative.** Two sequences either share an ancestor or they do not. There is no such thing as "45% homology". The quantity that can be measured is *similarity*, for example the percentage of identical residues in an alignment (*percent identity*) or the percentage of similar residues (*percent similarity*). Similarity is the observation; homology is the conclusion drawn from it.
2. **There is only one kind of homology.** Expressions such as "structural homology" or "functional homology" mix up the evidence with the conclusion. Two proteins can be *structurally similar* because they are homologous, or because the same fold evolved twice. They can have the same function for the same two reasons. Structural similarity, like sequence similarity, is *evidence* for homology, sometimes the strongest evidence available. But it is not a separate type of homology.
3. **Homology need not cover the whole sequence.** Many proteins are mosaics of domains with different histories. Two proteins can be homologous over one domain and unrelated elsewhere, a situation sometimes called *partial homology*. Statements about homology should therefore refer to aligned regions or domains, not automatically to whole proteins.

These points were made forcefully by Reeck et al. (1987). Their paper, " 'Homology' in proteins and nucleic acids: a terminology muddle and a way out of it", was written by eleven leading molecular biologists and evolutionists, among them Doolittle, Fitch, Margoliash, Jukes and Zuckerkandl. It noted that a large fraction of papers used "homology" to mean similarity, and argued that the word should be reserved for common ancestry. The misuse persists nearly 40 years later, and you should expect to be asked about it.

> Example: how to report a result
>
> *Wrong:* "Protein X is 38% homologous to protein Y."
> *Right:* "Protein X and protein Y share 38% sequence identity over 240 aligned residues (E-value 10^{-35}). The similarity is far higher than expected by chance, so we conclude that they are homologous."

1.2.4 Orthologues, paralogues and xenologues

Homologous genes are classified according to the type of event at the node where their histories split. The terms were introduced by Walter Fitch (Fitch 1970) and later refined (Fitch 2000; Koonin 2005):

- **Orthologues** are homologues that diverged through a *speciation* event. When an ancestral species splits into two, the copies of a gene in the two daughter species are orthologues. Human and mouse β-globin (*HBB* and *Hbb-b1*) are orthologues. So are the cytochrome *c* genes of humans and yeast.
- **Paralogues** are homologues that diverged through a *gene duplication*. Human α-globin and β-globin are paralogues, produced by a duplication that occurred roughly 450 million years ago in an early vertebrate. Myoglobin is an even older paralogue of both. Paralogues are present in the same genome, but because the duplication can precede later speciations, a gene in one species can also be paralogous to a gene in another species (human α-globin and mouse β-globin, for example).
- **Xenologues** are homologues whose history includes a *horizontal gene transfer*. Antibiotic-resistance genes carried on plasmids, which have spread between distantly related bacteria, are typical examples.

Paralogy is further divided relative to a particular speciation event (Remm et al. 2001):

- **In-paralogues** (symparalogues) arose by duplication *after* the speciation, so they are all co-orthologous to the corresponding gene or genes in the other species.
- **Out-paralogues** (alloparalogues) arose by duplication *before* it.

For example, if a gene duplicated in the primate lineage after the split from rodents, the two human copies are in-paralogues relative to the human–mouse comparison. Both are orthologous to the single mouse gene. Paralogues produced by a *whole-genome duplication* are called **ohnologues**, after Susumu Ohno, who proposed that two rounds of genome duplication early in vertebrate evolution ("2R") supplied the raw material for vertebrate complexity (Ohno et al. 1968).

The distinction matters in practice because of how function evolves. After a speciation, orthologues usually continue to perform the same role in their respective species. After a duplication, the selective constraints on one or both copies may be relaxed. A copy is often lost, but it may also acquire a new function (*neofunctionalisation*), or the two copies may divide the ancestral functions between them (*subfunctionalisation*) (Lynch and Conery 2000). The resulting rule of thumb, that orthologues are more likely than paralogues to share function (sometimes called the *ortholog conjecture*), underlies the transfer of functional annotation between species (Chapter 10). It is a useful generalisation, not a law, and has been debated in the literature. The classic counterexample among paralogues is angiogenin, which derives from the pancreatic ribonuclease family but has a different biological function.

Orthology and paralogy are properties of a *gene tree reconciled with a species tree*. In principle they are determined by phylogenetic analysis (Chapter 4). In practice they are often inferred at genome scale with faster methods based on pairwise similarity. Examples are reciprocal best hits, COGs, InParanoid and OrthoFinder (Tatusov et al. 1997; Remm et al. 2001; Emms and Kelly 2019; Altenhoff et al. 2019). These methods are discussed in Chapter 3. Note that *similarity alone cannot tell orthologues from paralogues*. The most similar sequence in another genome is often, but not always, the orthologue, for instance when the true orthologue has been lost.

1.2.5 Analogy and convergent evolution

Similar features can also evolve independently. Such features are **analogous**, and the process is called **convergent evolution** (or *homoplasy* in cladistics). Insect and bird wings are analogous: both support

powered flight but evolved separately. The same feature can be homologous at one level and analogous at another. Bird and bat wings are analogous *as wings*, since the common ancestor did not fly, but homologous *as forelimbs*.

At the molecular level convergence is most convincing for *functional features*, especially active sites, because chemistry constrains the possible solutions. The textbook example is the **serine proteases**. Chymotrypsin (and trypsin, elastase and thrombin) and the bacterial protease subtilisin use the same Ser–His–Asp *catalytic triad*, arranged almost identically in space. Yet the two families have completely different folds: chymotrypsin is built from two β-barrels and subtilisin is an α/β protein. The order of the triad residues along the chain differs too: His–Asp–Ser in chymotrypsin and Asp–His–Ser in subtilisin. The similarity is analogous. Catalytic triads have evolved independently in more than 20 enzyme superfamilies. Another example is carbonic anhydrase, where at least three structurally unrelated classes (α, β, γ) catalyse the same reaction.

Convergence at the level of a *full sequence* is, by contrast, extremely unlikely. There are 20^{100} possible sequences of 100 residues, and two unrelated proteins with a similar function have no reason to arrive at similar sequences. Convergence of *simple folds* (helical bundles, β-hairpins, perhaps some common α/β architectures) is more plausible, which is one reason why structural similarity is somewhat weaker evidence for homology than significant sequence similarity. Deciding whether two proteins with similar folds but no detectable sequence similarity are distant homologues or analogues is one of the hard problems in protein classification (Section 1.9). Arguments then rest on shared unusual features: rare structural details, conserved functional residues in equivalent positions, or the same arrangement of secondary-structure elements in an unusual order.

1.2.6 From similarity to homology

How, then, do we conclude that two sequences are homologous? The argument is statistical. When two sequences are aligned, some identical or similar residues will always be found by chance. The question is whether the similarity is *greater than expected for unrelated sequences* of the same length and composition. If it is substantially greater, the most parsimonious explanation is common ancestry, because convergence of whole sequences is so unlikely. Doolittle made this argument explicit in "Similar amino acid sequences: chance or common ancestry?" (Doolittle 1981). Modern search programs implement it by reporting, for each alignment, how often a score at least that high would be expected by chance in a database search (the E-value; see Section 1.4).

Doolittle was also one of the first to show how powerful the approach could be. In 1983 he and his colleagues compared the newly determined sequence of platelet-derived growth factor with their small database of known sequences. They found that it was almost identical to the product of *v-sis*, an oncogene of simian sarcoma virus. A growth factor and a cancer-causing gene turned out to be the same protein: a discovery made entirely by sequence comparison (Doolittle et al. 1983; Doolittle 2010).

The inference is **asymmetric**:

- *Significant similarity implies homology.* If the alignment score is far above what is expected by chance, the sequences are homologous, with a few well-known exceptions discussed below.
- *Lack of significant similarity does not imply non-homology.* Homologous sequences can diverge until their similarity is indistinguishable from noise. Many protein families that are clearly related by structure and function share no detectable sequence similarity.

A consequence is that the *sensitivity* of a search method, its ability to detect distant homologues, is a central measure of its quality. Much of the progress described in this chapter, from pairwise alignment through profiles and HMMs to structure- and language-model-based search, consists of pushing the detection limit further into the region where similarity is faint.

1.2.6.1 The twilight zone

How much identity is needed? Because unrelated sequences can be aligned with gaps, two random protein sequences typically show 15–20% identity over an optimal alignment, and short alignments can show much more. Any fixed threshold must therefore depend on the alignment length. Doolittle coined the term *twilight zone* for the range of pairwise identity in which homology can be neither confirmed nor ruled out by identity alone. The often-quoted range of roughly 20–30% applies only to alignments of typical domain length (about 100 residues or more); for short alignments the zone lies at much higher identity. The term is also used more loosely for the general difficulty of detecting distant homologues. Rost (1999) later quantified it on a large set of structurally verified pairs. He found that above a length-dependent curve, almost all pairs were homologous (same structure), while below it false positives rose sharply. For alignments of about 100 residues the threshold is near 30% identity, and for 250 residues or more it approaches 20% (Figure 1.1). Below about 20% lies what Rost called the *midnight zone* (Rost 1997). Here many pairs are still homologous, as their structures show, but percent identity carries essentially no information.

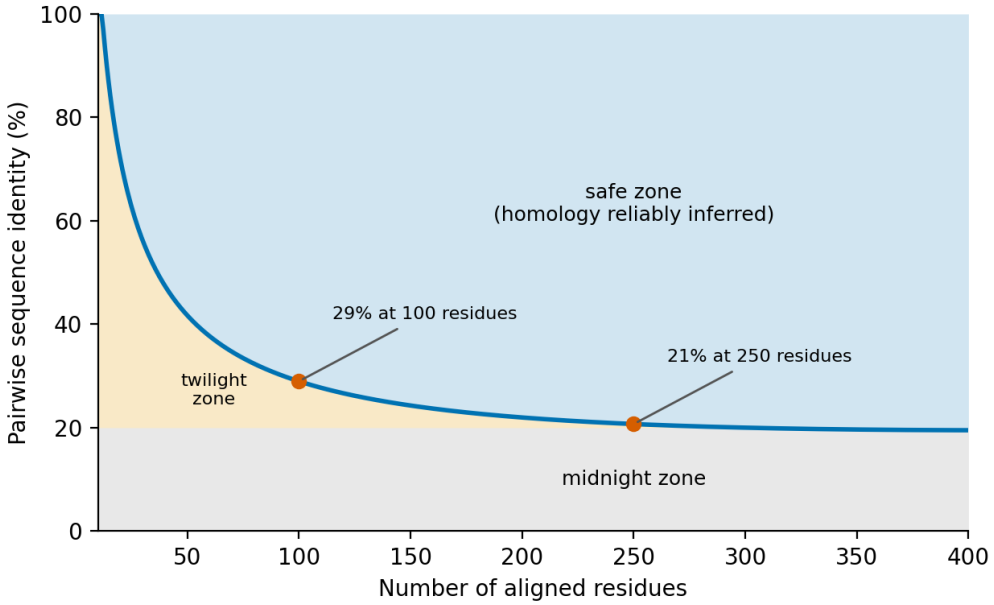

Figure 1.1: The twilight zone. The curve shows the length-dependent identity threshold of Rost (1999), $p(L) = 480\,L^{-0.32\,(1+e^{-L/1000})}$. Above it, homology can be inferred reliably from pairwise identity. Between the curve and about 20% identity (twilight zone), true and false relationships are mixed. Below about 20% (midnight zone), identity is uninformative even though many such pairs are homologous.

Percent identity is nevertheless a poor statistic for detecting homology. It ignores the type of substitution, is sensitive to how gaps are counted, and has no direct probabilistic interpretation. Scores computed with substitution matrices and gap penalties, converted to E-values, are much better. They are the basis of every method in this chapter. Percent identity remains useful for a different purpose: describing how *close* two known homologues are, for example when choosing a template for homology modelling (Chapter 9) or deciding whether annotation can be transferred.

1.2.6.2 Why compare proteins rather than DNA?

When a protein-coding gene is studied, it is almost always better to compare the translated protein sequences than the DNA. There are several reasons:

- **Alphabet size.** With 20 amino acids, a random match at one position occurs with a probability of about 6% (given typical amino-acid frequencies). With four nucleotides, it occurs about 25% of the time. The protein alphabet therefore carries more information per aligned position, and fewer positions are needed to reach significance.
- **Synonymous substitutions.** Because of the degeneracy of the genetic code, many nucleotide changes, especially at third codon positions, do not alter the protein. They accumulate quickly and erase DNA similarity even where the protein is conserved.
- **Substitution matrices.** Amino acids differ in their physicochemical properties, and the frequency with which one replaces another can be estimated from real alignments (Section 1.3). Conservative replacements can be scored as positive evidence. For DNA there is much less to exploit.
- **Composition and repeats.** Genomic DNA is full of repeats and low-complexity regions that produce spurious matches.

The effect is dramatic. DNA–DNA comparisons rarely detect homology between sequences that diverged more than a few hundred million years ago, whereas protein–protein comparisons routinely detect homologues that diverged more than two billion years ago, for example between bacteria and humans (Pearson 2013). DNA comparison is the right choice for non-coding sequences (RNA genes, regulatory regions), for very closely related sequences (resequencing, read mapping; see Chapter 5), and when the reading frame is unknown. Programs such as BLASTX and TBLASTN bridge the gap by translating nucleotide sequences in all six reading frames (Section 1.4).

1.2.6.3 Structure is more conserved than sequence

The three-dimensional structure of a protein changes much more slowly than its sequence. Pairs of homologous proteins with less than 20% sequence identity often still share the same fold, with most of their core superimposable within 2–3 Å (Chothia and Lesk 1986). Below about 30% identity, however, sequence similarity no longer reliably reveals the relationship. This is why structural comparison can detect homology far beyond the limits of sequence comparison. It is also why the structural classifications SCOP, CATH and ECOD group domains into superfamilies on the basis of structural and functional evidence that sequence alone cannot provide (Murzin et al. 1995; Holm and Sander 1996; Cheng et al. 2014). With accurate predicted structures now available for almost every known protein (Jumper, Evans, Pritzel, Green, Figurnov, Ronneberger, Tunyasuvunakool, Bates, Žídek, Potapenko, Bridgland, Meyer, Kohl, Ballard, Cowie, Romera-Paredes, Nikolov, Jain, Adler, Back, Petersen, Reiman, Clancy, Zielinski, Steinegger, Pacholska, Berghammer, Bodenstein, et al. 2021; Varadi et al. 2021), structure-based search has become a practical complement to sequence search (Section 1.4, Chapter 9). The caveat from above still applies: a shared fold is strong but not conclusive evidence of common ancestry.

1.2.6.4 Pitfalls: similarity that is not homology

The rule "significant similarity implies homology" fails in a few well-characterised situations. All of them involve sequences that violate the assumptions behind the statistics, which assume sequences composed roughly at random from standard background frequencies:

- **Low-complexity regions**, such as stretches rich in a few amino acids (poly-Q, proline-rich or serine-rich segments) or short tandem repeats. These can give high scores between unrelated proteins. Search programs therefore mask them, for example with the SEG filter (Wootton and Federhen 1993), or adjust the scores for composition (Schäffer et al. 2001).
- **Biased composition and repetitive structural motifs**, such as coiled coils (heptad repeats), transmembrane helices, collagen-like repeats or signal peptides. These can produce significant-looking alignments between proteins that are related only by shared physical constraints.

- **Multidomain proteins.** A significant hit establishes homology only for the aligned region. Annotating a whole protein from a hit to one of its domains is a frequent source of error. So is assuming transitivity: if A is homologous to B over one domain and B to C over another, A and C need not be related at all. Before transferring an annotation, therefore, check *coverage* as well as significance: the fraction of the query (*query coverage*) and of the hit (*target* or *subject coverage*) that is included in the alignment. A highly significant hit that covers only one domain of a multidomain query supports transfer of that domain's properties, not of the function of the whole protein. Many annotation pipelines and clustering tools (e.g. MMseqs2) require a minimum coverage of both sequences for this reason.

In addition, an E-value always refers to a *particular search*: one query, a database of a given size and a scoring scheme. Two different issues should be kept apart. First, the E-value of a single query already includes the size of the database (the search space): the same alignment score gives a larger E-value in a larger database. $E = 0.01$ means that one chance hit this good is expected in a hundred such searches, whatever the database size. Second, when thousands of *independent queries* are searched, about 0.01 chance hits per query at this threshold add up over the whole experiment (ten in a thousand queries). This experiment-wide multiple-testing problem is not covered by the per-query E-value (Section 1.4).

1.2.7 Homology and the rest of this chapter

The remainder of this chapter follows from the ideas above. To measure similarity we need *alignments* and a *scoring scheme* grounded in how proteins evolve (Section 1.3). To use those scores to infer homology, we need to know their distribution for unrelated sequences, and to apply them to databases of hundreds of millions of sequences we need fast *heuristics* (Section 1.4). To push detection into the twilight zone we pool information from many homologues into *profiles* and *hidden Markov models* (Section 1.6). Because homology is often a property of domains rather than of whole proteins, we need *domain databases* (Section 1.9). The newest approach uses *protein language models*, trained on hundreds of millions of sequences. Their embeddings can, empirically, recover many family and structural relationships, although they are not themselves a test of common ancestry (Section 1.10).

1.3 Dynamic programming and sequence alignment

An alignment arranges two sequences in rows so that corresponding residues stand in the same column. Gaps (written −) are inserted where one sequence has gained or lost residues relative to the other. For homologous sequences, the intended interpretation is evolutionary: each column groups residues believed to derive from the same ancestral position, and the alignment is a *hypothesis* about the substitutions, insertions and deletions that separate the two sequences since their common ancestor (1). The algorithms themselves will align any two sequences, related or not; whether the alignment means anything biologically is a separate, statistical question. To choose between the astronomically many possible alignments we need two things:

1. a **scoring scheme**, which assigns a number to each alignment so that biologically plausible alignments score higher than implausible ones; and

2. an **algorithm** that finds the alignment with the best score without enumerating them all.

This section deals with both. The algorithm is *dynamic programming*, which finds the optimal alignment exactly, in time proportional to the product of the sequence lengths. The scoring scheme consists of a *substitution matrix*, which scores each pair of aligned residues, and a *gap penalty*, which scores insertions and deletions. Everything in this section is "exact": given the scores, the result is guaranteed to be optimal. The heuristics that trade some of this guarantee for speed are covered in Section 1.4.

1.3.1 A short history

The mathematical idea of dynamic programming was developed by **Richard Bellman** at the RAND Corporation in the early 1950s, for multistage decision problems in operations research (Bellman 1954). Bellman later explained that he chose the name partly because "programming" (in the sense of planning) and "dynamic" sounded impressive and were hard to object to politically. The same principle was then discovered independently in many fields that compare sequences:

- **1965–1966**: Vladimir Levenshtein defined the *edit distance* between two strings, the minimum number of insertions, deletions and substitutions needed to turn one into the other.
- **1968**: Taras Vintsyuk used dynamic programming to align speech signals (the forerunner of *dynamic time warping*).
- **1970**: **Saul Needleman and Christian Wunsch** published "A general method applicable to the search for similarities in the amino acid sequence of two proteins" (Needleman and Wunsch 1970). This was the first application of dynamic programming to biological sequences and the origin of *global* alignment. Their original formulation scored matches only and did not penalise gaps, and as published it required time proportional to the cube of the sequence length.
- **1972–1976**: David Sankoff, Peter Sellers, Michael Waterman, Temple Smith and William Beyer put the method on a rigorous footing: Sellers showed how to compute an evolutionary *distance* between sequences, and Waterman, Smith and Beyer (1976) introduced general gap penalties. The same algorithm for edit distance was published in computer science by Wagner and Fischer (1974).
- **1975**: Dan Hirschberg showed how to compute the longest common subsequence in linear space, a trick later adapted to alignment.
- **1978**: Margaret Dayhoff published the **PAM** substitution matrices (Dayhoff et al. 1978), the first scoring scheme derived from observed evolution.
- **1981**: **Temple Smith and Michael Waterman** published the *local* alignment algorithm (Smith and Waterman 1981), in a paper of only three pages. Local alignment finds the best-matching *segments* of two sequences and is the basis of all database searching.
- **1982**: Osamu Gotoh showed that alignment with *affine* gap penalties (a cost for opening a gap plus a smaller cost for extending it) can be done in quadratic time (Gotoh 1982).
- **1988**: Eugene Myers and Webb Miller combined Gotoh's algorithm with Hirschberg's linear-space idea (Myers and Miller 1988).
- **1990–1992**: Samuel Karlin and Stephen Altschul derived the statistics of local alignment scores (Karlin and Altschul 1990); this also explained what substitution matrices mean. Steven and Jorja Henikoff published the **BLOSUM** matrices (Henikoff and Henikoff 1992), still the default for protein searches.

Since then, the algorithms themselves have changed little. The main developments have been in speed — vectorised (SIMD) and GPU implementations of Smith–Waterman, and above all the heuristics of Section 1.4 — and in scoring, where position-specific profiles (Section 1.6) replace a single substitution matrix.

1.3.2 What is dynamic programming?

Dynamic programming solves a problem by breaking it into smaller, *overlapping* subproblems, solving each subproblem once, storing its solution in a table and building the solution of larger problems from the stored solutions. It applies when a problem has two properties:

- **Optimal substructure** (Bellman's *principle of optimality*): an optimal solution to the whole problem contains optimal solutions to its subproblems.
- **Overlapping subproblems**: the same subproblems recur many times, so storing their solutions (rather than recomputing them) saves time.

Sequence alignment has both properties. Consider an optimal alignment of the sequences $A = a_1 a_2 \dots a_n$ and $B = b_1 b_2 \dots b_m$. Its last column can only be one of three things: a_n aligned to b_m, a_n aligned to a gap, or b_m aligned to a gap. Whichever it is, the rest of the alignment must itself be an *optimal* alignment of the remaining prefixes — otherwise we could replace it by a better one and improve the whole. So the best score for the prefixes $a_1 \dots a_i$ and $b_1 \dots b_j$ can be computed from the best scores of three smaller pairs of prefixes, and the problem can be solved by filling in a table of $(n+1) \times (m+1)$ prefix scores.

Why is this necessary? The number of possible alignments grows exponentially. Two sequences of length n can be aligned in

$$\binom{2n}{n} \approx \frac{2^{2n}}{\sqrt{\pi n}}$$

ways (counting alignments that differ only in the order of adjacent gaps in the two sequences as the same) (Durbin et al. 1998). For two proteins of 300 residues this is about 10^{179} alignments, far more than could ever be enumerated. Dynamic programming finds the best one in about 9×10^4 steps.

A useful picture is the **alignment graph** (or *edit graph*): a grid with one sequence along the top and the other down the side. Every alignment is a path from the top-left to the bottom-right corner. A diagonal step aligns two residues, a horizontal step aligns a residue of the top sequence to a gap, and a vertical step aligns a residue of the side sequence to a gap. Finding the best alignment is the same as finding the highest-scoring path through this grid — a *longest-path problem in a directed acyclic graph*, which is the general form of almost every dynamic programming algorithm in bioinformatics (including the Viterbi algorithm for hidden Markov models, Section 1.6).

1.3.3 Global alignment: the Needleman–Wunsch algorithm

Global alignment aligns two sequences over their entire length. It is appropriate when the sequences are expected to be homologous along their whole length, for example two orthologous proteins of similar length with the same domain structure.

Let $s(a, b)$ be the score for aligning residue a with residue b (taken from a substitution matrix), and let each gap position cost d (a *linear* gap penalty; affine gaps are treated below). Define $F(i, j)$ as the score of the best alignment of the prefixes $a_1 \dots a_i$ and $b_1 \dots b_j$. Then

$$F(i,j) = \max \begin{cases} F(i-1, j-1) + s(a_i, b_j) & \text{align } a_i \text{ with } b_j \\ F(i-1, j) - d & a_i \text{ aligned to a gap} \\ F(i, j-1) - d & b_j \text{ aligned to a gap} \end{cases}$$

with the boundary conditions $F(0,0) = 0$, $F(i,0) = -i\,d$ and $F(0,j) = -j\,d$ (a prefix aligned entirely to gaps). The table is filled row by row, so that the three cells needed for each new cell are always available. The optimal global score is $F(n, m)$.

```
NEEDLEMAN-WUNSCH(A[1..n], B[1..m], s, d)
    F[0,0] ← 0
    for i ← 1 to n:  F[i,0] ← −i·d
    for j ← 1 to m:  F[0,j] ← −j·d
    for i ← 1 to n:
        for j ← 1 to m:
            F[i,j] ← max( F[i−1,j−1] + s(A[i],B[j]),    # diagonal
                          F[i−1,j]   − d,               # up: gap in B
                          F[i,j−1]   − d )              # left: gap in A
    return F[n,m]
```

Traceback. The table gives the optimal *score*; the alignment itself is recovered by tracing back from $F(n, m)$ to $F(0, 0)$. At each cell we ask which of the three cases produced the value (either by storing a pointer while filling the table or by recomputing the three candidates), and step to that cell. A diagonal step emits the column $\binom{a_i}{b_j}$, a vertical step emits $\binom{a_i}{-}$ and a horizontal step $\binom{-}{b_j}$; the alignment is read off in reverse. When two or three cases give the same maximum, there are several **co-optimal alignments** with the same score. This is common, and it is a reminder that the optimal alignment is not necessarily the *correct* (biologically true) one.

Worked example: global alignment

Align GCATGCG and GATTACA with match +1, mismatch −1 and gap −1. Each cell holds $F(i, j)$; the blue cells and arrows show one traceback from the bottom-right corner (orange).

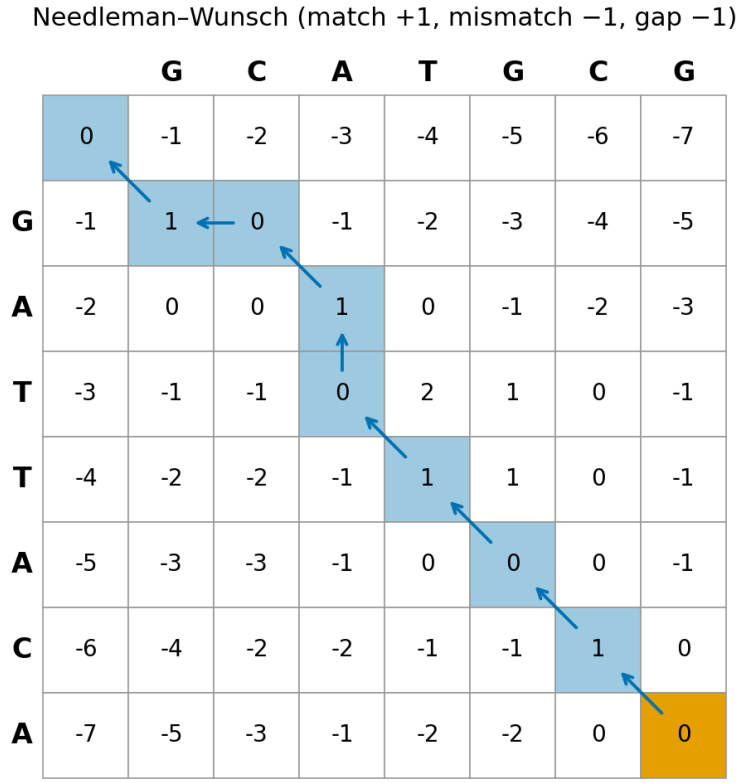

Figure 1.2: Needleman–Wunsch matrix for GCATGCG (top) and GATTACA (side), with one optimal traceback.

Needleman–Wunsch (global; match +1, mismatch −1, gap −1). Optimal score 0; there are 3 co-optimal alignments, one of which is:

```
GCA-TGCG
|  |  |  |
G-ATTACA
```

Check one cell: the cell for G (side) against G (top) is $\max(0+1,\ -1-1,\ -1-1) = 1$, coming from the diagonal.

1.3.4 Local alignment: the Smith–Waterman algorithm

Most real problems are *local*. Proteins are built from domains that can be shared between otherwise unrelated proteins (Section 1.9), a query may be a fragment, and distantly related sequences may be similar only in their conserved core. A global alignment would force the dissimilar parts to be aligned too, and their noise could swamp the signal of the similar part. **Local alignment** instead finds the pair of *segments* (one from each sequence) with the highest alignment score.

Smith and Waterman's insight was that only two changes to the global algorithm are needed (Smith and Waterman 1981):

1. **A fourth option of zero.** If the best alignment ending at (i, j) has a negative score, it is better to start a new alignment there:

$$H(i,j) = \max \begin{cases} 0 & \text{start a new local alignment} \\ H(i-1, j-1) + s(a_i, b_j) & \\ H(i-1, j) - d & \\ H(i, j-1) - d & \end{cases}$$

   with $H(i, 0) = H(0, j) = 0$.

2. **A different traceback.** The best local alignment can end anywhere, so the traceback starts from the *highest* value anywhere in the matrix and stops when it reaches a cell with value zero.

Because the matrix never goes below zero, a region of poor similarity "resets" the score, and the algorithm effectively finds the best-scoring diagonal stretch, gaps included. Further, non-overlapping local alignments can be found by declumping the matrix and repeating the traceback (Waterman and Eggert, 1987), which is how programs report several alignments between the same pair of sequences.

A condition on the scoring scheme. Local alignment only makes sense if the *expected* score of aligning two random residues is negative:

$$\sum_{a,b} p_a\, p_b\, s(a,b) < 0,$$

where p_a are the background frequencies of the residues, and at least one score is positive. If the expected score were positive, any long random alignment would accumulate a positive score, and the "local" alignment would simply extend over the full length of both sequences — the algorithm would behave like global alignment. All standard substitution matrices satisfy this condition, for a reason explained under *Substitution matrices* below.

Worked example: local alignment

Align TGTTACGG and GGTTGACTA with match +3, mismatch −3 and a linear gap penalty of 2 per position. Negative values never appear; the traceback starts at the maximum (13, orange) and stops at the first zero.

Smith–Waterman (match +3, mismatch −3, gap −2)

		G	G	T	T	G	A	C	T	A
	0	0	0	0	0	0	0	0	0	0
T	0	0	0	3	3	1	0	0	3	1
G	0	3	3	1	1	6	4	2	1	0
T	0	1	1	6	4	4	3	1	5	3
T	0	0	0	4	9	7	5	3	4	2
A	0	0	0	2	7	6	10	8	6	7
C	0	0	0	0	5	4	8	13	11	9
G	0	3	3	1	3	8	6	11	10	8
G	0	3	6	4	2	6	5	9	8	7

Figure 1.3: Smith–Waterman matrix for TGTTACGG (side) and GGTTGACTA (top). The best local alignment contains one gap.

Smith–Waterman (local; match +3, mismatch −3, gap −2). Highest cell 13; the traceback stops at the first zero and gives the local alignment:

```
GTT-AC
||| ||
GTTGAC
```

The alignment score is $5 \times 3 - 2 = 13$: five matches and one gap position.

1.3.5 Other alignment modes

Between fully global and fully local there are useful intermediate forms, all obtained by changing the boundary conditions and the cells where the traceback starts and stops:

- **Semi-global ("glocal" or end-gap-free) alignment** aligns all of one sequence to part of another — for example a short read to a genome, or a domain to a full-length protein. Leading and trailing gaps in the longer sequence are not penalised: the first row is initialised to zero, and the traceback starts from the best cell in the last row.

- **Overlap alignment** allows free end gaps in both sequences, so that the end of one sequence is aligned to the start of the other. It is used to detect overlaps between reads in genome assembly (Chapter 5).
- **Banded alignment** restricts the computation to a band of width k around a diagonal. This reduces the cost to $O(k\,n)$ and is exact if the optimal path is known to stay within the band, as when two sequences are already known to be very similar. Banded dynamic programming is used to refine the hits of heuristic methods (Section 1.4).

1.3.6 Edit distance: maximising similarity or minimising distance

Alignment can be framed in two equivalent ways. **Similarity** scores are maximised: matches score positively and mismatches and gaps negatively, as above. **Distances** are minimised: each operation has a non-negative cost. The simplest distance is the *Levenshtein* or *edit distance*, the minimum number of single-character substitutions, insertions and deletions needed to transform one string into the other. It is computed by the same recursion with min instead of max, a cost of 1 for each mismatch or gap and 0 for a match. For global alignment with suitable parameters, the two formulations give the same optimal alignments. Local alignment, however, has no natural distance formulation — a distance can always be made smaller by aligning shorter segments — which is one reason why bioinformatics works with similarity scores.

1.3.7 Gap penalties

Insertions and deletions (*indels*) arise from replication slippage, unequal crossing-over, transposition and other events, and one event often inserts or deletes several residues at once. A good gap penalty should therefore make one gap of length 3 cheaper than three separate gaps of length 1. Several forms are used; let $w(k)$ be the penalty for a gap of length k:

Gap penalty	$w(k)$	Comment
Linear	$k\,d$	Simplest; every gap position costs the same, so long gaps are over-penalised and gaps tend to be scattered.
Constant	g	Gap length does not matter; sometimes used for genomic DNA.
Affine	$g_o + (k-1)\,g_e$ with $g_o > g_e$	A cost for opening a gap plus a smaller cost for each extension. The standard choice.
Convex (e.g. logarithmic)	$g_o + g_e \log k$	Each additional gap position costs less than the previous one; fits observed indel length distributions better, but is more expensive to compute.
General	any function	Needs $O(n^2 m)$ time, as in the original Smith–Waterman paper.

(Some programs, such as BLAST, define the affine penalty as $g_o + k\,g_e$, counting the extension cost for every position including the first; the parameters are then not directly comparable between programs.)

Typical affine parameters for proteins are an opening penalty of about 10–12 and an extension penalty of 0.5–2 in units of the substitution matrix; BLAST with BLOSUM62 uses 11 and 1 by default.

The difference matters in practice. With a linear gap penalty the alignments of `TACGGGCCCGCTAC` and `TAGCCCTATCGGTCA` contain several isolated gap positions; with an affine penalty the same sequences align with a few longer gaps — fewer, biologically more plausible, indel events.

1.3.7.1 Affine gaps in quadratic time: Gotoh's algorithm

With a general gap function, each cell must consider gaps of every possible length ending there, which gives $O(n^2 m)$ time. Gotoh showed that for affine penalties it is enough to keep **three** matrices, one for each possible state of the last column (Gotoh 1982):

- $M(i, j)$: best score of an alignment of the prefixes that ends with a_i aligned to b_j;
- $I_x(i, j)$: best score of an alignment that ends with a_i aligned to a gap (a gap in B);
- $I_y(i, j)$: best score of an alignment that ends with b_j aligned to a gap (a gap in A).

With an affine penalty $w(k) = g_o + (k-1)g_e$ the recursions are

$$
\begin{aligned}
M(i,j) &= s(a_i, b_j) + \max\{M(i-1,j-1),\ I_x(i-1,j-1),\ I_y(i-1,j-1)\} \\
I_x(i,j) &= \max\{M(i-1,j) - g_o,\ \ I_x(i-1,j) - g_e\} \\
I_y(i,j) &= \max\{M(i,j-1) - g_o,\ \ I_y(i,j-1) - g_e\}
\end{aligned}
$$

and the score of the best alignment is the maximum of the three matrices in the final cell. (This version forbids a gap in A to be directly followed by a gap in B, which is never optimal when s is not too negative.) Opening a gap means leaving the match state; extending it means staying in the gap state. Each cell is still computed in constant time, so the cost remains $O(nm)$. The local version adds the zero option to M. Gotoh's original traceback procedure contained an error that could miss the optimal alignment in some cases; this was pointed out and corrected by Altschul and Erickson (1986).

The three matrices can be seen as the three states of a small finite-state machine — match, insertion, deletion — with transitions whose costs are the gap-opening and gap-extension penalties. This is exactly the structure of a *pair hidden Markov model*, in which the scores become log-probabilities (Durbin et al. 1998). Profile HMMs (Section 1.6) extend the same idea to whole families of sequences.

1.3.8 Time and space complexity

Filling one cell takes constant time, so all variants above need $O(nm)$ **time**. Storing the full matrix for the traceback needs $O(nm)$ **space**. For two proteins this is trivial, but for two sequences of 100,000 residues it already amounts to 10^{10} cells.

Linear space. The *score* alone needs only the previous row, so it can be computed in $O(\min(n, m))$ space. To recover the *alignment* in linear space, Hirschberg's divide-and-conquer method is used:

1. Compute the scores of the forward alignments of the top half of A against all prefixes of B, and the scores of the reverse alignments of the bottom half of A against all suffixes of B, keeping only the last row of each.
2. The optimal path must cross the middle row of A at the column j where the sum of the forward and reverse scores is maximal. This splits the problem into two independent subproblems — top-left and bottom-right of that point.
3. Recurse on each half.

The total work is about twice that of the ordinary algorithm, still $O(nm)$, while the space is $O(n+m)$. Myers and Miller extended this to affine gap penalties (Myers and Miller 1988), and it is the basis of space-efficient alignment tools.

Faster than quadratic? The "Four Russians" technique reduces the time to $O(nm/\log n)$ for small alphabets, but has little practical importance. More importantly, there is strong theoretical evidence that edit distance cannot be computed in strongly subquadratic time in the worst case. In practice, Smith–Waterman is accelerated by computing many cells at once: SIMD instructions on ordinary processors (as in the `SSEARCH` program of the FASTA package and in the SWIPE and Parasail libraries) and GPUs reach billions of cell updates per second.

Even so, exact local alignment of every query against a large database is expensive. UniProt contains roughly 10^{11} residues, so comparing one 300-residue protein against all of it requires about 3×10^{13} cell updates — minutes to hours on a modern computer, for a *single* query. Comparing all proteins of a newly sequenced genome, or a metagenome with millions of proteins, against the database would take years. This is the motivation for the heuristic methods of Section 1.4.

1.3.9 Substitution matrices

The algorithm guarantees the optimal alignment *for a given scoring scheme*; whether that alignment is biologically meaningful depends entirely on the scores. For DNA, simple schemes are often adequate. For proteins, the 20 amino acids differ greatly in size, charge, polarity and other properties, and some substitutions (for example isoleucine to valine) are accepted by evolution far more often than others (for example tryptophan to glycine). A **substitution matrix** is a 20×20 table of scores $s(a, b)$ that captures these differences.

1.3.9.1 Scores as log-odds ratios

Substitution scores are best understood as **log-odds scores** comparing two hypotheses about an aligned pair of residues a and b:

- the *match* (homology) model, in which a and b are derived from a common ancestral residue and occur together with **target frequency** q_{ab}, estimated from alignments of true homologues; and
- the *random* model, in which a and b are unrelated and occur together with probability $p_a p_b$, the product of their background frequencies.

The score is the logarithm of the ratio of these probabilities,

$$s(a,b) = \frac{1}{\lambda} \log \frac{q_{ab}}{p_a\, p_b},$$

where λ is a scale factor chosen so that the scores can be rounded to convenient integers. Matrices are usually given in *bits* (logarithm base 2) or fractions of bits; BLOSUM62, for example, is in half-bit units, so a score of $+2$ means the pair is $2^{2/2} = 2$ times more likely under the homology model than by chance. A positive score means the pair occurs more often in true alignments than expected by chance, a negative score that it occurs less often, and zero that there is no information.

Because scores are logarithms of probability ratios, and positions in an ungapped alignment are treated as independent, the **total score** of an ungapped alignment is the log-likelihood ratio of the whole alignment:

$$S = \sum_{k} s(x_k, y_k) = \frac{1}{\lambda} \log \frac{P(\text{alignment} \mid \text{homologous})}{P(\text{alignment} \mid \text{random})}.$$

Dynamic programming thus finds the alignment that is most likely under the homology model *relative* to the random model. The same interpretation underlies profile scores and hidden Markov models (Section 1.6).

Two further consequences follow:

- **The expected score is always negative.** The expected score of a random pair is

$$\sum_{a,b} p_a p_b \, s(a,b) = -\frac{1}{\lambda} \sum_{a,b} p_a p_b \log \frac{p_a p_b}{q_{ab}} \le 0,$$

  because the sum on the right is a relative entropy (Kullback–Leibler divergence), which is never negative. Any log-odds matrix therefore automatically satisfies the requirement of local alignment.
- **Every matrix is a log-odds matrix.** Karlin and Altschul showed the converse (Karlin and Altschul 1990): for any scoring matrix with a negative expected score and at least one positive entry, there is a unique $\lambda > 0$ with $\sum_{a,b} p_a p_b e^{\lambda s(a,b)} = 1$, and $q_{ab} = p_a p_b e^{\lambda s(a,b)}$ are the target frequencies for which the matrix is optimal. Choosing a matrix is therefore always, implicitly, choosing what kind of alignments one expects to find. The same λ appears in the statistics of alignment scores (Section 1.4).

The **relative entropy**

$$H = \sum_{a,b} q_{ab} \log_2 \frac{q_{ab}}{p_a p_b}$$

is the average score per aligned position in true alignments, in bits. It measures how much information each aligned pair carries for distinguishing homology from chance (Altschul 1991). Matrices for closely related sequences have high relative entropy (each position is informative, so a short alignment suffices); matrices for distant relationships have low relative entropy (a longer alignment is needed to reach significance).

1.3.9.2 Scoring DNA

For nucleotides, a simple match/mismatch scheme is usually used, for example $+1/-2$ or $+2/-3$ for highly similar sequences and $+1/-1$ for more divergent ones (the ratio sets the implied target identity). Since transitions (purine–purine or pyrimidine–pyrimidine changes, A↔G and C↔T) are about twice as common as transversions in most genomes, they can be given a less negative score. For protein-coding genes, alignment of the translated sequences is far more sensitive than DNA alignment, because the genetic code is degenerate and synonymous changes saturate quickly.

1.3.9.3 PAM matrices

The first substitution matrices derived from evolutionary data were Margaret Dayhoff's **PAM** matrices (Dayhoff et al. 1978). A *point accepted mutation* is the replacement of one amino acid by another that has been accepted by natural selection, that is, has become fixed in the population. Dayhoff's approach was explicitly evolutionary:

1. **Data.** 1572 accepted substitutions were counted on the branches of phylogenetic trees reconstructed for 71 families of closely related proteins (at least 85% identical), so that each observed difference could be assumed to be a single substitution.
2. **Mutation probability matrix.** From the counts, together with the *mutability* of each amino acid (how often it changes relative to how often it occurs) and the amino-acid frequencies, a matrix M_1 of transition probabilities was computed, scaled so that on average 1% of the amino acids change. This is **PAM1**: one accepted point mutation per 100 residues.

3. **Extrapolation.** Evolution was modelled as a Markov chain, so the matrix for a longer evolutionary distance is a power of M_1: $M_n = M_1^n$. PAM250 corresponds to 250 accepted mutations per 100 residues — many positions have changed several times — and to about 20% sequence identity.
4. **Log-odds scores.** The PAMn score is $s(i,j) = 10 \log_{10}\big(M_n(i,j)/f_i\big)$, the probability that j has become i after n PAM units relative to the background frequency of i.

Dayhoff found that asparagine, serine and aspartate are among the most mutable amino acids, and cysteine and tryptophan the least, in line with their special structural roles. The main weakness of PAM is the extrapolation: the substitution pattern of very similar sequences, which is dominated by single-nucleotide changes in the codon, is assumed to hold over long distances. The data set was also small by modern standards. Later matrices of the same type, such as JTT (1992) and WAG (2001), were estimated from much larger data sets and are used as substitution models in phylogenetics (Chapter 4).

1.3.9.4 BLOSUM matrices

Steven and Jorja Henikoff took a different, empirical approach (Henikoff and Henikoff 1992). Instead of extrapolating from close relatives, they counted substitutions directly in conserved regions of distantly related proteins:

1. **Data.** The BLOCKS database contains ungapped multiple alignments ("blocks") of the most conserved regions of protein families — about 2000 blocks from more than 500 families in the original work.
2. **Clustering.** To avoid over-counting closely related sequences, the sequences in each block that are more than r% identical are clustered, and each cluster contributes with a total weight of one sequence.
3. **Counting.** All pairs of amino acids in each column, between sequences in different clusters, are counted. This gives the observed pair frequencies q_{ab}, and from them the background frequencies p_a.
4. **Log-odds scores.** $s(a,b) = 2 \log_2\big(q_{ab}/(p_a p_b)\big)$, rounded to the nearest integer (half-bit units).

The number in the name is the clustering threshold: **BLOSUM62** is computed from blocks in which sequences more than 62% identical were clustered together. A higher number means less clustering, more similar sequences contribute and the matrix is suited to closely related sequences; a lower number suits distant relationships. The numbering therefore runs in the *opposite* direction to PAM. For PAM, a *higher* number means a greater evolutionary distance (more accepted mutations); for BLOSUM, a *lower* number is intended for more divergent sequences. BLOSUM80 corresponds roughly to a low PAM number, BLOSUM45 to a high one. The two numbers measure different things (an extrapolated distance and a clustering threshold) and cannot be compared directly.

In comparisons with PAM, BLOSUM matrices performed better in database searches, especially for distant relationships, and BLOSUM62 became the default of BLAST and most other protein search programs. Its relative entropy is about 0.70 bits per position, similar to PAM160; BLOSUM45 (about 0.38 bits) is comparable to PAM250. The derivation of BLOSUM62, and why it works so well, is explained in a short and very readable note by Eddy (2004b). A curious footnote is that the program originally used to compute BLOSUM62 contained errors, discovered only in 2008. The "correct" matrix turned out to perform slightly *worse* in searches than the miscalculated one, which is still the standard — a reminder that the best matrix is ultimately an empirical question.

1.3.9.5 Choosing a matrix

Because each matrix is optimal for a particular evolutionary distance — its implicit target frequencies — the best matrix depends on what one is looking for (Altschul 1991):

Purpose	Typical matrices
Very similar sequences, short queries or short peptides	PAM30, PAM70, BLOSUM80
General database searching	BLOSUM62 (the usual default)
Distant relationships, long alignments	BLOSUM45, PAM250

A "deep" matrix (low relative entropy) can detect distant homologues but needs long alignments to give significant scores, and it tends to extend alignments into unrelated regions. A "shallow" matrix (high relative entropy) gives short, accurate alignments of close relatives but misses distant ones. Some programs therefore search with several matrices, and modern programs adjust the matrix to the amino-acid composition of the sequences being compared (*composition-based statistics*), which matters for proteins with unusual compositions such as transmembrane or low-complexity proteins.

1.3.9.6 Limitations of a single substitution matrix

A substitution matrix assumes that the same substitution pattern applies at every position of every protein. In reality, a buried hydrophobic position, a catalytic residue and a surface loop evolve very differently. Position-specific scores, estimated from a multiple alignment of the family, capture this variation and are the basis of profiles and profile HMMs (Section 1.6); environment-specific matrices, which depend on the structural context of each residue, are used in fold recognition (Chapter 9).

1.3.10 From scores to significance

An optimal alignment always exists, even between two random sequences. The scores of optimal *local* alignments between unrelated sequences are not normally distributed but follow an **extreme-value (Gumbel) distribution**, because each score is itself the maximum over many possible alignments. Karlin and Altschul derived its parameters for ungapped alignments (Karlin and Altschul 1990): the expected number of alignments with score at least S between random sequences of lengths m and n is

$$E = Kmne^{-\lambda S},$$

with λ the same scale factor as above and K a second constant that depends on the scoring system. For gapped alignments the parameters are estimated by simulation. These *E-values*, and their use in database searches, are treated in Section 1.4. Global alignment scores have no comparably simple theory, and their significance is usually assessed by shuffling the sequences.

1.3.11 Summary

- Dynamic programming finds the optimal alignment of two sequences under a given scoring scheme exactly, in $O(nm)$ time, by building optimal alignments of prefixes from optimal alignments of shorter prefixes.
- Global (Needleman–Wunsch), local (Smith–Waterman), semi-global and overlap alignment differ only in their boundary conditions, the zero option and where the traceback starts and stops.
- Affine gap penalties are handled in quadratic time with three matrices (Gotoh), and alignments can be recovered in linear space (Hirschberg, Myers–Miller).
- Substitution scores are log-odds ratios of target and background frequencies. Every matrix implies a set of target frequencies and is best suited to one evolutionary distance; PAM extrapolates from close relatives, BLOSUM counts directly in conserved blocks.

- The optimal alignment is only as good as the scoring scheme, and an optimal alignment is not necessarily the true one. Whether a score indicates homology is a statistical question (Section 1.4), and for sequence identities below about 25–30% the answer is often uncertain (1).

The worked examples follow those in the Needleman–Wunsch and Smith–Waterman articles.

1.4 Heuristic search methods

Dynamic programming (Section 1.3) is guaranteed to find the best alignment for a given scoring scheme, but it is expensive. Comparing a query of length m with a database of total length N takes time proportional to mN. For a typical protein of 300 residues searched against UniProtKB, with a few hundred million sequences, that means tens of trillions of dynamic-programming cells for every query. Even with modern vectorised implementations, which can fill billions of cells per second, this takes hours. Databases have also grown much faster than computers have become faster: sequence databases have roughly doubled every two years since the 1980s, and metagenomic projects now produce billions of protein sequences.

Practical database searching therefore uses **heuristics**: methods that first find short, promising regions of similarity quickly, and then spend the expensive dynamic-programming effort only on those regions. The price is that a heuristic can miss alignments that the full Smith–Waterman algorithm would have found. The heuristic lies mainly in the *filter*, the decision which sequences and regions are examined at all. The alignments that are finally reported are computed by dynamic programming, usually restricted to a band or by X-drop extension around the seed. For clear homologues they are therefore usually identical, or very close, to the Smith–Waterman alignment, although an X-drop extension can stop early and report a shorter alignment. The art of designing a search tool lies in choosing a filter that discards almost all unrelated sequences while keeping almost all true homologues. Equally important is the second half of the problem: deciding which of the reported hits are significant. This section covers both, from FASTA and BLAST to the tools used today for searching billions of sequences and structures, and the exact-matching indexes used for mapping sequencing reads.

1.4.1 FASTA

The first widely used heuristic was developed by David Lipman and William Pearson. FASTP, for protein searches, was published in 1985 (Lipman and Pearson 1985). Its successor FASTA, which extended the approach to nucleotide and translated protein–DNA searches, followed in 1988 (Pearson and Lipman 1988). The name lives on in the FASTA file format, which was introduced with the program and is now the standard way to store sequences.

FASTA builds on a simple observation. If two sequences are related, their alignment usually contains several short stretches of identical residues, and these lie on the same *diagonal* of the dot plot (the same offset between the two sequences). FASTA proceeds in four steps:

1. **Find word hits.** All identical words of length `ktup` (typically 1 or 2 for proteins, 4–6 for DNA) shared by the query and the database sequence are found with a lookup table. The time needed is proportional to the sequence lengths, not to their product.
2. **Find the best diagonal regions.** Hits on the same diagonal are grouped, and each diagonal region is scored by the number of hits minus a penalty for the distance between them. The ten best regions are kept and rescored with a substitution matrix (originally PAM250, now BLOSUM50 by default), which allows conservative substitutions and runs of identities shorter than `ktup` to contribute. The best single region gives the score `init1`.
3. **Join regions.** Regions on nearby diagonals are combined into one longer alignment containing gaps, at a cost of a joining penalty. The score of the best combination is `initn`.
4. **Optimise.** For the best-scoring database sequences, a banded Smith–Waterman alignment is computed in a narrow band (for example 32 residues wide) around the best diagonal. This gives the final score `opt`.

A smaller `ktup` makes the search more sensitive but slower. A distinctive feature of FASTA is how it estimates significance. Because a database search compares the query with many sequences, most of which are unrelated, the distribution of their scores can itself serve as the null model. FASTA fits an extreme-value distribution to the scores of the unrelated sequences and reports an expectation value for each hit (Pearson 2013). The FASTA package also contains SSEARCH, a full Smith–Waterman implementation that is often used as a gold standard for sensitivity.

1.4.2 BLAST

The **Basic Local Alignment Search Tool** was published in 1990 by Stephen Altschul, Warren Gish, Webb Miller, Eugene Myers and David Lipman at the NCBI (Altschul et al. 1990). It became one of the most cited papers in all of science. BLAST combined two ideas. The first was a faster and more selective seeding strategy than FASTA's. The second, at least as important, was a rigorous statistical theory for local alignment scores, developed in parallel by Samuel Karlin and Altschul (Karlin and Altschul 1990) and described below.

1.4.2.1 The original algorithm (1990)

BLAST looks for **high-scoring segment pairs** (HSPs): pairs of equal-length segments, one from each sequence, aligned without gaps, whose score cannot be improved by extending or shortening them. The highest-scoring of these is the **maximal segment pair** (MSP). The original BLAST approximated the MSP score in three steps.

1. **Compile a word list.** The query is split into all overlapping words of length w (usually $w = 3$ for proteins). For each query word, BLAST lists all words of the same length that score at least T against it with the substitution matrix (BLOSUM62 by default). These are the *neighbourhood words*. For example, with BLOSUM62 the query word PQG scores 15 against PEG ($7 + 2 + 6$) and 12 against PQA ($7 + 5 + 0$). With $T = 13$, PEG is in the neighbourhood of PQG but PQA is not. The neighbourhood is what distinguishes BLAST from FASTA: seeds do not have to be identical, only similar, so they are much more informative. For DNA, BLAST instead uses exact matches of a longer word (by default $w = 11$).
2. **Scan the database.** The neighbourhood words are compiled into a finite-state automaton (or a lookup table), so that each database sequence can be scanned in a single pass for exact occurrences of any of them. Each occurrence is a *hit*.

3. **Extend the hits.** Each hit is extended in both directions without gaps, adding the substitution scores residue by residue. The extension stops when the running score has fallen more than X below the best score seen so far (the *X-drop* rule). The best segment found is reported as an HSP if its score is high enough.

The parameter T controls the trade-off between speed and sensitivity. A high T gives few neighbourhood words and few hits to extend, so the search is fast but may miss alignments that contain no high-scoring word. A low T gives the opposite.

1.4.2.2 Gapped BLAST and the two-hit method (1997)

The 1990 BLAST reported only ungapped alignments. A real alignment interrupted by indels therefore appeared as several separate HSPs, and weak alignments could be missed altogether. In 1997, Altschul and co-workers published gapped BLAST together with PSI-BLAST (Altschul et al. 1997), with two main improvements.

- **The two-hit method.** Most time in the original BLAST was spent extending hits that led nowhere. The authors observed that a biologically meaningful HSP is usually much longer than a single word, so it will typically contain *two* word hits on the same diagonal. In gapped BLAST, an ungapped extension is triggered only when two non-overlapping hits occur on the same diagonal within a distance A (by default 40 residues) of each other. This allowed T to be lowered, increasing sensitivity, while the number of extensions fell sharply.
- **Gapped extension.** If an ungapped HSP scores above a moderate threshold, a gapped alignment is computed by dynamic programming, starting from a central residue pair of the HSP and extending in both directions. The extension uses the X-drop rule: cells whose score has fallen more than X_g below the best score are not explored. This confines the computation to a small region around the seed rather than the whole matrix.

The result was a program about three times faster than the original, which reports gapped alignments. PSI-BLAST, the iterative profile search introduced in the same paper, is described in Section 1.6.

1.4.2.3 Low-complexity filtering

Regions of biased composition, such as stretches rich in a single amino acid, short tandem repeats or coiled coils, align with high scores to many unrelated sequences. Because they violate the assumptions of the statistical model, they produce many false positives with apparently excellent E-values. Such hits can be very strong and still biologically meaningless: two proteins that both contain a polyglutamine or a proline-rich stretch are not thereby homologous. Two remedies are used. *Masking* identifies low-complexity regions in the query, with SEG (Wootton and Federhen 1993) for proteins and DUST for DNA, and replaces them by X (protein) or N (DNA) so that they cannot seed alignments (*soft masking* excludes them from seeding only, but allows them in the extension). *Composition-based statistics* (Schäffer et al. 2001) instead adjust the scores of each alignment to the amino-acid composition of the two sequences (see below). Which of these is on by default differs between programs and versions (in current BLAST+, DUST masking is the default for blastn, and composition-based statistics rather than SEG for blastp), so the settings should be checked and reported. Masking is also a common reason why a search misses a hit that seems obvious.

1.4.2.4 The BLAST family of programs

The same engine is used in a family of programs that differ in what is compared with what:

Program	Query	Database	Typical use
blastp	protein	protein	find homologues of a protein
blastn	nucleotide	nucleotide	DNA/RNA similarity
megablast	nucleotide	nucleotide	very similar sequences (long exact seeds, $w = 28$); fast
blastx	nucleotide, translated in six frames	protein	find what protein a DNA fragment or transcript encodes
tblastn	protein	nucleotide, translated in six frames	find (unannotated) genes for a protein in genomes
tblastx	translated nucleotide	translated nucleotide	compare two DNA sequences at the protein level; slow

Translated searches are important because protein sequences diverge much more slowly than the DNA that encodes them. Two genes whose DNA is no longer recognisably similar, because of synonymous changes and codon usage, may still encode clearly similar proteins. In general, searching at the protein level is far more sensitive than at the DNA level. Translated searches are also how nucleotide data (genomes, transcripts, metagenomic reads) are connected to the protein databases, where most functional annotation lives. Two practical points follow from the translation. The search space is measured in amino-acid residues, so a translated nucleotide sequence contributes about a third of its length per reading frame. And a sequencing error that causes a frameshift splits a translated alignment into pieces in different frames; some tools, such as FASTX and FASTY in the FASTA package and DIAMOND's frameshift-aware mode, can align across such frameshifts.

1.4.2.5 BLAT and other genome-scale tools

BLAST builds its word index from the *query* and scans the database. For aligning millions of mRNAs or ESTs to a genome, the reverse is more efficient. BLAT, the BLAST-like alignment tool written by Jim Kent for the human genome project (Kent 2002), builds an index of non-overlapping k-mers of the whole genome, keeps it in memory, and then looks up the k-mers of each query. It is designed for finding very similar sequences (for example the same gene in the same or a closely related species) and is hundreds of times faster than BLAST for that task, but much less sensitive for distant homologues. The same idea, an index of the *reference*, underlies the read mappers discussed at the end of this section. Aligning whole genomes to each other, where rearrangements, duplications and repeats must be handled, needs further steps, described in Section 1.8.

1.4.3 The statistics of alignment scores

Every search reports a best hit, even for a random query. The crucial question is therefore not "how similar is the hit?" but "how often would we see a score this high by chance?" Answering it requires knowing the distribution of scores between unrelated sequences.

1.4.3.1 Why not a normal distribution?

The score of an alignment of two *fixed* segments is a sum of many substitution scores, and so by the central limit theorem it is approximately normally distributed. But a local alignment score is the **maximum** over all possible pairs of segments. The maximum of many random variables does not follow a normal distribution. Its distribution belongs to the family of **extreme value distributions**, and for local alignment scores it is of the **Gumbel** type. The Gumbel distribution has a much heavier right tail than a normal distribution: it decays exponentially, as $e^{-\lambda x}$, whereas the normal tail falls off as $e^{-x^2/2}$. Using a normal model, or a z-score, therefore greatly underestimates how often high scores occur by chance.

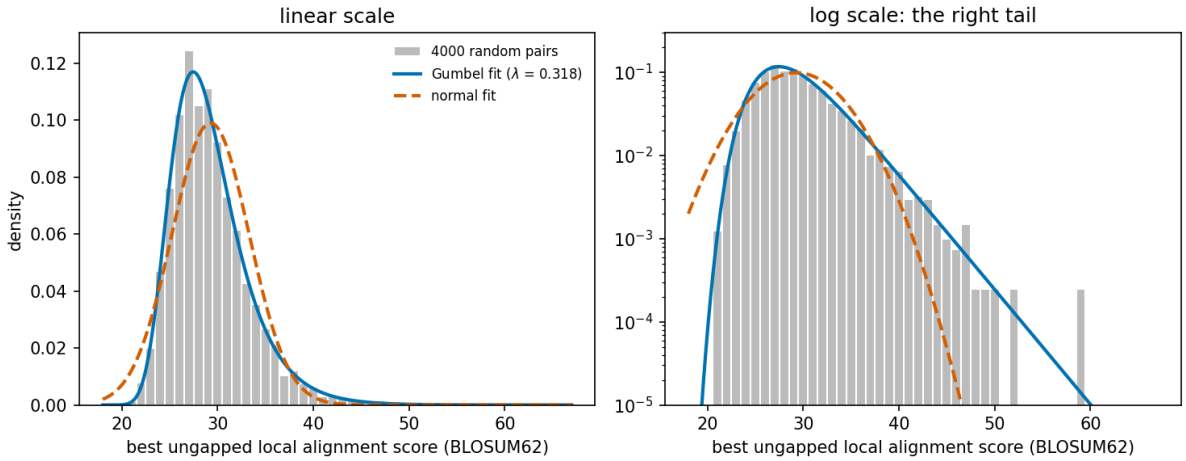

Figure 1.4: Distribution of the best ungapped local alignment score between pairs of random protein sequences (length 250, BLOSUM62). A Gumbel distribution (blue) fits the data, including the right tail; a normal distribution fitted to the same data (orange, dashed) underestimates the probability of high scores by orders of magnitude.

In this simulation (4000 pairs of random sequences of length 250, BLOSUM62, background frequencies of Robinson & Robinson), the fitted Gumbel distribution has $\lambda \approx 0.318$ and $K \approx 0.099$, close to the value $\lambda = 0.318$ predicted by solving $\sum_{ij} p_i p_j e^{\lambda s_{ij}} = 1$. For a score of 48, the Gumbel model gives $P(S \geq x) = 1.5 \times 10^{-3}$, whereas a normal distribution fitted to the same data gives 1.7×10^{-6}: the normal model underestimates how often high scores occur by chance.

1.4.3.2 Karlin–Altschul statistics

For *ungapped* local alignments, Karlin and Altschul derived the score distribution analytically (Karlin and Altschul 1990). The theory assumes:

- the residues of the two sequences are independent and drawn from background frequencies p_i;
- the expected score of aligning two random residues is negative, $\sum_{ij} p_i p_j s_{ij} < 0$ (otherwise the best "local" alignment would grow with the length of the sequences and become a global one);
- at least one score s_{ij} is positive.

Under these conditions, for two random sequences of lengths m and n that are long enough, the number of distinct HSPs with score at least S is approximately Poisson-distributed with mean

$$E = Kmne^{-\lambda S}.$$

This is the **E-value**: the number of alignments with score $\geq S$ expected by chance. Two parameters depend on the scoring system and the background frequencies. λ is the unique positive solution of

$$\sum_{i,j} p_i \, p_j \, e^{\lambda s_{ij}} = 1,$$

and acts as a scale that converts raw scores into natural units. K is a smaller correction factor for the fact that high-scoring alignments are not independent: an HSP is usually surrounded by overlapping, slightly lower-scoring ones. For BLOSUM62 with standard amino-acid frequencies, $\lambda \approx 0.318$ and $K \approx 0.13$ for ungapped alignments. Equivalently, the maximal score follows a Gumbel distribution,

$$P(S \geq x) \approx 1 - \exp\!\left(-e^{-\lambda(x-\mu)}\right), \qquad \mu = \frac{\ln(Kmn)}{\lambda}.$$

The theory also connects to substitution matrices (Section 1.3). Every scoring matrix with negative expected score is implicitly a log-odds matrix, $s_{ij} = \frac{1}{\lambda} \ln \frac{q_{ij}}{p_i p_j}$, for some *target frequencies* q_{ij}. These are the frequencies with which residue pairs occur in the alignments the matrix is best at finding.

1.4.3.3 E-values, P-values and bit scores

Raw scores depend on the scoring system, so they cannot be compared between searches that use different matrices. Normalising with λ and K gives the **bit score**

$$S' = \frac{\lambda S - \ln K}{\ln 2},$$

in terms of which the E-value takes a particularly simple form:

$$E = m n \, 2^{-S'}.$$

Every extra bit of score halves the E-value. The "search space" mn appears explicitly: in a database search, n is the total length of the database. Since the number of chance HSPs is Poisson-distributed, the probability of finding *at least one* with score $\geq S$ is the **P-value**

$$P = 1 - e^{-E}.$$

For small values, $P \approx E$. For large values they differ: $E = 3$ means that about three such hits are expected by chance, but P can never exceed 1. BLAST therefore reports E-values, which are easier to interpret over the whole range.

1.4.3.4 Corrections and gapped alignments

Several refinements are needed in practice.

- **Edge effects.** An alignment cannot start near the end of a sequence and still be long. BLAST therefore uses *effective lengths*: m and n are shortened by the expected length of an HSP, $\ell \approx \ln(Kmn)/H$, where H is the relative entropy of the scoring system. For a database of many sequences, the correction is applied to each sequence.
- **Gapped alignments.** No exact theory exists for gapped alignments. Simulations show that their scores still follow a Gumbel distribution to a good approximation, but λ and K must be estimated empirically for each combination of matrix and gap penalties. For example, for BLOSUM62 with gap open 11 and extend 1, $\lambda \approx 0.267$ and $K \approx 0.041$. These precomputed values are built into BLAST, which is why only certain combinations of matrix and gap costs are allowed. Very low gap penalties make the score behave like a global one, and the statistics break down.
- **Composition.** Proteins with unusual amino-acid composition, such as transmembrane or low-complexity proteins, violate the assumption of standard background frequencies. Modern BLAST uses *composition-based statistics*, which rescale the scores, or adjusts the substitution matrix itself to the composition of the two sequences being compared (Schäffer et al. 2001).
- **Multiple HSPs.** When two sequences share several HSPs, for example around an indel, *sum statistics* combine them into a single, more significant E-value (Karlin and Altschul 1993).

A different approach to significance is to estimate the null distribution directly. FASTA fits the distribution of scores from the database search itself (Pearson 1998). HMMER uses probabilistic models whose score distributions can be derived or calibrated (Eddy 2008). Another approach is to re-align the hit after shuffling one of the sequences many times.

1.4.3.5 Interpreting E-values

- **The E-value depends on the database.** Because $E = mn\,2^{-S'}$ and n is the length of the whole database, the same alignment, with exactly the same raw score and bit score, gets a ten times larger E-value when it is found in a database ten times larger. The score measures the similarity of the two sequences; the E-value measures how surprising that score is in this particular search. This is not a flaw but the correct accounting for the number of comparisons: the E-value is a built-in correction for multiple testing *within one query's search*. For the same alignment score, searching a smaller, targeted database therefore gives a smaller E-value, so a borderline relationship can pass a fixed significance threshold that it would not pass in a much larger database (the search algorithm finds the same alignment either way). E-values from searches of different database releases are not directly comparable (bit scores are). As databases grow, a borderline hit can become non-significant without any change in its alignment.
- **Many queries are a separate problem.** The E-value does not account for the number of *queries*. When 10,000 proteins of a genome are each searched with a threshold of $E = 0.01$, about 100 chance hits are expected over the whole experiment. For genome-scale analyses the threshold must be chosen with this experiment-wide error in mind (see Section 7.4 for family-wise error and false discovery rates).
- **Thresholds.** For a single protein search, $E < 10^{-3}$ is usually safe evidence of homology, and many studies use $E < 10^{-5}$ or lower to be conservative. E-values around 0.01–1 are a "twilight" region that needs other evidence, for example reciprocal searches, profiles or structure.
- **Significance means homology, not identical function.** A significant E-value means that the similarity is very unlikely to arise by chance. The most plausible explanation is common ancestry (1). Homology is a yes/no statement, so a better E-value does not mean "more homologous", and it does not guarantee that the hit has the same function (Chapter 10).

- **Non-significance does not mean non-homology.** Many homologues have diverged too far to be detected by pairwise comparison. Profiles, profile HMMs (Section 1.6) and structure comparison detect many of them.
- **The model can fail.** Low-complexity regions, repeats, coiled coils and transmembrane segments can give spurious significant E-values. So can searches against databases full of near-identical sequences, where one real hit appears thousands of times.

1.4.4 Searching at the scale of billions of sequences

BLAST was designed when databases contained tens of thousands of sequences. Metagenomics now produces billions of protein sequences, and analyses such as annotating every read of a microbiome sample or building multiple alignments for structure prediction need millions of searches. A new generation of tools reaches BLAST-like sensitivity at speeds hundreds to thousands of times higher. They combine better filters with cache-efficient and vectorised (SIMD) implementations on modern hardware.

1.4.4.1 DIAMOND

DIAMOND was written by Benjamin Buchfink and Daniel Huson, first for aligning short metagenomic DNA reads against protein databases (a blastx task) (Buchfink et al. 2014), and later extended to sensitive protein searches at the scale of the whole tree of life (Buchfink et al. 2021). Its main ideas are:

- **A reduced alphabet.** Amino acids are grouped into 11 classes of similar residues, so that seeds can match across conservative substitutions.
- **Spaced seeds.** A seed is defined by a pattern in which some positions must match and others are ignored, for example `111011`. Spaced seeds are more sensitive than contiguous words of the same weight, because hits at different positions of a real alignment are less correlated.
- **Double indexing.** Instead of scanning the database for the words of each query, DIAMOND builds seed tables for *both* the query set and the database, sorts them, and walks through the two lists together. Matches are found in a single linear pass with very good use of the CPU cache. This makes DIAMOND particularly efficient when many queries are searched at once.

Seed hits are then extended by ungapped and gapped alignment much as in BLAST, and E-values are computed with BLAST-style statistics. In its most sensitive modes, DIAMOND reaches the sensitivity of blastp while being roughly 100 times faster or more (Buchfink et al. 2021).

1.4.4.2 MMseqs2

MMseqs2 (Many-against-Many sequence searching), developed by Martin Steinegger and Johannes Söding (Steinegger and Söding 2017), is now one of the most widely used tools for large-scale protein search and clustering. A search proceeds in three stages, each more expensive and more selective than the last.

1. ***k*-mer prefilter.** For each query, MMseqs2 generates all *similar* *k*-mers (k = 6 or 7): all words that score above a threshold against a *k*-mer of the query with the substitution matrix, exactly like BLAST's neighbourhood words but longer. These are looked up in an index of the target database. The key filter is to require **two consecutive *k*-mer matches on the same diagonal**, a generalisation of BLAST's two-hit method. The sensitivity parameter (`-s`) controls how many similar *k*-mers are generated: higher sensitivity means more *k*-mers, more candidate hits and a slower search.

2. **Ungapped alignment.** Candidates that pass the prefilter are scored by a fast vectorised ungapped alignment along the matching diagonal.
3. **Gapped alignment.** The remaining candidates are aligned with a vectorised Smith–Waterman algorithm, and E-values are computed.

Because the stages are separated, MMseqs2 can also run **iterative profile searches**, analogous to PSI-BLAST (Section 1.6): the hits of one iteration are turned into a position-specific scoring profile that is used as the query in the next. In this mode it is more sensitive than PSI-BLAST at a small fraction of the cost (Steinegger and Söding 2017). MMseqs2 also includes tools for taxonomic assignment of metagenomic sequences and for clustering.

1.4.4.3 Clustering huge sequence sets

Many applications need non-redundant databases, in which similar sequences are represented by a single *representative*. Examples are UniRef, which clusters UniProt at 100%, 90% and 50% sequence identity (Suzek et al. 2014), and the large metagenomic databases used for structure prediction. Clustering by all-against-all comparison scales as $O(N^2)$ in the number of sequences, which is impossible for billions of them. **Linclust** (Steinegger and Söding 2018) clusters in time proportional to N:

1. for each sequence, select a small number m of its k-mers, chosen by a hash function so that similar sequences tend to select the same k-mers;
2. group sequences that share a selected k-mer, and pick the longest sequence in each group as its centre;
3. align each sequence only with the centre of its group, and accept it as a member if the alignment meets the identity and coverage criteria.

Each sequence is compared with only a few centres, so the cost grows linearly. Linclust was used to cluster more than a billion metagenomic protein fragments. These clustered databases, searched with MMseqs2, are now used to build the multiple sequence alignments for protein structure prediction. ColabFold, for example, uses an MMseqs2 server to replace the slower HMMER/HHblits searches of the original AlphaFold2 pipeline, making structure prediction tens of times faster (Mirdita et al. 2022) (see Chapter 9).

1.4.5 Searching with structure: Foldseek

Protein structure is conserved much longer than sequence: proteins with less than 20% sequence identity, whose relationship is invisible to sequence search, often still have the same fold. Structure comparison can therefore detect homologues that sequence methods miss. But traditional structural aligners are slow, typically fractions of a second to seconds per pair. DALI aligns two structures by comparing their matrices of intramolecular Cα–Cα distances, so that residues with similar distance patterns to their neighbours are matched (Holm and Sander 1993). TM-align searches for the superposition and residue alignment that maximise the TM-score, a length-normalised measure of structural similarity (Zhang and Skolnick 2005). CE builds the alignment from fragment pairs with similar local geometry. That was acceptable for the PDB, with about 200,000 structures, but not for the more than 200 million predicted structures in the AlphaFold database (Chapter 2).

Foldseek (van Kempen et al. 2023), from the Steinegger and Söding groups, solves this by turning a structure into a *sequence* over a new alphabet, so that the fast sequence-search machinery of MMseqs2 can be reused.

- **The 3Di alphabet.** Each residue is described by the geometry of its interaction with its spatially closest residue: distances and angles between the two backbones and their neighbours. These descriptors are mapped to one of 20 discrete states by a *vector-quantised variational autoencoder* (VQ-VAE), a neural network trained so that the states are maximally conserved between structurally aligned residues of homologous proteins. A protein structure thus becomes a string of 3Di letters, one per residue. Unlike classical structural alphabets, which describe the local *backbone* conformation (such as helix or strand), 3Di describes *tertiary* interactions. These are more informative and better conserved.
- **A 3Di substitution matrix.** As for amino acids, a log-odds substitution matrix for 3Di states was derived from alignments of homologous structures. Foldseek scores alignments with the sum of the 3Di score and an amino-acid score, which improves sensitivity further.
- **MMseqs2 search.** Prefiltering, ungapped and gapped alignment then work exactly as for sequences. Alignments can optionally be refined with TM-align to give global structural superpositions and TM-scores.

Foldseek reduced search times by four to five orders of magnitude, while reaching most of the sensitivity of DALI and TM-align on benchmarks (van Kempen et al. 2023). Searching the entire AlphaFold database with a single structure now takes seconds to minutes. Combined with the clustering methods above, it was used to cluster the 214 million structures of the AlphaFold database into about 2.3 million non-singleton structural clusters. Many of these clusters have no known function, and some represent folds that had never been seen before (Barrio-Hernandez et al. 2023). Structure comparison is discussed further in Chapter 9.

1.4.6 Exact matching: suffix arrays and the Burrows–Wheeler transform

A different problem arises with high-throughput sequencing: mapping hundreds of millions of short reads, each 100–300 bases long and nearly identical to the reference, to a genome of three billion bases. Here the challenge is not finding distant homologues but finding near-exact matches extremely fast. The solution is to *index the reference* once, in a data structure that allows any pattern to be located in time that depends on the length of the pattern rather than of the genome.

1.4.6.1 Suffix trees and suffix arrays

A **suffix tree** of a text is a compressed tree containing all suffixes of the text. Every substring is a path from the root, so a pattern of length p can be found in $O(p)$ time. Suffix trees can be built in linear time, but they need 10–20 bytes per character, far too much for a mammalian genome. A **suffix array**, introduced by Manber and Myers in 1990 (Manber and Myers 1993), stores only the start positions of all suffixes, sorted lexicographically. A pattern is found by binary search in $O(p \log n)$ time. This needs less memory (4–8 bytes per character), but still about 12 GB for the human genome.

1.4.6.2 The Burrows–Wheeler transform

The **Burrows–Wheeler transform** (BWT) was invented by David Wheeler in 1983 and published with Michael Burrows in 1994 as the basis of a text compression algorithm, which is used in `bzip2`. The transform is defined as follows:

1. append a unique end-of-text symbol \$, which sorts before all other characters;
2. write down all rotations of the text;
3. sort the rotations lexicographically;
4. the BWT is the last column L of the sorted matrix.

Because the rows are sorted, the first column F is simply the sorted characters of the text. The rows of the matrix correspond one-to-one to the suffixes of the text, so the order of the rows is given by the suffix array. The BWT has two remarkable properties. First, it is reversible: the original text can be reconstructed from L alone. Second, it tends to group equal characters into runs, because characters followed by the same context end up next to each other. This makes it very compressible.

The key to reversing it, and to searching with it, is the **last-to-first (LF) mapping**. The i-th occurrence of a character c in L and the i-th occurrence of c in F are the *same* character of the text. This is because both sets of occurrences are ordered by the text that follows them. In addition, $L[i]$ is the character that precedes $F[i]$ in the text. Using these two facts, one can walk backwards through the text one character at a time.

1.4.6.3 The FM-index and backward search

Paolo Ferragina and Giovanni Manzini showed in 2000 that the BWT, together with two small auxiliary tables, forms a compressed full-text index: the **FM-index** (Ferragina and Manzini 2000). The tables are:

- $C[c]$: the number of characters in the text that are smaller than c. The rows starting with c form the interval $[C[c], C[c] + n_c)$, where n_c is the number of occurrences of c;
- $\mathrm{Occ}(c, k)$: the number of occurrences of c in the first k positions of L. It is stored at regular checkpoints, so it can be computed in constant time.

A pattern is located by **backward search**. We start with the interval of rows beginning with the last character of the pattern, and extend the match one character to the left at a time, using the LF mapping to compute the new interval. After p steps, the size of the interval is the number of occurrences of the pattern, and the suffix array (sampled to save memory) gives their positions. Counting takes $O(p)$ time, independent of the size of the genome, and the whole index for the human genome fits in a few gigabytes. A small example:

Step 1 — sort the rotations of `ACAACG$`. The rows of the sorted matrix are the suffixes of the text in lexicographic order, so the column *SA* (the start position of each suffix) is the suffix array. F is the first and L the last column; L is the BWT.

Row	Sorted rotation	F	L	SA
0	`$ACAACG`	`$`	`G`	6
1	`AACG$AC`	`A`	`C`	2
2	`ACAACG$`	`A`	`$`	0
3	`ACG$ACA`	`A`	`A`	3
4	`CAACG$A`	`C`	`A`	1
5	`CG$ACAA`	`C`	`A`	4
6	`G$ACAAC`	`G`	`C`	5

The BWT of `ACAACG$` is **`GC$AAAC`**. Note how equal characters tend to cluster in L; in a real genome this makes the BWT highly compressible.

Step 2 — the tables used by the FM-index. $C[c]$ is the number of characters in the text that are smaller than c; $\mathrm{Occ}(c, k)$ is the number of times c occurs in the first k positions of L.

c	`$`	`A`	`C`	`G`
$C[c]$	0	1	4	6

Step 3 — backward search for `AC`. The rows whose rotation starts with a given string always form one contiguous interval $[s, e)$. We start with the interval for the last character of the pattern and extend it one character to the left at a time with $s \leftarrow C[c] + \mathrm{Occ}(c, s)$ and $e \leftarrow C[c] + \mathrm{Occ}(c, e)$.

Step	Character	Suffix matched	Interval $[s, e)$	Rows
1	`C`	`C`	$[4, 6)$	4, 5
2	`A`	`AC`	$[2, 4)$	2, 3

The final interval contains 2 rows, so `AC` occurs 2 times. Looking up these rows in the suffix array gives the positions 0, 3 (0-based) in `ACAACG$`. Each step costs a constant number of table look-ups, so counting takes $O(p)$ time for a pattern of length p, independent of the length of the text.

1.4.6.4 Use in read mapping

The FM-index is the basis of the short-read mappers of the late 2000s, most importantly **Bowtie** (Langmead et al. 2009) and **BWA** (Li and Durbin 2009). Reads are not exact copies of the reference: they contain sequencing errors and genetic variants. These mappers therefore extend backward search with *backtracking*: when the interval becomes empty, they try substituting a different base at a recent position, within a limited budget of mismatches and gaps, and use quality values to prioritise the least confident bases. Later tools (BWA-SW (Li and Durbin 2010) and BWA-MEM) use the FM-index to find maximal exact matches as seeds, which are then extended by dynamic programming. This is the same seed-and-extend idea as BLAST, with exact seeds found in an index of the reference. For long, error-prone reads, minimap2 instead uses *minimizers*: for every window of consecutive k-mers it stores only the smallest k-mer according to some ordering, which gives a compact hash-based index. Hits are chained by dynamic programming before the final alignment (Li 2018). Read mapping, mapping quality and variant calling are discussed in Chapter 5.

1.4.7 Choosing a method

Task	Typical tools	Key idea
Find homologues of one or a few proteins	BLAST (blastp), FASTA/SSEARCH	Neighbourhood words, two hits, X-drop gapped extension; Karlin–Altschul E-values
Search millions of queries or metagenomes	DIAMOND, MMseqs2	Reduced alphabets, spaced or similar k-mers, double indexing, vectorised alignment
Find remote homologues	PSI-BLAST, MMseqs2 profiles, HMMER, HHblits	Profiles and profile HMMs (Section 1.6)
Cluster huge sequence sets	Linclust, MMseqs2, CD-HIT	Compare each sequence only with a few cluster centres
Search large structure databases	Foldseek	3Di structural alphabet with sequence-search (MMseqs2) machinery
Accurate pairwise structural alignment	DALI, TM-align	DALI: compares the intramolecular distance patterns of the two structures; TM-align: superposition and alignment that optimise the TM-score

Task	Typical tools	Key idea
Map reads to a reference genome	Bowtie, BWA, minimap2	Index the reference: FM-index (short reads), minimizers (long reads)
Align mRNAs to a genome	BLAT, minimap2	Genome *k*-mer index held in memory

In all cases, the same trade-off applies. A heuristic is defined by its filter, and every filter that makes a search faster can also make it miss something. Understanding *what* a filter requires, such as two similar 3-mers within 40 residues on one diagonal, tells you *which* alignments can be missed: short ones, ones with many gaps, and ones with no conserved stretch.

1.4.8 From a search hit to an annotation

A list of hits sorted by E-value is not yet a biological conclusion. The step from "this sequence is similar to that one" to "this protein is an X" is where most annotation errors are made (Section 2.2), and it is a favourite topic in oral exams.

Check the query first. The query is itself the result of an experiment and a pipeline: a sample, a sequencing run, an assembly and a gene model. A frameshift, a wrong exon boundary, a truncated open reading frame, a chimeric contig or a contaminant changes what is being aligned. Before searching, it is worth predicting low-complexity regions, transmembrane helices, signal peptides and domain boundaries, and asking whether the sequence is complete.

Read the alignment, not only the E-value. For each hit of interest, look at:

- the bit score and E-value, remembering that the E-value depends on the database searched;
- the percent identity *together with its denominator*. 90% identity over 20 residues says something different from 40% over 600 residues;
- the coverage of *both* the query and the target, and *where* the alignment lies. A tiny E-value over one 80-residue domain says nothing about the other 900 residues of two large proteins;
- whether the alignment is driven by a low-complexity region, a coiled coil, a transmembrane segment or a repeat. Comparing masked with unmasked searches shows how much of the score comes from such regions;
- the domain architecture of the query and the hit (Section 1.9).

The best hit is not the orthologue. The ranking of hits depends on how fast each gene has evolved and on what happens to be in the database. A fast-evolving orthologue can score lower than a conserved paralogue, so the top hit, or even a reciprocal best hit, is only screening evidence. Orthology needs a gene tree (Section 3.4, Chapter 4).

Escalate the method, not the conclusion. If a fast search gives no clear answer, the next step depends on the data: an iterative profile search or a curated profile HMM when a family alignment exists (Section 1.6), a structure search with Foldseek when a reliable (experimental or confidently predicted) structure exists, or an embedding search to suggest candidates (Section 1.10). Each of these produces candidates that must pass the same checks as a BLAST hit (Figure 1.5). Structural similarity can also arise by convergence, and an embedding distance is not a calibrated test of homology.

State a conclusion that matches the evidence. Each step from similarity to homology, from homology to orthology, and from orthology to the same detailed function needs *more* evidence, not a smaller E-value (Chapter 10). Consider a 620-residue bacterial protein whose best hit ($E = 10^{-35}$, 41% identity) is a eukaryotic enzyme, but where the alignment covers only a central domain of about 230 residues,

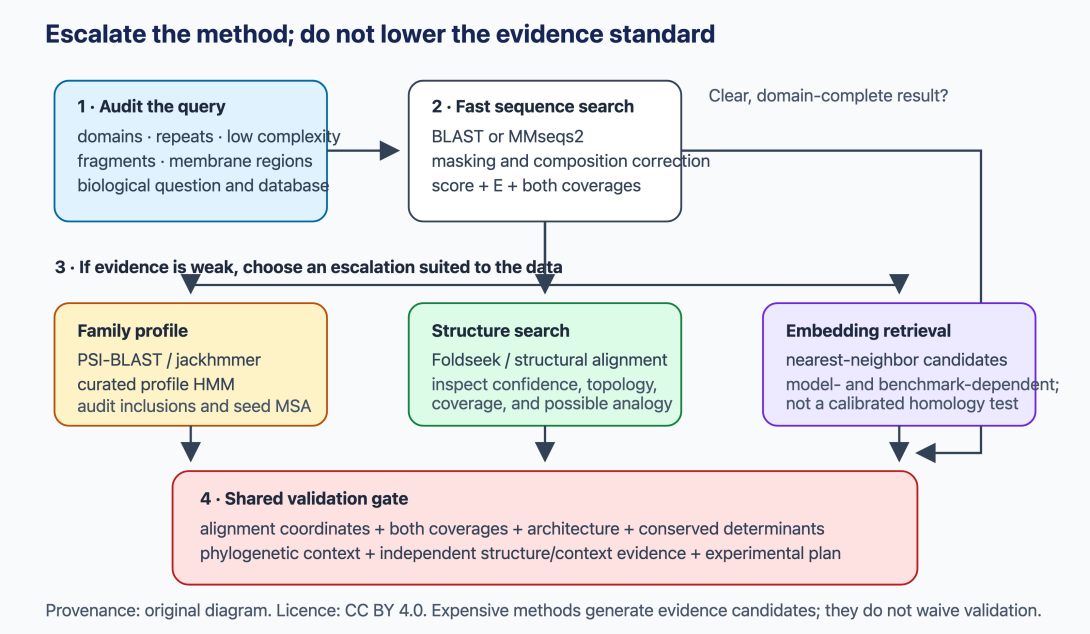

Figure 1.5: A workflow for difficult searches. The query is checked first, and a fast sequence search is run. If the evidence is weak, the search is escalated to profiles, structure or embeddings, depending on the data available. Every candidate, however it was found, then passes the same checks: coordinates and coverage of the alignment, domain architecture, conserved functional residues, phylogenetic context and independent evidence. Figure: Matteo Tadiello, *Modern Bioinformatics: From Foundations to Frontiers* (CC BY 4.0).

while the N-terminus is low-complexity and the C-terminus has a transmembrane helix. A defensible annotation is "contains a domain of family F", and "putative" enzyme only if the catalytic residues are conserved. Copying the name of the top hit to the whole protein is how errors start to propagate through the databases.

Record what was done. The database and its release, the program and its version, and all parameters (matrix, gap costs, masking, E-value and coverage thresholds, and for iterative searches the inclusion threshold of each round) are part of the result. Without them a search cannot be repeated, and its E-values cannot be compared with those of another search.

1.5 Alignment-free sequence comparison

Every method so far starts from an alignment, or at least from seeds that are extended into one. Alignment has two drawbacks for some problems. First, it is computationally expensive for very long sequences such as whole genomes. Second, it assumes that the two sequences are *collinear*: homologous

positions appear in the same order. That is not true for genomes that have undergone rearrangements, recombination or horizontal gene transfer. **Alignment-free** methods compare sequences through summary statistics, most often the sets or frequencies of their short words, without computing an alignment at all (Zielezinski et al. 2017).

1.5.1 Word (k-mer) statistics

The simplest approach represents each sequence by the counts of all its k-mers, the words of length k. There are 4^k possible k-mers for DNA and 20^k for proteins. Two sequences are then compared by a distance between their count vectors, for example the Euclidean distance, or the D_2 statistic, which counts the number of shared k-mer occurrences. Variants correct the counts for what is expected from the composition of shorter words, so that only *unexpected* word frequencies contribute. The choice of k matters. A small k gives words that occur by chance in any sequence. A large k gives words that are almost never shared once the sequences have diverged. Other families of methods use the lengths of the longest common substrings, matches of spaced words (as in the spaced seeds of Section 1.4), or information-theoretic measures such as how well one sequence compresses given the other.

1.5.2 MinHash and Mash

For large-scale comparisons the most successful idea comes from computer science. The similarity of two sets A and B, for example the sets of k-mers of two genomes, can be measured by the **Jaccard index** $J = |A \cap B| / |A \cup B|$. Computing it exactly requires storing all k-mers. **MinHash** (Broder 1997) estimates it from a small *sketch*. Every k-mer is mapped to a number by a hash function, and only the s smallest hash values of each set are kept, typically $s = 1000$. The fraction of shared values among the smallest s values of the union is an unbiased estimate of J. A genome of millions of bases is thus summarised in a few kilobytes, and two sketches are compared in microseconds.

Mash (Ondov et al. 2016) turned this into a tool for genomics. It also converts the Jaccard index into an estimate of the evolutionary distance. Under a simple model in which mutations are independent and each one destroys the k-mers that overlap it, the Mash distance is

$$D = -\frac{1}{k} \ln \frac{2J}{1 + J},$$

which approximates the proportion of differing positions (substitutions per site) for closely related sequences. Mash can compare a new genome against all sequenced genomes in seconds, cluster tens of thousands of genomes, or find which known organisms are present in a metagenome.

The same principle of selecting a small, consistent subset of k-mers appears in other tools of this chapter. Minimizers in minimap2 (Section 1.4) and the k-mer selection in Linclust are both ways of finding candidate matches without looking at every word.

1.5.3 Applications and limitations

Alignment-free methods are now standard where speed matters more than detail:

- **Species delimitation and genome comparison.** The *average nucleotide identity* (ANI) between two prokaryotic genomes, computed rapidly from matching fragments by tools such as FastANI, shows a clear gap at about 95%, which is widely used as an operational species boundary for bacteria and archaea, although exceptions occur (C. Jain et al. 2018).

- **Metagenomic classification.** Kraken (Wood and Salzberg 2014) assigns each read to a taxon by looking up its k-mers in a database that maps every k-mer to the lowest common ancestor of all genomes that contain it. Millions of reads can be classified per minute.
- **Transcript quantification.** Pseudo-alignment in tools such as kallisto determines which transcripts a read is compatible with from shared k-mers, without aligning it base by base (Chapter 7).
- **Phylogenies of many genomes**, where the distances are used as input to distance methods such as neighbour joining (Chapter 4).

These measures answer related but different questions, and they should not be confused. The *Jaccard index* of k-mer sets (estimated by MinHash) measures how much sequence *content* two sets share. It depends on k and is lowered by differences in genome size or gene content even when the shared parts are identical. *ANI* measures the identity of the *shared* part only: it is computed over fragments that can be matched, and is reported together with the fraction of each genome that was matched. The *Mash distance* converts a Jaccard index into an approximate substitution rate, but only under its simple mutation model and only for close relatives. *Homology*, finally, is a statement about common ancestry (1). A low Jaccard index or the absence of shared k-mers is not evidence against homology; it usually means only that the sequences have diverged beyond what exact words can detect.

The limitations follow from the method. Exact k-mer matches disappear quickly as sequences diverge, so alignment-free methods are accurate for closely related sequences, for example within a species or a genus. They are poor at detecting distant homology, where alignment with substitution matrices and profiles is far more sensitive. They also give no alignment, so they cannot say *which* positions correspond or where the differences are. In practice, the two approaches are complementary. Alignment-free methods are used to decide quickly which sequences to compare, and alignment is used to analyse the comparisons that matter.

1.6 Profiles and multiple sequence alignments

Pairwise methods compare one sequence with another. However, homologous sequences rarely come in pairs. A protein usually belongs to a *family* of tens to millions of related sequences, and the family as a whole carries much more information than any single member. When many homologues are aligned, it becomes visible which positions are invariant (often catalytic or structurally essential residues), which tolerate only certain kinds of amino acid (e.g. only hydrophobic ones in a buried strand), and where insertions and deletions are common (usually surface loops). This section covers how such alignments are built, how short conserved signals (motifs) are described and found, and how the information in an alignment is condensed into a *profile* that can search databases far more sensitively than a single sequence. The probabilistic version of the profile, the profile hidden Markov model, is described in the next part of this section.

1.6.1 Multiple sequence alignment

1.6.1.1 What a multiple alignment is

A multiple sequence alignment (MSA) of N sequences $S_1, \dots, S_N$ is obtained by inserting gaps into each sequence so that all of them have the same length $L \geq \max_i |S_i|$. The aligned sequences are written as rows of a matrix, and no column may consist only of gaps. Removing the gaps from a row gives back the original sequence. The intended meaning of a column is that its residues are *homologous*: they descend from the same position in a common ancestral sequence (1). In practice, a column is a hypothesis of homology. It is most reliable in conserved core regions and least reliable in gap-rich, variable loops.

Multiple alignments are among the most widely used objects in bioinformatics. They are the input to phylogenetic tree reconstruction (Chapter 4). They are used to identify conserved functional residues and sequence motifs, to build profiles and profile HMMs for database search (see the rest of this section and Section 1.9), and to define protein families. They are also central to structure prediction: the coevolution signal that made modern contact and structure prediction possible, including AlphaFold, is extracted from deep MSAs (Chapter 9).

1.6.1.2 Scoring a multiple alignment

To speak of a "best" alignment, we need an objective function. The most common one is the **sum-of-pairs (SP) score**. Each column is scored by adding the substitution score for every pair of residues in it, and the alignment score is the sum over columns minus gap penalties:

$$\mathrm{SP} = \sum_{\text{columns } c} \sum_{i<j} s(a_{ic}, a_{jc}),$$

where a_{ic} is the residue (or gap) of sequence i in column c and s is taken from a substitution matrix such as BLOSUM62 (Section 1.3). Gap–gap pairs are usually scored as zero. Equivalently, the SP score is the sum of the scores of all $N(N-1)/2$ pairwise alignments *induced* by the MSA.

The SP score is simple, but it has known weaknesses. It implicitly treats every sequence as equally independent, so a family dominated by many near-identical sequences gives them too much weight. This is why practical methods use *sequence weights* (see below). It also lacks a sound evolutionary interpretation: in a column with N copies of the same residue the score grows as N^2, although the evidence comes from a single ancestral residue that has been conserved. Alternative column scores include **entropy-based scores**, where a column c with residue frequencies $p_{a,c}$ is scored by $H_c = -\sum_a p_{a,c} \log p_{a,c}$ and a good alignment *minimises* the total entropy. There are also tree-based scores that count the substitutions required on a phylogeny. When alignment programs are compared with reference alignments, two further measures are used. The *SP accuracy* is the fraction of correctly aligned residue pairs, and the *total column (TC) score* is the fraction of reference columns that are reproduced exactly.

It is worth stating plainly that there is **no single biologically correct objective function** for a multiple alignment. The true alignment is defined by evolutionary history (which residues descend from the same ancestral position), and that history is not observed. Every practical method therefore optimises a *surrogate*: the SP score (progressive methods such as ClustalW), agreement with a library of pairwise alignments (*consistency*, T-Coffee and the accurate MAFFT modes), expected accuracy under a probabilistic model of alignment (ProbCons, HMM-based aligners), a phylogeny-aware treatment that distinguishes insertions from deletions on a guide tree (PRANK), or agreement with known or predicted structures (structure-aware methods such as 3D-Coffee). These surrogates can disagree, and

the "best" alignment under one need not be the best under another. Benchmarks, which use structural superposition as a proxy for homology, are themselves a further surrogate.

1.6.1.3 Exact alignment is intractable

Dynamic programming (Section 1.3) extends directly from two to N sequences. Instead of a two-dimensional matrix we fill an N-dimensional lattice with one axis per sequence. Each cell can be reached from $2^N - 1$ predecessor cells (every non-empty subset of the sequences advances by one residue). For sequences of length L this costs $O(L^N)$ memory and $O(2^N L^N)$ time. Already three proteins of length 300 need 2.7×10^7 cells; ten proteins of that length would need $\approx 6 \times 10^{24}$.

Two observations made exact methods somewhat more practical. First, Carrillo and Lipman showed in 1988 (Carrillo and Lipman 1988) that the score of each induced pairwise alignment can be bounded using the optimal pairwise alignments. The search can therefore be restricted to the region of the lattice near the intersection of the pairwise optima. The program MSA (Lipman et al. 1989) used this idea to align up to about eight moderately long sequences optimally under the SP score. Second, and more fundamentally, the problem cannot be solved efficiently in general: Wang and Jiang (1994) proved that finding the optimal SP alignment is NP-hard. All widely used MSA programs are therefore *heuristics*. They give good alignments in practice, but there is no guarantee that they find the optimum of any objective function.

1.6.1.4 Progressive alignment

The heuristic behind almost all practical MSA programs is **progressive alignment**, introduced by Feng and Doolittle (1987). The idea is to follow the evolutionary history. Sequences that are closely related can be aligned reliably, so they are aligned first, and the growing alignments are then combined in the order given by an approximate tree. The method has three steps:

1. **Pairwise distances.** All $N(N-1)/2$ pairs are compared, either by full dynamic programming or, for speed, by counting shared short words (k-tuples). The similarity of each pair is converted into a distance.
2. **Guide tree.** A tree is built from the distance matrix with a fast clustering method, typically UPGMA or neighbour joining (Chapter 4). The guide tree is not intended as a phylogeny. It only determines the order in which sequences are joined.
3. **Progressive joining.** Following the guide tree from the leaves to the root, sequences and sub-alignments are aligned to each other: sequence to sequence, sequence to alignment, or alignment to alignment. Aligning two alignments ("profile–profile alignment") is ordinary pairwise dynamic programming in which each "residue" is a column, scored for example by the average substitution score over all residue pairs between the two columns.

Progressive alignment needs only $O(N^2)$ pairwise comparisons plus $N-1$ profile alignments, so it scales to thousands of sequences. Its fundamental weakness is greed. Feng and Doolittle stated it as **"once a gap, always a gap"**: decisions taken early, when two close sequences are aligned, are frozen into the sub-alignment and are never revised when more distant sequences are added. In their method, gaps placed early were replaced by a neutral symbol so that they would not be penalised again. Errors in the early alignments, or in the guide tree, therefore propagate to the final result. This matters most when all sequences are distantly related, because then no reliable early alignments exist.

1.6.1.5 The Clustal family

The Clustal programs, developed by Des Higgins and colleagues, have been the most widely used implementations of progressive alignment, and two Clustal papers are among the most cited scientific papers of all time.

- **Clustal (1988).** The first program (Higgins and Sharp 1988) was written to run on the personal computers of the time. Its name reflects the use of *clustering* (UPGMA) to build the guide tree, computed from fast k-tuple similarity scores. ClustalV (1992) was a rewrite in C. It added profile alignment (aligning an alignment to an alignment) and neighbour-joining trees.
- **ClustalW (1994).** The W stands for *weighting*. Thompson et al. (1994) added three improvements that made progressive alignment much more accurate and that remain standard ideas:

  - *Sequence weighting.* Weights are derived from the branch lengths of the guide tree, so that groups of near-identical sequences are down-weighted and divergent sequences are up-weighted.
  - *Varying substitution matrices.* The choice of matrix depends on the divergence of the sequences being aligned. Closely related sequences are aligned with "hard" matrices (high-identity BLOSUM or PAM matrices), divergent ones with "soft" ones.
  - *Position-specific gap penalties.* Gap-opening penalties are reduced in runs of hydrophilic residues, which usually form surface loops, and at positions where the existing alignment already has gaps. They are increased close to existing gaps, so that gaps cluster in the same places instead of being scattered.

  In addition, the joining of very divergent sequences is delayed until the rest of the alignment has been built. ClustalW uses neighbour joining for the guide tree. Because all pairwise distances are computed, the method is $O(N^2)$ in the number of sequences. ClustalX (1997) added a graphical interface, and Clustal 2 (2007) packaged both.
- **Clustal Omega (2011).** By the 2000s, families with tens or hundreds of thousands of members had become common, and computing all pairwise distances was no longer feasible. Clustal Omega (Sievers et al. 2011) replaced the core of the method:

  - Guide trees are computed with **mBed**. Each sequence is represented by its distances to a small set of "seed" sequences (an embedding in a low-dimensional space). The sequences are clustered (k-means) in that space, and a UPGMA tree is built within clusters. This reduces the cost from $O(N^2)$ to $O(N \log N)$.
  - The progressive joining step uses **HHalign** from the HH-suite. Each sub-alignment is turned into a profile hidden Markov model, and the two HMMs are aligned, which is more sensitive than simple profile–profile scoring.

  As a result, Clustal Omega can align more than 100,000 sequences on a single processor in a few hours, while keeping accuracy comparable to the best methods on small benchmarks. Its authors also stressed that alignment accuracy *decreases* when very many sequences are aligned with most methods, and that big alignments need methods designed for them.

1.6.1.6 Consistency and iterative refinement

Two further ideas address the greediness of progressive alignment.

Consistency. If residue x in sequence A aligns with residue y in sequence C, and y aligns with residue z in B, then the pairwise alignment of A and B should preferably align x with z. T-Coffee (Notredame et al. 2000) uses this transitivity. It first computes a *primary library* of pairwise alignments of all pairs, using both global alignments (from ClustalW) and local ones (from LALIGN). Each aligned residue pair is

weighted by the identity of the alignment it came from. The library is then *extended*: the weight of a pair (x, z) is increased by the support from every third sequence C through which x and z are consistently aligned. Finally, an ordinary progressive alignment is carried out, but using the extended library weights instead of a substitution matrix as the scores. Information from all sequences thus influences every pairwise step, and errors made early are much less likely. The cost is time and memory that grow as $O(N^3 L^2)$, which limits T-Coffee to at most a few hundred sequences. Consistency is also the basis of probabilistic aligners such as ProbCons, and of the most accurate modes of MAFFT.

Iterative refinement. An alignment can be improved after it has been built. A typical refinement step divides the sequences into two groups (for example by deleting one edge of the guide tree), realigns the two sub-alignments to each other, and keeps the result if the objective score improves. **MUSCLE** (Edgar 2004) combines progressive alignment with such refinement in three stages:

1. A *draft progressive* alignment using fast k-mer distances and a UPGMA tree.
2. An *improved progressive* alignment: the tree is rebuilt from the (Kimura-corrected) identities of the draft alignment, and the alignment is recomputed for the parts of the tree that changed.
3. *Refinement* by tree-dependent restricted partitioning: edges of the tree are deleted in turn, the two resulting profiles are realigned, and the change is accepted if the score improves.

MUSCLE scores profile columns with a "log-expectation" function, and it was notable for being both faster and more accurate than ClustalW and T-Coffee on the benchmarks of the time.

MAFFT, first published by Kazutaka Katoh and colleagues in 2002 (Katoh et al. 2002; Katoh and Standley 2013), introduced a different speed-up for the pairwise step. Each amino acid is represented by numerical values of its volume and polarity. The correlation between two sequences at every possible relative offset can then be computed with the **fast Fourier transform (FFT)** in $O(L \log L)$ time. Peaks in this correlation reveal homologous segments, and dynamic programming is restricted to the regions between them. MAFFT offers a range of strategies. FFT-NS-2 is a fast progressive method. FFT-NS-i adds iterative refinement. L-INS-i, G-INS-i and E-INS-i are consistency-based iterative methods using local, global or generalised pairwise alignments, and they are among the most accurate methods available for up to a few hundred sequences. Modern versions also include options for very large data sets and for adding new sequences to an existing alignment.

1.6.1.7 How good are multiple alignments?

Because the true alignment is unknown, MSA methods are evaluated on reference alignments in which the correct homologous positions are believed to be known. The most widely used benchmarks, such as BAliBASE (Thompson et al. 1999), derive the reference from superpositions of known three-dimensional structures, since structurally equivalent residues are the best available proxy for homologous ones. Methods are compared by the SP accuracy and the TC score defined above. Three conclusions have held for decades:

- For sequences above about 30–40% identity, all good methods agree and are essentially correct. Below about 20–25% identity (the "twilight zone",

    1) all methods make many errors, and the differences between them become large.

- Consistency-based and iterative methods are the most accurate on small and medium-sized sets. Clustal Omega and the fast modes of MAFFT are the practical choices for very large sets.
- Alignment errors are concentrated in loops and at the ends of sequences. They can affect downstream analyses, for example phylogenetic trees (Chapter 4), so variable regions are often removed ("trimmed") before tree building. Phylogeny-aware aligners such as PRANK (Löytynoja and Goldman 2008) treat insertions and deletions more realistically than methods that systematically minimise the number of gaps.

1.6.1.8 Alignment uncertainty

A multiple alignment is an estimate, but it is usually used as if it were data. A tree, a conservation score or a profile built from it inherits its errors, and nothing in a single alignment shows which columns are reliable. Different programs, different guide trees and even different input orders can give different alignments of the same sequences, and the differences are concentrated in exactly the divergent regions that matter most for remote homology and deep phylogeny.

One response is to make the uncertainty visible. **MUSCLE5** (Edgar 2022) builds an *ensemble* of alignments by perturbing the guide tree and the scoring parameters. The fraction of ensemble members in which a column, or a whole downstream result such as a branch of a tree, is recovered is a measure of its confidence. Its benchmarks also showed that a single confident-looking alignment can hide considerable uncertainty, and that conclusions which change between equally plausible alignments should not be trusted. Consistency-based aligners such as T-Coffee and probabilistic aligners can likewise report a reliability score for each column.

Trimming (removing unreliable columns) is a related choice. It can reduce noise, but it also removes fast-evolving positions that carry real signal (Section 4.4). Whether and how to trim is therefore a modelling decision, best tested by checking whether the conclusion changes.

1.6.2 Sequence motifs

A **sequence motif** is a short, recurring pattern in DNA, RNA or protein sequences that is assumed to have a biological function. Examples are transcription factor binding sites in DNA, splice signals in RNA, and in proteins, catalytic sites, metal-binding sites, sorting signals and sites of post-translational modification. Motifs are often only 5–20 residues long. They may lie in otherwise unrelated sequences: regulatory sites in promoters are not, in general, homologous to each other. Such sites may have arisen independently many times, because only the binding specificity of the protein recognising them is conserved (1). Short protein motifs such as phosphorylation sites can also arise by convergence.

1.6.2.1 Consensus sequences and patterns

The simplest description of a motif is a **consensus sequence**: the most common residue at each position, for example `TATAAT` for the bacterial promoter −10 box (the "Pribnow box"). A consensus discards the information about how variable each position is. Very few real sites actually match the consensus exactly.

A more expressive description is a **pattern**, written as a regular expression. The PROSITE database, created by Amos Bairoch in 1988 (Bairoch 1991; Sigrist et al. 2012), made such patterns standard for proteins. In PROSITE notation:

- elements are separated by `-`;
- `x` means any residue;
- `[ST]` means S or T;
- `{P}` means any residue except P;
- `x(2,4)` means between two and four arbitrary residues;
- `<` and `>` anchor the pattern to the N- or C-terminus.

Three well-known examples:

Motif	PROSITE pattern
N-glycosylation site	`N-{P}-[ST]-{P}`
ATP/GTP-binding P-loop (Walker A)	`[AG]-x(4)-G-K-[ST]`
C2H2 zinc finger	`C-x(2,4)-C-x(3)-[LIVMFYWC]-x(8)-H-x(3,5)-H`

Patterns are easy to read and to search for. However, matching is binary: a sequence either matches or it does not. Every allowed residue counts the same, however rare it is at that position, and a single unusual residue causes a miss. Short patterns also match many sequences by chance; the N-glycosylation pattern is found in most proteins, while only a minority of the matches are real glycosylation sites. PROSITE therefore documents the expected numbers of true and false matches for each pattern. For divergent families it uses *profiles* (below) instead.

1.6.2.2 Position weight matrices

A **position weight matrix** (PWM), also called a position-specific scoring matrix (PSSM), assigns a score to every residue at every position of a gap-free motif of length w. It is built from a set of aligned sites in three steps:

1. **Counts.** $n_{b,j}$ is the number of sites with residue b at position j (the *position frequency matrix*).
2. **Probabilities.** These are estimated with **pseudocounts**, which prevent residues that are absent from a small training set from getting probability zero (and a score of $-\infty$):

$$p_{b,j} = \frac{n_{b,j} + \alpha_b}{N + \sum_{b'} \alpha_{b'}},$$

   where N is the number of sites and α_b the pseudocount for residue b.
3. **Log-odds weights.** The probabilities are compared with a background model q_b, typically the overall base or amino acid composition:

$$W_{b,j} = \log_2 \frac{p_{b,j}}{q_b}.$$

The score of a candidate site $x_1 \ldots x_w$ is the sum of the weights, $\sum_j W_{x_j,j}$. It is the log-likelihood ratio between "this is an instance of the motif" and "this is background sequence", under the assumption that positions are independent. A score above zero means the site is more likely under the motif model than under the background. In practice, a threshold is set to balance true and false matches, as for the substitution scores of Section 1.3, which are log-odds scores of the same kind. For DNA-binding proteins, the PWM score is also approximately proportional to the binding energy, which gives the model a physical interpretation (Stormo 2000).

Worked example (illustrative data):

Ten aligned sites (illustrative): `TATAAT`, `TATAAT`, `TAAAAT`, `TATACT`, `GATAAT`, `TATGAT`, `TACAAT`, `TATATT`, `AATAAT`, `TATAAG`.

Counts (position frequency matrix):

	1	2	3	4	5	6
A	1	10	1	9	8	0
C	0	0	1	0	1	0
G	1	0	0	1	0	1
T	8	0	8	0	1	9

Log-odds weights $W_{b,j} = \log_2(p_{b,j}/q_b)$ in bits, with a pseudocount of 0.25 per base and a uniform background $q_b = 0.25$:

	1	2	3	4	5	6
A	-1.14	+1.90	-1.14	+1.75	+1.58	-3.46
C	-3.46	-3.46	-1.14	-3.46	-1.14	-3.46
G	-1.14	-3.46	-3.46	-1.14	-3.46	-1.14
T	+1.58	-3.46	+1.58	-3.46	-1.14	+1.75

Information content per position (bits, from the raw frequencies): 1.08, 2.00, 1.08, 1.53, 1.08, 1.53; total 8.3 bits.

Scores of three test sequences (sum of the weights at each position):

Sequence	Score (bits)
`TATAAT (consensus)`	+10.15
`TACGAT`	+4.54
`GCGCGC`	-18.43

The consensus `TATAAT` gets the highest possible score. `TACGAT`, which differs at two positions, still gets a clearly positive score. A GC-rich sequence gets a strongly negative score.

How much a motif stands out from the background is measured by its **information content**. For position j it is the relative entropy (Kullback–Leibler divergence) between the motif and the background distributions:

$$I_j = \sum_b p_{b,j} \log_2 \frac{p_{b,j}}{q_b}.$$

With a uniform background this is $I_j = \log_2 |\mathcal{A}| - H_j$, where H_j is the Shannon entropy of the column and $|\mathcal{A}|$ is the alphabet size. The maximum is therefore 2 bits for DNA and $\log_2 20 \approx 4.3$ bits for proteins. **Sequence logos** (Schneider and Stephens 1990) display this graphically: the height of the stack at each position is I_j, and each letter's height is proportional to its frequency (Figure 1.6). For small samples a correction term is usually subtracted, because entropy estimated from few sequences is biased downwards.

The total information content of a motif also says how often it is expected to occur by chance. A motif with I bits matches a random sequence about once every 2^I positions. The 8.3 bits of the example above therefore correspond to one chance match every few hundred base pairs, which is why real promoters are recognised by combinations of signals, not by the -10 box alone.

PWMs assume that positions contribute independently and that motifs have no insertions or deletions. Models with dependencies between positions exist. Allowing insertions and deletions leads to profile HMMs, described later in this section.

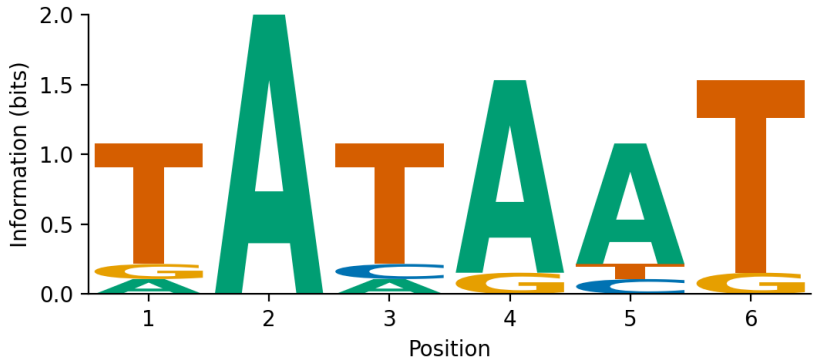

Figure 1.6: Sequence logo of the ten illustrative −10 box sites above. The height of each stack is the information content of the position in bits (uniform background, no small-sample correction). Within a stack, letters are scaled by their frequency.

1.6.2.3 Finding motifs de novo

Often the sites are not known in advance. We may have, for example, a set of promoters of co-regulated genes and want to find the motif that they share. This **motif-finding problem** can be stated as follows. Given N sequences, find one site of width w in each (or in most), such that the sites are as similar to each other as possible, for example as measured by the information content of the resulting PWM. The search space is huge (about L^N combinations of starting positions for sequences of length L), so stochastic and statistical methods are used.

Gibbs sampling (Lawrence et al. 1993) is a Markov chain Monte Carlo method. The algorithm is:

1. Choose a random starting position a_i for a site in each sequence i.
2. Choose one sequence z and remove it.
3. Build a PWM (with pseudocounts) from the current sites in the remaining $N - 1$ sequences.
4. For every possible position x in sequence z, compute the ratio Q_x/P_x. Here Q_x is the probability of the w-long segment starting at x under the PWM, and P_x its probability under the background model.
5. Sample a new site position a_z with probability proportional to Q_x/P_x, i.e. randomly rather than greedily.
6. Repeat from step 2 until the motif stops improving.

Because the new position is sampled rather than chosen as the best, the algorithm can escape from poor local optima, and it gradually converges on a strong shared motif if one exists. Lawrence and colleagues also introduced "phase shift" moves, which shift all sites a few positions left or right, because the sampler otherwise tends to get stuck on a shifted version of the true motif. Gibbs sampling was originally applied to find subtle shared motifs in sets of weakly similar proteins, but it became particularly popular for transcription factor binding sites.

MEME (Multiple EM for Motif Elicitation; Bailey and Elkan (1994)) uses the **expectation–maximisation (EM)** algorithm instead. The data are modelled as a mixture of motif occurrences, described by a PWM, and background sequence. EM alternates two steps:

- **E-step:** for every position in every sequence, compute the posterior probability that a motif occurrence starts there, given the current PWM.
- **M-step:** re-estimate the PWM as a weighted average over all positions, weighted by those probabilities.

Each iteration cannot decrease the likelihood, so EM converges, but only to a local optimum. MEME therefore starts EM from many initial PWMs built from substrings that actually occur in the data, and keeps the best result. After a motif is found, its occurrences are down-weighted and the search is repeated to find further motifs. MEME also made the model of how many sites a sequence contains explicit:

- **OOPS**: exactly one occurrence per sequence;
- **ZOOPS**: zero or one occurrence per sequence;
- **TCM** (two-component mixture): any number of occurrences.

Each motif is reported with an E-value for its significance, and the companion program MAST searches databases with the discovered motifs.

Both approaches have the same basic limitations. They need the motif width in advance (or try several), and they find statistically over-represented patterns, which may include repeats or low-complexity sequence as well as functional sites. A motif found de novo is a hypothesis, which needs support from experiments or from conservation across species.

1.6.3 Profiles: from patterns to position-specific scoring

1.6.3.1 PROSITE patterns versus profiles

The limitations of patterns, together with the observation that the conserved positions of a family are far more informative than the variable ones, led to **profiles**. Gribskov et al. (1987) defined a profile as a position-specific scoring table derived from a multiple alignment. It has one row for each alignment position, with a score for each of the 20 amino acids and a position-specific penalty for opening and extending gaps. A query sequence is aligned to the profile by ordinary dynamic programming, using the profile row instead of a fixed substitution score at each position.

In Gribskov's construction, the score for amino acid b at position j is an average of substitution-matrix scores, weighted by the residues seen in the alignment column: $W_{b,j} = \sum_a f_{a,j}\, s(a,b)$. Here $f_{a,j}$ is the frequency of residue a in column j and s is a substitution matrix such as PAM250. This simple formula already has the crucial property that a residue never seen at a position, but similar to those that are, still scores well. The profile therefore generalises beyond the sequences it was built from.

The differences from a pattern can be summarised as:

	Pattern (regular expression)	Profile
Representation	Allowed residues per position	Score for every residue at every position
Matching	Yes/no	Graded score; significance estimated
Insertions/deletions	Fixed ranges such as `x(2,4)`	Position-specific gap penalties
Rare but allowed residues	Weighted like common ones	Lower score
Best suited for	Short, highly conserved sites	Whole domains and divergent families

PROSITE added such "generalised profiles" in the 1990s to cover families that patterns could not describe (Sigrist et al. 2012). The profile idea is also the basis of PSI-BLAST and, in probabilistic form, of the profile HMMs in Pfam (Section 1.9).

1.6.3.2 Building a good profile

How well a profile works depends on how it is estimated. Three issues recur in all profile methods, including profile HMMs:

- **Sequence weighting.** Sequence databases are very redundant. If a family alignment contains 50 nearly identical sequences from one subfamily and five divergent ones, unweighted frequencies describe that subfamily, not the family. Weighting schemes give less weight to sequences that are similar to many others. A widely used simple scheme is the position-based weighting of Henikoff and Henikoff (Henikoff and Henikoff 1994). In each column with r different residue types, a sequence whose residue occurs s times receives $1/(rs)$, and these contributions are summed over all columns. ClustalW's tree-based weights serve the same purpose.
- **Pseudocounts and priors.** A column with few sequences, or few *effective* sequences after weighting, gives unreliable frequencies. Pseudocounts are added to fill in residues that have not been observed. Better than uniform pseudocounts are ones that use what we know about amino acid substitutions. One option is to derive them from a substitution matrix: residues similar to those observed get more pseudocounts. Another is **Dirichlet mixture priors** (Sjölander et al. 1996), which encode typical kinds of alignment columns ("hydrophobic", "small", "aromatic", ...) learnt from many alignments. The fewer the sequences, the more the estimate relies on the prior.
- **Position-specific gaps.** Insertions and deletions are frequent in loops and rare in the core. Profiles that use lower gap penalties where the training alignment has gaps align new sequences more accurately.

1.6.3.3 A worked PSSM

A small example shows how the pieces fit together (Figure 1.7). Let column i of an alignment contain $n_i(a)$ copies of amino acid a and N_i residues in total (gaps are not counted), and let $p(a)$ be the background frequency of a. With a pseudocount of total weight α, distributed in proportion to the background, the estimated frequency and the score in bits are

$$\hat{q}_i(a) = \frac{n_i(a) + \alpha\, p(a)}{N_i + \alpha}, \qquad w_i(a) = \log_2 \frac{\hat{q}_i(a)}{p(a)}.$$

Take the six aligned sequences `ADKLG`, `ADKLG`, `AEKLG`, `ADQLG`, `-DKLG` and `ADKIG`, and $\alpha = 1$. Column 2 has five D and one E. With $p(\mathrm{D}) = 0.059$, $\hat{q}_2(\mathrm{D}) = (5 + 0.059)/7 = 0.72$ and $w_2(\mathrm{D}) = \log_2(0.72/0.059) = +3.6$ bits. With $p(\mathrm{E}) = 0.058$, E scores +1.4 bits. A residue not seen in the column, such as A, gets $\hat{q}_2(\mathrm{A}) = p(\mathrm{A})/7$ and therefore $\log_2(1/7) = -2.8$ bits: a penalty, but not the $-\infty$ that raw frequencies would give. (With this simple background-weighted pseudocount, every unobserved residue gets the same score; a substitution-matrix or Dirichlet prior would penalise I less than W in a column of L, for example.) The score of an ungapped sequence segment $x_1 \ldots x_L$ is the sum $\sum_i w_i(x_i)$, one cell per column. A positive sum does not by itself mean that the sequence belongs to the family: as for any score, a threshold or an E-value must be calibrated, and gaps need their own model.

1.6.3.4 PSI-BLAST

PSI-BLAST (Position-Specific Iterated BLAST; Altschul et al. (1997)) made profile searching fast, automatic and widely used. It builds a profile from its own search results, without a pre-made family alignment:

1. **Round 1** is an ordinary BLAST search (Section 1.4) of the query against a large database such as UniRef or NCBI nr.

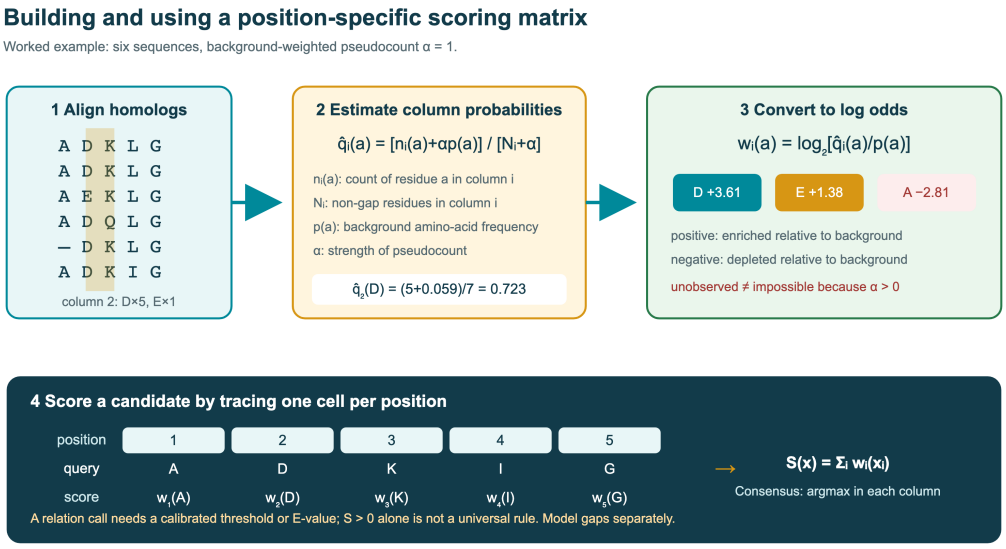

Figure 1.7: Building and using a position-specific scoring matrix for the six-sequence example in the text: (1) count residues in each column of the alignment, (2) estimate column frequencies with background-weighted pseudocounts, (3) convert them to log-odds scores in bits, and (4) score a new sequence by adding one cell per position. Figure: Matteo Tadiello, *Modern Bioinformatics: From Foundations to Frontiers* (CC BY 4.0).

2. All hits with an E-value below an **inclusion threshold** (typically 0.001–0.005) are collected into a multiple alignment, which is anchored on the query (columns where the query has a gap are ignored).
3. A **PSSM** with one column per query position is computed from this alignment. The sequences are weighted to reduce redundancy, and pseudocounts are derived from the BLOSUM62 matrix. The amount of pseudocount decreases as the number of effectively independent sequences grows.
4. The PSSM replaces the query and the substitution matrix in the next search round. BLAST's word seeding, extension and Karlin–Altschul statistics work unchanged with position-specific scores.
5. Steps 2–4 are repeated for a fixed number of iterations, or until no new sequences are found ("convergence").

Each round, the profile represents the family better than the query alone did, so homologues too distant to be found in the first round can be found in later ones. In a benchmark based on structurally classified domains in SCOP, Park et al. (1998) showed that profile methods (PSI-BLAST and the HMM-based SAM-T98) detected about **three times as many** remote homologues as pairwise methods (BLAST, FASTA and Smith–Waterman) at the same error rate. This was one of the clearest demonstrations of the value of family information, and PSI-BLAST profiles became the standard input to secondary structure, contact and fold prediction methods in the 1990s and 2000s (Chapter 9).

The iteration also has a well-known failure mode, **profile corruption** (also called profile drift). If a single unrelated sequence passes the inclusion threshold, perhaps through a low-complexity region, a coiled coil or a promiscuous domain shared with the query, it is included in the profile. In the next round it pulls in its own relatives, and after a few iterations the profile may describe a different family. The E-values of the later rounds are then misleading, because they measure similarity to the corrupted profile, not to the original query. The same problem affects every iterative profile search, including jackhmmer, HHblits and MMseqs2 profile searches.

Corruption can often be recognised by inspecting the rounds rather than only the final list. Warning

signs are a sudden jump in the number of hits from one round to the next; new hits that align only to a short part of the query, such as a single low-complexity segment, coiled coil or repeat; and hits whose annotations belong to a clearly different family. Several things reduce the risk:

- a strict inclusion threshold;
- masking low-complexity regions;
- composition-based statistics, which correct scores for sequences with unusual amino acid composition (Schäffer et al. 2001);
- checking that new hits are plausible;
- limiting the number of iterations.

A second limitation is that PSI-BLAST, like BLAST, uses ad hoc gap penalties and treats the profile as a series of independent columns. The probabilistic framework of hidden Markov models, which models insertions and deletions position by position and calculates significance in a principled way, addresses both of these points. It is the subject of the next part of this section.

1.6.4 Hidden Markov models

Position-specific scoring matrices and PSI-BLAST profiles score each column of a family independently, and they treat insertions and deletions with ad hoc, position-independent gap penalties. Hidden Markov models (HMMs) put the whole idea of a profile on a probabilistic footing. Substitutions, insertions and deletions all become probabilities that can be estimated from data, and an alignment of a sequence to a family becomes a path through a probabilistic model. The same small set of dynamic programming algorithms then gives the best alignment, the total probability of the sequence, and the confidence of every aligned residue. HMMs are the basis of HMMER, Pfam and the HH-suite. They are also used, under other names, for gene finding (Chapter 5) and membrane-protein topology prediction (Chapter 9). They are the most important probabilistic model in sequence bioinformatics. The textbook treatment is Durbin et al. (1998); short introductions are Eddy (2004a) and Rabiner (1989).

1.6.4.1 From Markov chains to hidden Markov models

A **Markov chain** is a sequence of random variables $x_1, x_2, \dots, x_L$ in which the probability of each symbol depends only on the previous one:

$$P(x) = P(x_1) \prod_{i=2}^{L} P(x_i \mid x_{i-1}) = P(x_1) \prod_{i=2}^{L} a_{x_{i-1} x_i}.$$

The transition probabilities a_{st} form a matrix whose rows sum to one. A first-order Markov chain over the four nucleotides can, for example, capture the fact that CG dinucleotides are rare in most of the human genome (the C is often methylated and mutates to T). It can also capture that they are more common in *CpG islands* near promoters. Two such chains, one trained on islands and one on background,

can be used to classify a given stretch of DNA by the log-odds ratio of the two models (Durbin et al. 1998).

Classification of a *given* stretch is not the real problem, however. In a chromosome we do not know where the islands start and end. A **hidden Markov model** solves this by separating what we observe from what we want to infer. An HMM has:

- a set of hidden **states** $k = 1, \dots, N$ (for example "island" and "background", or "exon", "intron" and "intergenic");
- **transition probabilities** $a_{kl} = P(\pi_i = l \mid \pi_{i-1} = k)$ between states, where $\pi = \pi_1 \dots \pi_L$ is the *state path*. The path itself is a Markov chain;
- **emission probabilities** $e_k(b) = P(x_i = b \mid \pi_i = k)$, the probability of observing symbol b when the model is in state k;
- start (and optionally end) probabilities, often written as transitions a_{0k} from a silent begin state 0.

The observed sequence is generated by walking along the state path and emitting one symbol from each state. The joint probability of a sequence x and a path π is simply the product of all transitions and emissions used:

$$P(x, \pi) = a_{0\pi_1} \prod_{i=1}^{L} e_{\pi_i}(x_i)\, a_{\pi_i \pi_{i+1}},$$

with $a_{\pi_L \pi_{L+1}}$ the transition to the end state (or 1 if there is no end state). The model is "hidden" because many different paths can generate the same observed sequence, and in general we only see x.

The standard teaching example, from Durbin et al. (1998), is the **occasionally dishonest casino**. A casino uses a fair die most of the time, but occasionally switches to a loaded die that shows a six half of the time. We observe only the rolls. The hidden states are *Fair* (F) and *Loaded* (L), with emission probabilities $e_F(b) = 1/6$ for all faces, $e_L(6) = 0.5$ and $e_L(b) = 0.1$ for $b = 1, \dots, 5$. The transition probabilities are $a_{FL} = 0.05$ and $a_{LF} = 0.1$. The model is used as a worked example below.

1.6.4.2 History

Hidden Markov models were described by Leonard Baum and colleagues at the Institute for Defense Analyses in Princeton in a series of statistical papers from 1966 to the early 1970s. These included the estimation algorithm now called the **Baum–Welch algorithm**, developed by Baum and Lloyd Welch (Baum et al. 1970). Independently, Andrew Viterbi published in 1967 the dynamic-programming decoding algorithm for convolutional codes in noisy communication channels that now carries his name (Viterbi 1967). The Viterbi algorithm has a history of multiple invention. It is essentially the same recursion that Needleman and Wunsch used for alignment (Section 1.3), and at least seven independent discoveries have been documented.

The first major application was **speech recognition**, from James Baker's work in 1975 and Frederick Jelinek's group at IBM, where the hidden states are phonemes or words and the observations are acoustic features. Lawrence Rabiner's 1989 tutorial (Rabiner 1989) became the standard introduction and brought the methods to a wide audience. In the second half of the 1980s HMMs began to be used to segment DNA, for example by base composition (Churchill 1989). In the early 1990s David Haussler's group in Santa Cruz, with Anders Krogh, introduced **profile HMMs** for protein families (Krogh et al. 1994). Within a few years HMMs were used for gene finding (GENSCAN, GeneMark.hmm; Burge and Karlin (1997); Lukashin and Borodovsky (1998)), transmembrane topology prediction (TMHMM; Krogh et al. (2001)), signal peptides and many other problems. Sean Eddy's 1998 review of profile HMMs (Eddy 1998) and the textbook by Durbin, Eddy, Krogh and Mitchison (Durbin et al. 1998) made them standard bioinformatics tools.

1.6.4.3 The three (four) problems

Rabiner formulated the use of an HMM as three basic problems. Biology adds a fourth, posterior decoding, which turns out to be very important.

Problem	Question	Algorithm
Evaluation	What is the probability $P(x)$ of the sequence, summed over all paths?	Forward
Decoding	Which single path π^* is most probable?	Viterbi
Posterior decoding	What is the probability that residue i was emitted by state k?	Forward–backward
Learning	Which parameters $a_{kl}, e_k(b)$ make the training data most probable?	Baum–Welch (EM), Viterbi training

The naive solution to the first two problems is to enumerate all paths, but there are N^L of them. All the algorithms below avoid this by dynamic programming over the sequence positions. They use the fact that, because of the Markov property, the best (or summed) way to reach state l at position $i+1$ only depends on the values for all states at position i.

1.6.4.3.1 Viterbi: the most probable path

Let $v_k(i)$ be the probability of the most probable path that ends in state k after emitting $x_1 \dots x_i$. Then

$$v_l(i+1) = e_l(x_{i+1}) \max_k \big(v_k(i)\, a_{kl}\big), \qquad v_k(1) = a_{0k}\, e_k(x_1).$$

For each cell we store a *traceback pointer* to the k that gave the maximum. The probability of the best path is $P(x, \pi^*) = \max_k v_k(L) a_{k0}$, and the path itself is recovered by following the pointers back from the best final state. This is exactly the structure of the alignment recursions in Section 1.3: a table filled from left to right, a max over predecessors, and traceback.

1.6.4.3.2 Forward: the probability of the sequence

If we replace the maximum by a sum, we obtain the probability of the sequence summed over all paths. Let $f_k(i) = P(x_1 \dots x_i, \pi_i = k)$. Then

$$f_l(i+1) = e_l(x_{i+1}) \sum_k f_k(i)\, a_{kl}, \qquad P(x) = \sum_k f_k(L)\, a_{k0}.$$

$P(x)$ is what we want when we ask whether a sequence belongs to a family. It does not depend on choosing one particular alignment, and it is the natural quantity to compare with a null model.

1.6.4.3.3 Backward and posterior decoding

The **backward** variable $b_k(i) = P(x_{i+1} \dots x_L \mid \pi_i = k)$ is computed by the same kind of recursion, from the end of the sequence:

$$b_k(i) = \sum_l a_{kl}\, e_l(x_{i+1})\, b_l(i+1), \qquad b_k(L) = a_{k0}.$$

Combining the two gives the **posterior probability** that residue i was emitted by state k, given the whole sequence:

$$P(\pi_i = k \mid x) = \frac{f_k(i)\, b_k(i)}{P(x)}.$$

Posterior decoding chooses, at each position, the state with the highest posterior probability. It can give a better per-residue accuracy than the Viterbi path, but the resulting sequence of states is not guaranteed to be a valid path (it may use a transition with zero probability). More importantly, the posteriors measure how *certain* each part of the result is. In profile HMM alignments they tell which aligned residues are reliable and which are essentially guesses. HMMER reports them under each alignment.

1.6.4.3.4 Complexity and numerical issues

For an HMM with N states and a sequence of length L, all three algorithms need $O(N^2 L)$ time, because every cell considers every predecessor state, and $O(NL)$ memory. If the model has a sparse transition structure, as profile HMMs do, the time is proportional to the number of non-zero transitions, $O(NL)$ for a profile. The Viterbi path can be found in linear memory with the same divide-and-conquer trick used for pairwise alignment (Hirschberg; Myers and Miller (1988)).

The probabilities quickly become smaller than the smallest number a computer can represent: a product of a few hundred probabilities below 0.1 underflows double precision. Viterbi is therefore computed in **log space**, where products become sums and the maximum is unchanged. The forward and backward algorithms need sums of probabilities. They are computed either with **scaling** (normalising the column at each position and keeping track of the scaling factors, as in Rabiner (1989)) or in log space with the identity $\log(e^a + e^b) = \max(a,b) + \log\left(1 + e^{-|a-b|}\right)$, often implemented with a lookup table.

1.6.4.3.5 Learning the parameters

If the state paths of the training sequences are known (for example, annotated genes, or sequences in a curated multiple alignment), the maximum-likelihood parameters are just normalised counts: $a_{kl} = A_{kl} / \sum_{l'} A_{kl'}$ and $e_k(b) = E_k(b) / \sum_{b'} E_k(b')$, where A and E count the transitions and emissions used. Pseudocounts or priors are added to avoid zero probabilities for events that happen not to be observed.

If the paths are unknown, the **Baum–Welch algorithm** estimates the parameters iteratively. It is a special case of the expectation–maximisation (EM) algorithm. In the E step, the forward and backward variables give the *expected* number of times each transition and emission is used, given the current parameters:

$$A_{kl} = \sum_j \frac{1}{P(x^j)} \sum_i f_k^j(i)\, a_{kl}\, e_l(x^j_{i+1})\, b_l^j(i+1), \qquad E_k(b) = \sum_j \frac{1}{P(x^j)} \sum_{i\,:\,x_i^j = b} f_k^j(i)\, b_k^j(i).$$

In the M step, these expected counts replace the observed counts in the formulas above. Each iteration is guaranteed not to decrease the likelihood of the training data, but the algorithm converges to a *local* maximum, so the result depends on the starting point. A cheaper alternative is **Viterbi training**: align all sequences with the current model, count the transitions and emissions on the Viterbi paths, and re-estimate. It optimises the probability of the best paths rather than the full likelihood, and is often used in practice. HMMs can also be trained discriminatively, or with Bayesian priors on the parameters, for example Dirichlet distributions (see below).

1.6.4.4 Worked example: the dishonest casino

To see the algorithms at work, 300 rolls were simulated from the casino model above, and the Viterbi and forward–backward algorithms were then run on the observed rolls only. Figure 1.8 shows the true (hidden) states, the Viterbi path, and the posterior probability that each roll came from the loaded die.

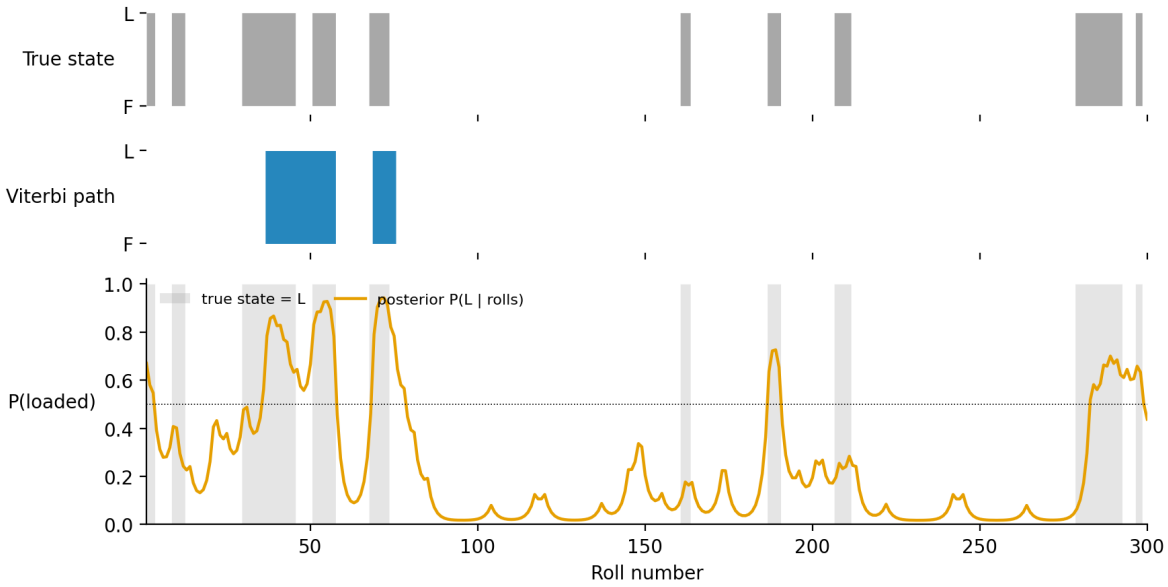

Figure 1.8: The occasionally dishonest casino. Top: the hidden state actually used for each of 300 rolls (grey = loaded). Middle: the Viterbi path decoded from the rolls alone. Bottom: the posterior probability $P(\pi_i = L \mid x)$ from the forward–backward algorithm, with the true loaded segments shaded.

In this run of 300 rolls the loaded die was used for 21% of the rolls and 22% of all rolls were sixes. The Viterbi path assigns the correct state to 83% of the rolls, and thresholding the posterior at 0.5 gives 87%. The log-probability of the single best path is -550.7 nats, while the forward algorithm gives $\log P(x) = -533.4$ nats for the sum over all paths.

Several general lessons can be read from the figure:

- The Viterbi path is a "hard" answer that misses short loaded segments altogether. Switching into the loaded state costs $\log 0.05$, which a few sixes cannot pay for.
- The posterior is a "soft" answer. It rises in every loaded segment, even where Viterbi does not switch, and shows how uncertain the boundaries are.
- The probability of the single best path is much smaller than the total probability of the sequence: many paths contribute. When the question is "does this sequence come from this model?", the forward score is the right one to use, and this is what HMMER3 does.

The first rows of the dynamic-programming tables (natural logarithms) show the difference between taking the maximum (Viterbi, v) and the sum (forward, f) over predecessors. At the first roll both are identical; a six favours the loaded die. After that, the forward values are always at least as large as the Viterbi values.

t	roll	$\log v_F(t)$	$\log v_L(t)$	$\log f_F(t)$	$\log f_L(t)$	$P(L \mid x)$
1	6	-2.48	-1.39	-2.48	-1.39	0.67

1.6.5 Profile hidden Markov models

A **profile HMM** is an HMM whose architecture mirrors a multiple sequence alignment of a protein (or nucleic-acid) family (Krogh et al. 1994; Eddy 1998). Each consensus column of the alignment becomes a node with three states (Figure 1.9):

- a **match state** M_k, which emits a residue with column-specific probabilities $e_{M_k}(a)$. This is the HMM equivalent of one column of a PSSM;
- an **insert state** I_k, which emits residues between columns k and $k+1$, usually with background frequencies. Its self-transition $I_k \to I_k$ allows insertions of any length;
- a **delete state** D_k, a *silent* state that emits nothing and lets the sequence skip column k.

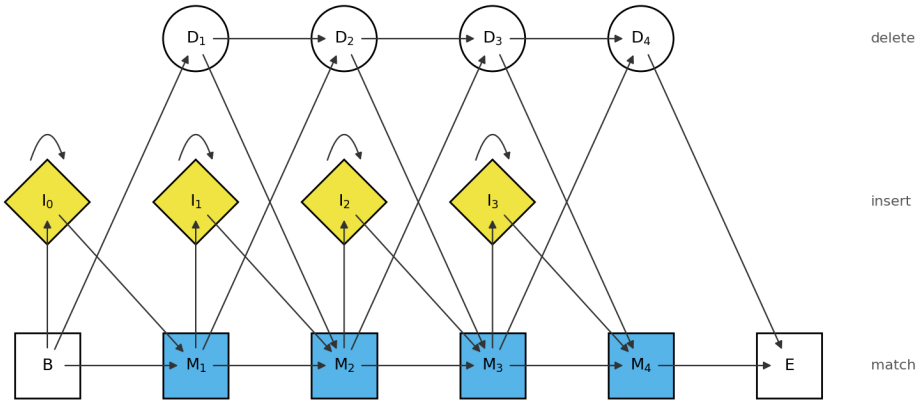

Figure 1.9: The core architecture of a profile HMM with four match states. Squares are match states (and the begin and end states), diamonds are insert states with self-loops, and circles are silent delete states. The transitions shown are those of HMMER's Plan 7 architecture, which has no transitions between insert and delete states.

A path through the model from begin to end is an alignment of the sequence to the family. Matches use M states, insertions relative to the consensus use I states, and deletions use D states. Unlike a PSSM with fixed gap penalties, the transition probabilities differ between positions. A loop region where insertions are common in the family gets a high $M_k \to I_k$ probability (a cheap gap), while a conserved

core gets very expensive gaps. With log-odds scoring this is equivalent to position-specific affine gap penalties: the gap-open cost is $\approx -\log a_{M_k I_k}$ (or $-\log a_{M_k D_{k+1}}$) and the extension cost $\approx -\log a_{I_k I_k}$ (or $-\log a_{D_k D_{k+1}}$).

> **Profiles, PSSMs, profile HMMs and pair HMMs are not the same**
>
> The terms are often used loosely, but they describe different models.
>
> - A **PWM/PSSM** gives a score for every residue at every position. A PWM for a motif has no gaps at all. The PSSM of PSI-BLAST is used with ordinary affine gap penalties that are the same at every position.
> - A **Gribskov profile** (and PROSITE's generalised profiles) adds position-specific gap penalties, but the scores need not come from a probabilistic model.
> - A **profile HMM** models a family with explicit match, insert and delete states. Residue emissions *and* insertion and deletion behaviour are position-specific probabilities, and scores (including the forward score summed over all alignments) have a probabilistic interpretation.
> - A **pair HMM** models the alignment of *two* sequences, with one match and two gap states (Section 1.3). It is the probabilistic version of Gotoh's algorithm and contains no family information.

1.6.5.1 Architecture: from Krogh's model to Plan 7

The model of Krogh et al. (1994) had nine transitions per node, including transitions between insert and delete states. HMMER2 and HMMER3 use the simpler **Plan 7** architecture, with seven transitions per node: $M \to M$, $M \to I$, $M \to D$, $I \to M$, $I \to I$, $D \to M$ and $D \to D$. Removing $I \leftrightarrow D$ transitions costs little, since an insertion directly followed by a deletion is rarely the best explanation of an alignment, and simplifies the algorithms.

Plan 7 also adds special states around the core model to control *how* a sequence may align to it:

- **N** and **C** states emit unaligned flanking sequence before and after the match to the model (with background composition);
- **B** and **E** are silent begin and end states of the core;
- a **J** ("joining") state allows the model to be used several times in one sequence. This is needed for proteins that contain several copies of the same domain.

Through the transitions out of B and into E, the same model can be used in different **alignment modes**. *Global* (with respect to the model) alignment requires the whole family model to be matched, from M_1 to M_K. *Local* alignment allows entry and exit at any match state, so that only a fragment of the model needs to be present. Local alignment with respect to both the model and the sequence corresponds to Smith–Waterman. Global with respect to the model but local with respect to the sequence is often called **glocal**. The N, C and J states make it *multi-hit* or *uni-hit*. HMMER3 searches use local (multi-hit) alignment by default, and the statistics for its forward scores are worked out for that mode.

1.6.5.2 Building a profile HMM from a multiple alignment

A profile HMM is usually estimated from a multiple sequence alignment (for example a Pfam seed alignment; Section 1.9) in a few steps. In HMMER this is done by `hmmbuild`.

1. **Choosing match columns.** Columns in which a sufficient fraction of sequences have a residue (by default at least half, after weighting) become match states. The remaining columns are treated as insertions.

2. **Counting.** With the columns assigned, the state path of every sequence is known, so emissions and transitions can be counted directly. No Baum–Welch is needed.
3. **Sequence weighting.** Alignments are biased: they often contain many near-identical sequences from well-studied organisms. Weighting schemes down-weight redundant sequences, for example position-based weights that give more weight to sequences with rare residues in a column. HMMER3 also reduces the *effective number of sequences* so that the model has a target information content. This stops a model built from thousands of sequences from becoming too specific to detect distant members.
4. **Priors.** Counts from a column with only a handful of sequences are poor estimates of the residue distribution of the whole family. They are combined with prior knowledge in the form of a **Dirichlet mixture prior**. Its components describe the typical kinds of alignment column (hydrophobic, aromatic, small, charged, conserved glycine, and so on). The posterior mean estimate of the emission probabilities is then $e_{M_k}(a) = (c_{ka} + \alpha_a) / \sum_{a'} (c_{ka'} + \alpha_{a'})$ for a single Dirichlet component with parameters α. With a mixture, each component is weighted by how well it explains the observed counts. This is a principled replacement for the pseudocounts of PSI-BLAST.

Profile HMMs can also be trained from *unaligned* sequences with Baum–Welch, which simultaneously produces a multiple alignment (Krogh et al. 1994). This was demonstrated on globins and kinases. In practice, alignment programs (Section 1.6) followed by HMM estimation work better, because Baum–Welch easily gets stuck in poor local optima.

1.6.5.3 Scoring and statistics

To decide whether a sequence belongs to a family, its probability under the profile HMM is compared with its probability under a **null model** R, usually a simple model that emits residues independently with background frequencies q_a (with a geometric length distribution). The score is the log-odds ratio, reported in **bits** (logarithm base 2):

$$S = \log_2 \frac{P(x \mid \text{HMM})}{P(x \mid R)}.$$

With the Viterbi path instead of the sum, this reduces to a sum of position-specific log-odds scores, $\log_2 \left(e_{M_k}(a)/q_a\right)$ for match emissions plus log transition probabilities, just like a PSSM with position-specific gap penalties. Because real sequences often have biased composition (low-complexity regions, transmembrane segments), HMMER also applies a second null model ("null2") that corrects scores for composition bias.

A bit score must be converted into a measure of significance (see Section 1.4 for the general theory). Viterbi scores of local alignments of random sequences follow a Gumbel (extreme-value) distribution, as for BLAST. Eddy showed that a probabilistic local alignment model has a fixed slope parameter $\lambda = \log 2$ when scores are in bits, both for Viterbi scores (Gumbel) and for forward scores (whose high-scoring tail is exponential) (Eddy 2008). Only the location parameter has to be estimated, which `hmmbuild` does with a short simulation. HMMER2 had needed a separate, slow calibration step (`hmmcalibrate`). This made it possible for HMMER3 to report E-values for **forward scores**. Summing over all alignments is more sensitive than using the single best one, because the alignment of a remote homologue is often uncertain. The E-value is, as in BLAST, the number of hits with at least this score expected by chance in a search of a database of this size.

1.6.5.4 HMMER and HMMER3

HMMER, written by Sean Eddy, is the standard implementation of profile HMMs. It is the engine behind Pfam, InterPro and many other family databases. HMMER1 appeared in the mid-1990s, and HMMER2 (1998) introduced Plan 7 and local alignment. Its main drawback was speed: a profile HMM search was 100–1000 times slower than BLAST, which limited it to searching the relatively small family databases. An independent profile HMM package, SAM (Sequence Alignment and Modeling system), was developed in parallel by the Santa Cruz group.

HMMER3 (Eddy 2011), a complete rewrite released in 2010, made profile HMM searches about as fast as BLAST without losing sensitivity. It uses a pipeline of increasingly expensive filters. Each target sequence must pass a score threshold, expressed as a P-value, to continue to the next stage:

1. **MSV filter** ("multiple segment Viterbi"). This is an ungapped, local, multi-hit alignment of the model to the sequence. It finds one or more high-scoring ungapped segments, similar in spirit to BLAST's ungapped extension. By default only about 2% of sequences ($P < 0.02$) pass.
2. **Viterbi filter**. This is a full gapped Viterbi alignment, computed with reduced numerical precision. About 0.1% of sequences ($P < 10^{-3}$) pass.
3. **Forward filter**. The full forward score in floating point, passed at $P < 10^{-5}$.
4. **Domain definition and alignment**. For the surviving sequences, forward–backward is used to compute posterior probabilities. From these HMMER identifies the individual domain hits and their boundaries, computes per-domain scores, and produces *maximum expected accuracy* alignments annotated with posterior probabilities.

The filters are fast because they are implemented with **SIMD vector instructions**. These process 16 one-byte scores (MSV) or 8 two-byte scores (Viterbi) in one instruction, using Farrar's "striped" layout of the dynamic-programming matrix, originally developed for Smith–Waterman (Farrar 2006). Because the early filters only need to be accurate enough to reject non-homologues, they can use reduced precision. The expensive full computation is done only for the small fraction of sequences that might be true hits.

The HMMER package contains programs for different search directions:

- `hmmbuild` builds a profile from an alignment;
- `hmmsearch` searches a profile against a sequence database;
- `hmmscan` searches a sequence against a profile database, for example annotating a protein with Pfam domains;
- `phmmer` searches a single sequence against a sequence database, using a profile built from the sequence and a substitution matrix;
- **`jackhmmer`** does iterative searches, like PSI-BLAST: each round builds a new profile HMM from the significant hits of the previous round. It was one of the programs used to build multiple alignments for AlphaFold2 (Jumper, Evans, Pritzel, Green, Figurnov, Ronneberger, Tunyasuvunakool, Bates, Žídek, Potapenko, Bridgland, Meyer, Kohl, Ballard, Cowie, Romera-Paredes, Nikolov, Jain, Adler, Back, Petersen, Reiman, Clancy, Zielinski, Steinegger, Pacholska, Berghammer, Bodenstein, et al. 2021);
- `nhmmer` and `nhmmscan` search DNA and RNA;
- `hmmalign` aligns many sequences to a profile, which is how large alignments (such as Pfam full alignments) are built from a small seed.

1.6.5.5 Sequence and domain scores

HMMER output has two levels, which are often confused. The **per-sequence** score and E-value measure the evidence that a whole target sequence contains the family, summed over all its matches. The

per-domain scores measure each individual match. The two can disagree. A protein with several weak copies of a repeat can be significant as a sequence although no single copy is; a multidomain protein can have one strong domain and a weak, doubtful second hit.

Each domain hit has two E-values. The **independent E-value** treats the domain as if it were the only hit and uses the whole database as the search space. The **conditional E-value** asks how significant the domain is *given* that the sequence has already been accepted as a member, and uses only the small number of sequences that passed. The conditional E-value is therefore much smaller and is meant for deciding whether additional, weaker domains in an accepted sequence are real; it is not a measure of database-wide significance. A report should say which statistic and which threshold were used.

Both HMMER and PSI-BLAST also separate a **reporting threshold** (which hits are shown) from an **inclusion threshold** (which hits count as members, and in iterative searches are used to build the next model). Changing the first only changes the output; changing the second changes the next profile, which is how profile drift begins.

1.6.5.6 Profile–profile comparison: the HH-suite

A profile HMM is more sensitive than a single sequence because it knows which positions are conserved and where gaps are likely. The logical next step is to represent *both* the query and the database entries as profile HMMs and align the two models. Johannes Söding's **HHsearch** (Söding 2004) does this. It aligns two profile HMMs by a Viterbi-like dynamic programming over pairs of states. The score for aligning column i of the query with column j of the template is the log of the probability that the two match states emit the same residue (their *co-emission* probability), relative to the background:

$$S_{aa}(q_i, t_j) = \log \sum_a \frac{q_i(a)\, t_j(a)}{f(a)},$$

where $q_i(a)$ and $t_j(a)$ are the emission probabilities and $f(a)$ the background frequencies. Optionally, a score for agreement between predicted and observed secondary structure is added. HHsearch, and the HHpred server built on it (Soding et al. 2005), became the most sensitive methods for detecting remote homologues of known structure, and HHpred-based servers performed among the best template-based modelling methods in several CASP experiments.

HHblits (Remmert et al. 2011) made the approach iterative and fast enough to search the whole sequence space. The database is first clustered (for example UniProt into clusters at about 20–30% identity: uniprot20, later Uniclust30 (Mirdita et al. 2016), and the metagenomic BFD). Each cluster is represented by a profile HMM built from its alignment. HHblits then searches this HMM database with a query HMM in a PSI-BLAST-like iterative way. Each round adds the sequences of the significant clusters to the query alignment. A two-stage **prefilter**, with fast ungapped and then gapped comparisons of discretised profile columns, reduces the tens of millions of database HMMs to a few thousand before the expensive HMM–HMM alignment. HHblits builds multiple alignments that are both deeper and more accurate than those from PSI-BLAST, in a fraction of the time. **HH-suite3** (Steinegger et al. 2019) vectorised the HMM–HMM Viterbi and forward algorithms with SIMD instructions, much as HMMER3 did for sequence–profile comparison.

HH-suite tools are central to protein structure prediction (Chapter 9):

- HHsearch against a database of PDB-derived profiles (PDB70) finds templates for homology modelling;

- HHblits against Uniclust30 and BFD was used, together with jackhmmer, to construct the multiple sequence alignments that are the main input of AlphaFold2 (Jumper, Evans, Pritzel, Green, Figurnov, Ronneberger, Tunyasuvunakool, Bates, Žídek, Potapenko, Bridgland, Meyer, Kohl, Ballard, Cowie, Romera-Paredes, Nikolov, Jain, Adler, Back, Petersen, Reiman, Clancy, Zielinski, Steinegger, Pacholska, Berghammer, Bodenstein, et al. 2021).

The deep, accurate alignments needed for coevolution analysis and deep learning are therefore a direct product of profile HMM methods. Today, much of this work is done with faster MMseqs2-based pipelines (Section 1.4).

1.6.5.7 How much do profiles gain?

Benchmarks on structurally classified proteins, where homology can be established from structure even when sequence similarity is undetectable, give a consistent picture. In a classic comparison, Park et al. (1998) showed that methods using multiple sequences (PSI-BLAST and the HMM program SAM-T98) detected about three times as many remote homologues as pairwise methods at the same error rate. Profile–profile methods add another substantial gain over sequence–profile methods (Söding 2004). The resulting ordering is

$$\text{sequence–sequence} \;<\; \text{sequence–profile} \;<\; \text{profile–profile}.$$

The gain comes from more information on both sides, not from the HMM formalism alone. A PSSM built from a good alignment can come close to a profile HMM. The HMM's advantages are position-specific gap probabilities, principled priors, the forward score and calibrated statistics.

1.6.5.8 Limitations

- **Independence of positions.** A profile HMM assumes that columns evolve independently given the path. Correlations between positions, such as compensating mutations of residues in contact, are invisible to it. Models that capture them, such as Potts models and direct-coupling analysis, are the basis of coevolution-based contact prediction (Chapter 9). Protein language models (Section 1.10) learn such dependencies implicitly.
- **Simple length distributions.** Self-loops give geometric distributions of insertion lengths, and a first-order Markov chain has no memory beyond the previous state. Gene finders use *generalised* HMMs with explicit length distributions for exons for this reason (Chapter 5).
- **Dependence on the alignment.** A profile HMM is only as good as the multiple alignment it is built from. Misaligned regions or contaminating non-homologous sequences degrade it.
- **Profile drift.** In iterative searches (jackhmmer, HHblits, PSI-BLAST), a single false positive included in one round can pull the profile towards an unrelated family. The search then reports many confident but wrong hits. Inclusion thresholds should therefore be conservative, and hits near the threshold should be checked (see the warning signs listed under PSI-BLAST above).
- **Local optima in training.** Baum–Welch finds local maxima only, which is why profiles are usually estimated from fixed alignments.

Questions to think about

- Why is the forward score a better measure of homology than the Viterbi score for remote homologues, and why did it take until HMMER3 to use it in database searches?
- How do the transition probabilities of a profile HMM relate to the gap penalties of Smith–Waterman? What can a profile HMM express that affine gap penalties cannot?

- In what sense is a PSSM a special case of a profile HMM?
- Why does an iterative search (PSI-BLAST, jackhmmer, HHblits) find more homologues than a single search, and what can go wrong?
- Why is profile–profile comparison more sensitive than sequence–profile comparison?

1.7 RNA homology search

The methods discussed so far work well for proteins, and for DNA that is very similar. Many genes, however, do not code for proteins. Their products are *functional* non-coding RNAs (ncRNAs). Examples are transfer and ribosomal RNAs, the RNA components of RNase P and the signal recognition particle, small nuclear and small nucleolar RNAs, microRNA precursors, riboswitches and many regulatory RNAs in bacteria and viruses. These molecules are among the oldest in the cell: ribosomal RNA is conserved across all of life and was the basis of the three-domain tree (Chapter 4). Yet ncRNA genes are notoriously hard to find by sequence similarity. This section explains why, and how the problem was largely overcome by extending profile HMMs (Section 1.6) to models that also describe RNA secondary structure.

1.7.1 Why RNA is different

The function of most ncRNAs depends on their *structure*, and the structure is formed largely by base pairing within the molecule. Complementary segments pair to form double-helical **stems**, connected by single-stranded **hairpin loops**, **internal loops**, **bulges** and **multibranch loops**. Besides the Watson–Crick pairs G–C and A–U, the **G–U wobble pair** is common. The set of base pairs is the molecule's **secondary structure**. It is usually written in *dot-bracket* notation, where matching brackets mark paired bases and dots mark unpaired ones, for example `((((...))))` for a simple hairpin.

Three properties make RNA homology search harder than protein search:

- **In structured RNAs, structure is conserved better than sequence.** In RNAs whose function depends on a conserved fold (tRNAs, rRNAs, RNase P RNA, riboswitches and many other structured ncRNAs), selection acts largely on the base pairs, not on the individual bases. A G–C pair can change to A–U, C–G or G–U with little effect on the structure. Such **compensatory** (or *covarying*) mutations change two positions of the sequence at once, while the structure stays the same. Two homologous RNAs can therefore share the same fold with very low sequence identity. A sequence-only method sees two mismatches where the evolutionary signal is in fact a conserved base pair. This is not a property of all RNA genes. Where function depends on sequence motifs, for example the seed region of a microRNA or a protein-binding site, sequence can be the more conserved feature, and some ncRNAs conserve neither (see *Limitations* below).
- **A small alphabet.** With four nucleotides, a random position matches about a quarter of the time (1). Short ncRNAs of 70–300 nucleotides therefore give little statistical signal in a pairwise comparison.

- **Long-range dependencies.** The two halves of a stem can be hundreds of nucleotides apart in the sequence. A profile HMM treats positions as independent given the state path, so it cannot represent the fact that position i must be complementary to position j.

For close homologues, sequence-based tools work well enough: BLASTN, or profile HMMs for DNA such as nhmmer (Wheeler and Eddy 2013). For distant homologues, the structure has to be part of the model.

1.7.2 Predicting RNA secondary structure

Structure-aware search builds on algorithms for RNA folding, which are themselves dynamic programming (Section 1.3). The key simplification is that most base pairs in a secondary structure are **nested**: if i pairs with j and k pairs with l, with $i < k$, then either k and l both lie between i and j, or both lie outside. Nested structures can be decomposed recursively, because the pair (i, j) splits the sequence into an inside part and an outside part that do not interact. Structures that violate this rule are called **pseudoknots**. They occur in real RNAs, but they are usually left out of the models because they make the algorithms much more expensive.

- **Nussinov's algorithm** (Nussinov and Jacobson 1980) finds the structure with the maximum number of base pairs. The best structure of the subsequence $x_i \dots x_j$ is computed from the best structures of shorter subsequences: i is unpaired, j is unpaired, i pairs with j, or the subsequence splits into two independent parts at some k. Filling the table takes $O(L^3)$ time and $O(L^2)$ memory for a sequence of length L.
- **Minimum free energy (MFE) folding** (Zuker and Stiegler 1981) replaces "count the pairs" with a thermodynamic model. Most of the stability of a stem comes from *stacking* of adjacent base pairs, and loops cost energy depending on their type and size. The parameters (*nearest-neighbour* energies) are measured experimentally. The recursion has the same structure and the same $O(L^3)$ complexity. This is the approach of programs such as mfold and the ViennaRNA package (`RNAfold`). A refinement computes the partition function, and from it the probability of every possible base pair, instead of a single optimal structure.

Single-sequence prediction is far from perfect. Many structures have similar energies, the energy parameters are approximate, and in the cell proteins and other RNAs influence the fold. Only a minority of predicted structures are correct in every pair, especially for long RNAs.

1.7.3 Comparative analysis: covariation

The most reliable evidence for an RNA structure comes from evolution. If an alignment of homologous RNAs shows that positions i and j always form a Watson–Crick or G–U pair, even though both positions vary, they are almost certainly paired. This **comparative** approach was used to determine the secondary structures of ribosomal RNAs and other large RNAs long before their crystal structures were known, and it proved remarkably accurate. Covariation can be measured with *mutual information* between alignment columns, or combined with folding energies to predict a consensus structure for the whole alignment, as in RNAalifold (Hofacker et al. 2002). It is the RNA counterpart of the coevolution analysis used for protein contact prediction (Chapter 9).

Covariation is only evidence if it exceeds what is expected from the phylogeny of the sequences alone. Closely related sequences share many substitutions simply by descent. **R-scape** (Rivas et al. 2016) tests whether the covariation of each proposed pair is statistically significant, given the phylogeny and the amount of variation in the alignment. Applied to published structures, it confirmed the pairs of well-established RNAs such as tRNA and rRNA. However, it found no significant support for the

conserved structures proposed for several long non-coding RNAs. This is a useful reminder that a predicted structure, even in an alignment, is a hypothesis.

A harder problem is that structural alignment and structure prediction depend on each other. A correct structure requires a correct alignment, and for divergent RNAs a correct alignment requires knowing the structure. Sankoff (1985) gave a dynamic-programming algorithm that solves both simultaneously, folding and aligning two sequences at once. Its cost, $O(L^6)$ time and $O(L^4)$ memory for two sequences, makes it impractical in its full form. Tools such as LocARNA (Will et al. 2007) use restricted versions that work with base-pair probabilities and are fast enough to cluster thousands of ncRNA candidates into families.

1.7.4 From HMMs to stochastic context-free grammars

The step from profile HMMs to structure-aware models is easiest to see in the language of formal grammars. A **grammar** is a set of production rules that generate strings. In the Chomsky hierarchy, the simplest class, *regular grammars*, can only generate a string from left to right, with each step depending on the current state. HMMs are probabilistic regular grammars. **Context-free grammars** allow rules that emit symbols at both ends of a substring at once. For example,

$$S \to \mathtt{a}\,S\,\mathtt{u} \mid \mathtt{g}\,S\,\mathtt{c} \mid \ldots \mid \varepsilon$$

generates nested complementary pairs, which is exactly the structure of an RNA stem. A **stochastic context-free grammar** (SCFG) attaches a probability to every rule. A *parse* of a sequence, the series of rule applications that generates it, then corresponds to a secondary structure, and its probability is the product of the rule probabilities.

The algorithms for SCFGs mirror those for HMMs (Section 1.6):

HMM	SCFG	Purpose
Viterbi	CYK (Cocke–Younger–Kasami)	most probable parse, i.e. structure or structural alignment
Forward	Inside	total probability of the sequence
Forward–backward	Inside–outside	posterior probabilities; training by EM

The price of modelling pairs is complexity. Where an HMM fills a table indexed by sequence position, an SCFG fills a table indexed by *subsequences* (i, j). For a fixed grammar, the time is $O(L^3)$ instead of $O(L)$.

1.7.5 Covariance models

A **covariance model** (CM) is to an RNA family what a profile HMM is to a protein family. It is a profile SCFG built from a multiple alignment that is annotated with the family's consensus secondary structure (Eddy and Durbin 1994). The consensus structure is converted into a tree of **nodes**. There are nodes for base pairs, for unpaired positions on the left or right, and *bifurcation* nodes where the structure branches into two stems, as in a multibranch loop. Each node is expanded into states, much like the match, insert and delete states of a profile HMM:

- a **pair state** emits two nucleotides at once, with 16 probabilities for the 16 possible pairs. This is where covariation is captured: a family in which a position pair is G–C in some members and A–U in others gives high probability to both pairs, and low probability to mismatches such as G–A, even though each position on its own is variable;
- states for single-stranded positions emit one nucleotide;
- insert and delete states allow insertions and deletions relative to the consensus, with position-specific probabilities.

Parameters are estimated from the alignment with sequence weighting and Dirichlet priors, as for profile HMMs (Section 1.6). Sequences are scored by log-odds against a null model. Searching a genome means aligning the model to every window of the sequence. This scales roughly as the cube of the window length for every position of the genome, which made the first CM searches extremely slow.

1.7.6 Infernal

Infernal ("INFERence of RNA ALignment"), developed by Eric Nawrocki and Sean Eddy, is the standard implementation of covariance models. It plays the same role for RNA as HMMER does for proteins. The main problem was speed, and it was addressed in steps:

- **Banded dynamic programming.** *Query-dependent banding* precomputes, for each state of the model, the range of subsequence lengths it can plausibly generate, and restricts the CYK and inside computations to these bands (Nawrocki et al. 2009). Bands can also be derived from a profile HMM alignment of the same sequence.
- **HMM filters.** Infernal 1.1 (Nawrocki and Eddy 2013) adopted the filter pipeline of HMMER3 (Section 1.6). A profile HMM built from the same family first removes almost all of the genome using the fast MSV, Viterbi and forward filters. The full CM, with its much higher sensitivity, is only run on the remaining candidate regions. This made searches about 100 times faster than in Infernal 1.0.
- **Statistics.** As in HMMER, scores are reported in bits with E-values calibrated on random sequences. Local alignment modes allow hits that cover only part of the model, including *truncated* hits at the ends of sequencing reads or contigs.

With these improvements, searching a whole bacterial genome for all known RNA families, or a CM against large sequence databases, became routine.

1.7.7 Rfam

Rfam is the database of RNA families, designed explicitly as the RNA counterpart of Pfam (Section 1.9). It was started in 2003 at the Sanger Institute, by Sam Griffiths-Jones, Alex Bateman, Sean Eddy and colleagues (Griffiths-Jones et al. 2003), and is now maintained at EMBL-EBI (Kalvari et al. 2020; Ontiveros-Palacios et al. 2024). Each family has:

1. a curated **seed alignment** of representative sequences, annotated with the consensus secondary structure (in Stockholm format);
2. a **covariance model** built from the seed with Infernal;
3. a **full alignment** of all sequences in the database that score above the family's manually chosen gathering threshold.

The same design as Pfam means that only the seed has to be curated, while the full alignments are regenerated automatically. Related families are grouped into clans. Like Pfam, Rfam links its family descriptions to Wikipedia, and many Wikipedia articles on RNA families were written in this collaboration. The database has grown from 25 families in the first release to several thousand today. Rfam 13

reorganised the database around complete reference genomes, and recent releases have added many families from viruses, metagenomes and microRNAs. Until release 12, the slowness of CMs meant that candidates were first found by BLAST, but Infernal 1.1 made this filter unnecessary.

Rfam is used to annotate ncRNA genes in newly sequenced genomes, much as Pfam and InterPro are used for proteins. Its main difficulty is the opposite of Pfam's. Eukaryotic genomes contain many *pseudogenes* and repeats derived from ncRNAs, for example from tRNAs and small nuclear RNAs, which match the models well but are not functional genes. Separating these from the real genes requires additional evidence. Introns, which occur in some ncRNA genes, are also not described by the models.

1.7.8 Specialised tools: tRNAs

For the best-studied RNA families, specialised programs combine CMs with extra knowledge. **tRNAscan-SE** (Lowe and Eddy 1997; Chan et al. 2021) finds tRNA genes in genomes by first using fast filters, and then scoring the candidates with covariance models of the tRNA cloverleaf. The cloverleaf, with its acceptor stem, D arm, anticodon arm and T arm, is the classic example of a structure that is much better conserved than its sequence. tRNAscan-SE also identifies the anticodon and hence the amino acid specificity, and flags probable pseudogenes. It is used in essentially every genome annotation pipeline (Chapter 5).

1.7.9 Limitations

- **Pseudoknots and tertiary interactions** cannot be represented by context-free models, so CMs ignore them. This loses some information, for example in riboswitches and RNase P RNA, where pseudoknots are conserved.
- **Cost.** Even with filters, CM searches are much slower than profile HMM searches.
- **Dependence on the seed alignment.** A CM is only as good as the structural alignment and consensus structure it is built from.
- **Not all ncRNAs are structured.** Many long non-coding RNAs show little conservation of sequence or structure, and their function may depend on short sequence motifs or on the act of transcription itself. For them, structure-based homology search has little to offer, and homology can often only be inferred from conserved genomic position (synteny).

1.8 Whole-genome alignment and conservation

The methods earlier in this chapter align genes and proteins: sequences of a few hundred to a few thousand residues, whose homology is usually one-to-one along their length. Aligning whole genomes is a different problem, and its results, multiple genome alignments and the conservation scores computed from them, are among the most used tracks in genome browsers (Section 2.4).

1.8.1 Why genomes are not long genes

A genome alignment should identify, for every base, the homologous base (if any) in each of the other genomes. Several things make this harder than aligning two genes:

- **Rearrangements.** Inversions, translocations, fusions and fissions break the collinearity of genomes (Section 6.5). A single global alignment, as computed by Needleman–Wunsch, cannot represent a block that has moved or changed orientation.
- **Duplications and losses.** A region may have one copy in one genome and several in another, through segmental or whole-genome duplication. The alignment must then decide which copy is the orthologue, or allow one base to align to several.
- **Repeats.** Transposable elements and other repeats make up about half of mammalian genomes. They create huge numbers of short, spurious matches, so repeats are usually soft-masked (written in lower case) and used only to extend alignments, not to start them.
- **Size and divergence.** Mammalian genomes are billions of bases long, and most of their sequence is neutrally evolving, so between distant species only a small part can be aligned with confidence.

Whole-genome alignment is therefore done in stages: find local matches, chain them into collinear blocks, and decide which blocks represent orthology.

1.8.2 Pairwise alignment: BLASTZ/LASTZ, chains and nets

BLASTZ was developed to align the human and mouse genomes (Schwartz et al. 2002). It follows the seed-and-extend scheme of BLAST (Section 1.4), but with *spaced seeds* (by default 12 matching positions in a window of 19, with one transition allowed), which are more sensitive for diverged non-coding DNA than contiguous words. The best seed is not fixed: it depends on the length and similarity of the matches that are sought, so seed patterns and word sizes are search parameters to be tuned rather than constants (Gotea 2003). The seeds are followed by gapped extension and a second, more sensitive search between the anchors that were found. Its successor **LASTZ** is used in the same way.

The local alignments are then organised in two steps, introduced at UCSC (Kent et al. 2003):

- A **chain** is an ordered series of gapless blocks that are in the same order and orientation in both genomes. Gaps are allowed in *both* sequences between blocks, which is how insertions, deletions and unalignable sequence appear. Chains are found by dynamic programming over the local alignments, much like the chaining of seeds in minimap2.
- A **net** is a hierarchical selection of chains in which each base of the reference genome is covered at most once. The best chain is placed first, and gaps in it are filled with the best chains that fit there. Nets therefore distinguish the orthologous, collinear alignment from alignments to paralogous copies, and they show inversions and other rearrangements as nested chains.

Chains are also the basis of **liftOver**, the tool that converts coordinates between assemblies of the same genome (Section 2.4).

1.8.3 Multiple genome alignment

Pairwise alignments to one genome can be combined into a multiple alignment. **MULTIZ**, part of the threaded blockset aligner (Blanchette et al. 2004), progressively merges pairwise alignments that all share a reference genome, following a phylogenetic tree. The UCSC multiple alignments of vertebrates and mammals are built this way. Such alignments are *reference-based*: they only contain sequence that aligns to the reference (for example human), and sequence absent from the reference is lost.

Reference-free methods treat all genomes symmetrically. In Ensembl, **Enredo** builds a graph of collinear segments from anchors in all genomes, allowing for duplications and rearrangements, and **Pecan** aligns each segment with a consistency-based method in the spirit of T-Coffee (Section 1.6) (Paten et al. 2008). **Progressive Cactus** (Armstrong et al. 2020) represents the alignment as a *cactus graph*, in which rearrangements and duplications are natural, and aligns genomes progressively along a guide tree, reconstructing an ancestral genome at each internal node. Because each new genome only has to be aligned to its nearest ancestors, the method scales to hundreds of genomes. It was used to build the Zoonomia alignment of about 240 mammal species (Genereux et al. 2020; Christmas et al. 2023) and alignments of hundreds of bird genomes.

1.8.4 Evaluating genome alignments

There is no ground truth for real genomes, so genome aligners are hard to evaluate. The **Alignathon** competition (Earl et al. 2014) compared aligners on genomes simulated with a known evolutionary history, including rearrangements and duplications, where precision and recall of aligned base pairs can be computed, and on real fly genomes, where only indirect measures are possible. Methods differed substantially, especially for distant genomes, and no method was best on all measures. The lesson matches that for protein alignment (Section 1.11): a genome alignment is an estimate, and downstream results, such as which bases are conserved, inherit its errors.

1.8.5 Conservation scores

Given a multiple genome alignment and a phylogenetic tree with a *neutral model* of substitution, usually estimated from sites assumed to evolve without constraint, such as fourfold degenerate sites or ancient repeats, each column can be asked: did it change less than expected? Purifying selection removes mutations at functional positions, so a deficit of substitutions is evidence of function, whether or not the sequence codes for protein. Three scores are widely used:

- **phastCons** (Siepel et al. 2005) uses a two-state **phylo-HMM** (Section 1.6): a hidden Markov model along the genome whose states emit alignment columns according to a phylogenetic model. In the *conserved* state all branch lengths are scaled down by a factor $\rho < 1$. The posterior probability of the conserved state is reported for each base, and runs of high probability are called *conserved elements*. Because neighbouring bases share a state, phastCons finds elements rather than single positions.
- **phyloP** (Pollard et al. 2009) tests each base (or element) separately for a departure from the neutral rate, and reports $-\log_{10} p$-values: positive for conservation (slower than neutral) and negative for *acceleration* (faster than neutral). It can also test one lineage, for example the human branch, which is how **human accelerated regions**, conserved in other mammals but rapidly changed in humans, were found (Pollard et al. 2006).
- **GERP** (Cooper et al. 2005) measures constraint as **rejected substitutions**: the number of substitutions expected at a column under neutrality minus the number estimated to have occurred. A score of 4 means that four substitutions that would have happened have been removed by selection. GERP++ (Davydov et al. 2010) calls constrained elements from these scores.

Conservation scores are used to find functional non-coding elements, such as enhancers and non-coding RNAs, and to estimate how much of the genome is under constraint (Section 6.9). They are also among the most informative features for interpreting variants: a variant at a strongly constrained base is more likely to be harmful, and base-level constraint from the Zoonomia alignment helps to prioritise non-coding variants in rare disease and association studies (Sullivan et al. 2023). Scores such as CADD include phyloP and GERP among their features (Section 10.6), and variant calling itself is described in Section 5.4.

Conservation scores also have important limitations:

- **They depend on the alignment.** Misaligned paralogues, assembly errors and missing data in some species look like substitutions or conservation. Repeats are often poorly aligned and therefore under-scored.
- **They need enough evolution.** Single-base resolution requires a large total branch length in the tree. A handful of primates cannot show that a single base is constrained; hundreds of mammals can. Alignments of distant species, on the other hand, contain only the most conserved elements.
- **Function can be lineage-specific.** Elements that are new or turn over quickly, such as many transcription factor binding sites, are not conserved across the tree although they are functional in one lineage. Lack of conservation is therefore not evidence of lack of function.
- **Not all deviation is selection.** Mutation-rate variation and GC-biased gene conversion can make a region look conserved or accelerated, as discussed for some human accelerated regions.

A conserved base is evidence that *some* function has been maintained by selection over the depth of the tree used. It does not say what the function is, or whether it is the same in humans.

1.9 Databases and domains

So far we have mostly treated a protein as one sequence to be aligned from end to end, or at least as one region of local similarity. Real proteins are often built from several independent parts, *domains*, that have their own evolutionary histories. A protein of 800 residues may share one domain with a kinase, another with a transcription factor, and a third with nothing in the databases at all. Understanding domains is therefore essential for interpreting search results. It also explains why the most widely used annotation resources, Pfam and InterPro, are organised around domains and families rather than whole proteins. This section covers what a domain is, how domain families are built and searched (Pfam, Pfam-N and InterPro), and gives a first look at the structural classifications (SCOP, CATH, ECOD and TED) that are discussed further in Chapter 2 and Chapter 9.

1.9.1 What is a protein domain?

1.9.1.1 History of the concept

The idea of the domain grew out of the first protein crystal structures. In 1973 Donald Wetlaufer surveyed the structures then available, including hen lysozyme, papain and fragments of immunoglobulins produced by limited proteolysis. He noted that many proteins consist of separate, compact globular regions that are connected only by a few strands of polypeptide chain (Wetlaufer 1973). He proposed that such regions are *stable units of protein structure that can fold autonomously*, and suggested that folding of a large protein proceeds by nucleation within these regions. The immunoglobulins were a particularly clear case. Proteolysis cut the antibody into fragments that kept their structure and binding activity, and the sequence of each chain could be seen to consist of repeats of about 110 residues, each forming one compact “immunoglobulin domain”.

As more structures were determined, the term came to be used in three overlapping senses:

- **Structural domain:** a compact, globular sub-structure with more contacts within itself than with the rest of the protein, and usually with its own hydrophobic core.
- **Folding domain:** a unit that can fold, and remain stable, on its own when expressed or cut out of its parent protein.
- **Evolutionary (and functional) domain:** a unit that recurs in different proteins and different combinations. It has been moved around as one piece by gene duplication, fusion and recombination during evolution, and often carries a recognisable function, such as binding a ligand or catalysing a reaction.

In most cases these definitions agree: a compact structural unit found in many different proteins usually also folds on its own. But they need not agree, and different databases make different choices. This is one reason why domain boundaries and domain counts differ between resources.

1.9.1.2 Size and structure of domains

Domains are typically 50–250 residues long. Individual structural domains range from about 36 residues (in E-selectin) to almost 700 (in lipoxygenase), but about 90% are shorter than 200 residues, and the average is around 100 residues. Very small domains, below about 40 residues, are usually stabilised by metal ions or disulphide bridges; zinc fingers are the classic example. Domains longer than about 300 residues often turn out to contain more than one hydrophobic core and can be split further.

Each domain is built from secondary structure elements packed around a core. Domains are traditionally grouped into four classes by their secondary-structure content: *all-α*, *all-β*, *α/β* (mostly parallel β-sheets with β-α-β units, as in the TIM barrel or the Rossmann fold) and *α+β* (helices and mostly antiparallel strands in separate regions). These classes form the top level of both SCOP and CATH (below).

A domain need not be a single continuous stretch of sequence. When one domain has been inserted into a loop of another during evolution, the host domain is made up of two or more segments of the chain. Pyruvate kinase is the textbook example: its TIM-barrel domain is interrupted by an inserted β-barrel domain. About a quarter of structural domains are discontinuous in this way. A practical consequence is that a domain cannot always be represented by a single start and end position in the sequence, which complicates both sequence-based domain databases and automatic domain assignment.

Long-range interactions also matter in the other direction. Some proteins form oligomers by *domain swapping*, where a secondary-structure element or a whole domain of one chain replaces the equivalent part of a neighbouring chain. And in many multidomain proteins the domains are connected by flexible, often intrinsically disordered linkers, so their relative orientation varies. This is one reason why structure-based domain assignment, and structure prediction (Chapter 9), is usually more reliable for individual domains than for whole chains.

1.9.2 Multidomain proteins and domain architectures

Multidomain proteins are common, especially in eukaryotes. Estimates depend on the definitions and databases used, but roughly 40% of prokaryotic proteins and 65–80% of eukaryotic proteins are multidomain proteins, and the fraction is highest in multicellular animals (Apic et al. 2001). The linear order of domains along the chain, from N- to C-terminus, is called the protein's **domain architecture**.

Figure 1.10 shows three classic examples:

- **Src tyrosine kinase** has an N-terminal unique region followed by an SH3 domain, which binds proline-rich peptides; an SH2 domain, which binds phosphotyrosine; and a C-terminal kinase domain. The same SH2 and SH3 domains occur, in other combinations, in hundreds of other signalling proteins.

- **Tissue plasminogen activator** consists of a fibronectin type-I ("finger") module, an EGF-like module, two kringle domains and a trypsin-like serine protease domain. The extracellular proteins of blood clotting, fibrinolysis and complement are built from a small set of such modules, combined in many different ways. They were among the first examples of *domain shuffling*, the reuse of domains through exon shuffling and recombination.
- **The purine-biosynthesis enzymes** GARs, AIRs and GARt are three separate proteins in bacteria. In yeast, GARs and AIRs are fused into one chain while GARt is separate, and in vertebrates all three are fused into a single trifunctional polypeptide. The same activities are present in all three, but the way they are packaged into chains differs.

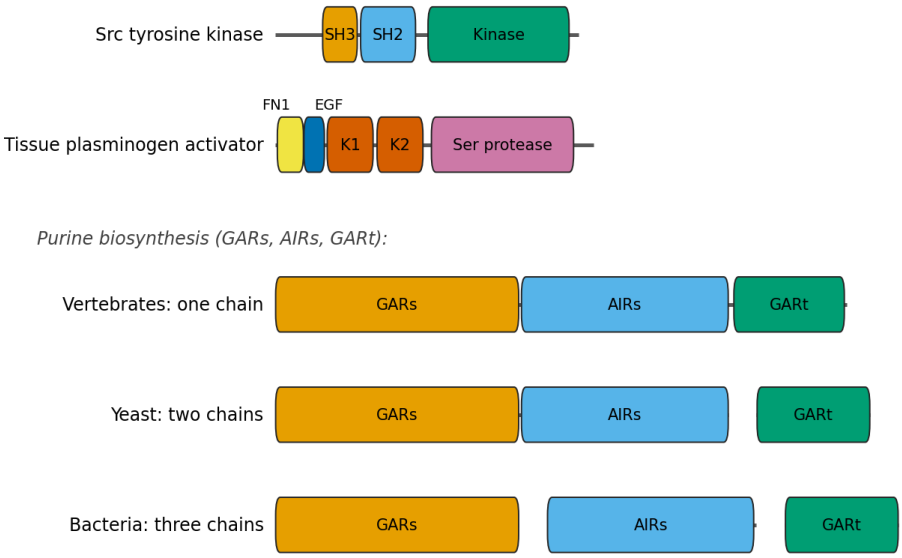

Figure 1.10: Schematic domain architectures (approximately to scale). Top: Src kinase and tissue plasminogen activator, two multidomain proteins built from widely reused domains (K1, K2: kringle domains; FN1: fibronectin type-I module). Bottom: the purine-biosynthesis enzymes GARs, AIRs and GARt are separate chains in bacteria, partly fused in yeast and fully fused in vertebrates.

The last example illustrates a general pattern. Many domains that form parts of multidomain proteins in eukaryotes exist as separate proteins in prokaryotes, which suggests that multidomain proteins have often arisen by *gene fusion* of previously independent genes. The opposite process, *gene fission*, also occurs. Because fused proteins usually function together, the observation that two proteins are fused in another genome is used to predict functional links ("Rosetta stone" proteins, Chapter 10).

1.9.2.1 How domain architectures evolve

Domain architectures change through a limited set of genetic mechanisms: duplication of a whole gene or part of it, fusion and fission, insertion of one domain into another, exon shuffling (in eukaryotes, where introns make recombination between domains easier), and transposition, including horizontal transfer between species. Several broad patterns have been found by comparing architectures across genomes:

- **Combinations are limited.** Although thousands of domain families are known, only a small fraction of all possible pairs of domains is ever observed together, and most domains combine

with only one or two partners. A few *promiscuous* domains, such as SH3, SH2, PH and the immunoglobulin domain, combine with very many others (Basu et al. 2008). Domain combinations also tend to keep their N-to-C order (Apic et al. 2001).

- **Most changes happen at the ends.** When architectures of related proteins are compared, most differences are the gain or loss of single domains at the N- or C-terminus, rather than insertions in the middle (Björklund et al. 2005).
- **Tandem repeats are common.** The simplest architecture is one domain repeated many times. Titin, a muscle protein of about 30,000 residues, contains more than a hundred immunoglobulin and fibronectin type-III domains. In some repeats, as in the two β-barrels of the trypsin-like serine proteases, the copies have diverged so far that their common origin is only visible in the structure.
- **Assembly mirrors evolution.** For protein complexes, the order in which subunits assemble often reflects the order in which they were added during evolution (Levy et al. 2008).

These patterns, and how domain rearrangements relate to gene duplication and to the evolution of new functions, are discussed further in Chapter 3.

1.9.2.2 Why domains matter for sequence searching

Domains have direct consequences for the search methods in this chapter:

- **Hits are local.** A significant hit between two multidomain proteins usually means that *one region* is homologous, not the whole chain. Local alignment (Section 1.3) will report the shared domain, but the rest of the two proteins may be unrelated.
- **Annotation transfer can go wrong.** If the query shares only an SH2 domain with a kinase, transferring the annotation "tyrosine kinase" is a mistake. Many errors in sequence databases have arisen in exactly this way and have then propagated as other proteins were annotated from the erroneous entries (Chapter 10).
- **Homology is not transitive across domains.** If protein A matches B through domain 1, and B matches C through domain 2, then A and C are not shown to be related at all. Iterative methods such as PSI-BLAST, and sequence clustering by single linkage, can "walk" from one family to another through multidomain proteins in this way. This is a common source of profile corruption (Section 1.6).
- **Search per domain.** For these reasons, sequences are often annotated by searching them against libraries of domain models, such as Pfam, instead of (or as well as) against whole sequences. Boundaries found in that way can then be used to cut a protein into domains before further analysis.
- **Low-complexity and repeat regions** (compositionally biased segments, coiled coils, transmembrane helices, short repeats) can produce high-scoring but non-homologous matches. They are often masked before searching, and are handled specially in domain databases.

1.9.3 Pfam

Pfam is the most widely used database of protein domains and families. It contains a curated multiple sequence alignment and a profile hidden Markov model (Section 1.6) for each family, and it is used to annotate the protein content of essentially every newly sequenced genome.

1.9.3.1 History

Pfam was started in 1995 by Erik Sonnhammer, Sean Eddy and Richard Durbin at the Sanger Centre in Cambridge, and was first described in 1997 (Sonnhammer et al. 1997). A major motivation was the

annotation of the first animal genome, that of the nematode *Caenorhabditis elegans*. The project was also inspired by Cyrus Chothia's argument (Chothia 1992) that most proteins belong to a limited number of families, perhaps around a thousand. If so, a manageable collection of family models could annotate a large fraction of all proteins. The estimate turned out to be too low: Pfam release 37.0 (June 2024) contains almost 22,000 families. But the main idea, that a library of family models gives broad and sensitive coverage, has been borne out. Already around release 29, about three quarters of all sequences in UniProtKB had at least one Pfam match.

Pfam was originally a consortium with sites in the UK, the USA and Sweden (Erik Sonnhammer, who now works at Stockholm University and SciLifeLab). Between 2012 and 2014 it moved to the European Bioinformatics Institute (EMBL-EBI), and since about 2022 it has been part of InterPro, through whose website it is now accessed (Mistry et al. 2020; Paysan-Lafosse et al. 2022).

1.9.3.2 How a Pfam family is built

What made Pfam different from earlier collections was its use of two alignments for each family, and of profile HMMs to connect them (Sonnhammer et al. 1997):

1. **Seed alignment.** A curator assembles a small, high-quality multiple alignment of representative members of the family. Sequences are taken from a non-redundant database of reference proteomes (pfamseq) and the alignment is checked by hand. Candidate families come mainly from proteins of known structure in the PDB, and from proteins in complete proteomes that have no Pfam match yet.
2. **Profile HMM.** A profile HMM is built from the seed alignment with HMMER (`hmmbuild`) (Eddy 1998).
3. **Search.** The HMM is searched against the full sequence database (`hmmsearch`). With HMMER3 (Eddy 2011), this became roughly a hundred times faster than before, which made frequent updates possible.
4. **Full alignment.** All sequences scoring above the family's threshold are aligned to the HMM. This gives the *full alignment*, which can contain millions of sequences.

The key advantage of this design is that only the small seed alignment has to be maintained by hand. When the sequence database grows, the full alignment is regenerated automatically by searching again with the HMM.

1.9.3.3 Thresholds: GA, TC and NC

Each Pfam family has a manually set **gathering threshold (GA)**, a bit score above which a match is accepted as a member of the family. HMMER scores are given both for the whole sequence and for each individual domain match, and the GA has a value for both. The curator chooses the threshold to include as many true members as possible while excluding false positives. Pfam also records two derived values:

- the **trusted cutoff (TC)**, the lowest score of any sequence included in the family;
- the **noise cutoff (NC)**, the highest score of any sequence that was *not* included.

The gap between NC and TC indicates how cleanly the family is separated from the background. False positives are recognised mainly as overlaps: if a region matches two different families that are not known to be related, at least one of the matches is probably wrong. Thresholds are re-checked at each release to prevent such overlaps. In practice, using the curated thresholds (`--cut_ga` in HMMER) is usually more reliable than using a fixed E-value cutoff for all families.

1.9.3.4 Entry types, clans and domains of unknown function

Pfam entries are classified as *families*, *domains*, *repeats* or *motifs*. "Family" is the default and just means that the members are related. "Domain" means an autonomous structural unit that can occur in different protein contexts. "Repeat" denotes units that are not stable on their own and only form a structure as tandem copies. "Motif" denotes short units, usually outside globular domains.

As families grew and more structures were solved, it became clear that many Pfam families are themselves distantly related. Since 2005 such families have been grouped into **clans** (Finn et al. 2006): sets of families that are believed to share a common evolutionary origin, based on structural similarity, functional similarity, and HMM–HMM comparison (Section 1.6). Pfam curators also use the ECOD structural classification (below) to identify clan relationships. A clan corresponds roughly to a superfamily in the structural classifications, but the two are defined on different units and need not coincide (see the table at the end of this section). Families in the same clan are not allowed to overlap in the same sequence region, so the best-scoring member family is reported.

A substantial part of Pfam consists of **domains of unknown function (DUFs)**: families that are clearly conserved across species but whose function has not been determined. They are named DUF followed by a number and are renamed when a function is found. Since around 2010 more than a fifth of all Pfam families have been DUFs, and their share has grown as new genomes are sequenced. Many DUFs are good targets for experimental work.

1.9.3.5 Pfam-A and Pfam-B

The curated families described above form **Pfam-A**. Since they did not cover all proteins, Pfam also provided **Pfam-B**, a large set of automatically generated families from sequence clustering. Pfam-B families were of lower quality, but could give a hint when no Pfam-A family matched. Pfam-B was discontinued with release 28.0 and later reintroduced (release 33.1), now generated with MMseqs2 clustering (Section 1.4).

1.9.3.6 Community curation through Wikipedia

Writing functional descriptions for thousands of families is more than a small curation team can do. From release 26.0, Pfam (together with its sister database Rfam for RNA families) therefore linked family descriptions to Wikipedia articles. Existing articles were connected to the corresponding families, and the community was invited to write new ones. Edits are reviewed by Pfam curators before they appear on the Pfam pages. Many Wikipedia articles on protein domains therefore originate from, and are maintained together with, Pfam.

1.9.4 Pfam-N: deep learning for domain annotation

Profile HMMs are sensitive, but they still miss many sequences that do belong to a family, especially in poorly studied lineages and metagenomes. In 2022, Maxwell Bileschi, Lucy Colwell and colleagues at Google Research showed that deep neural networks can be trained to classify protein sequences into Pfam families directly (Bileschi et al. 2022). Their model, **ProtCNN**, is a convolutional neural network (Chapter 12) trained on Pfam seed alignments. It takes a protein domain sequence as input and outputs the probability that it belongs to each Pfam family. An ensemble of such networks (**ProtENN**) was then combined with HMMER.

Two features of this work are important. First, the networks were evaluated on a split of the data in which test sequences had low sequence identity to the training sequences. This tests the ability to

detect remote homologues rather than near-duplicates, a point that applies to all machine-learning methods in bioinformatics (Chapter 12). On such a split, the deep models made fewer classification errors than profile HMMs, and the combination of the two was better than either. Second, the models were used to annotate UniProt sequences that had no Pfam match. This added several million new domain annotations and raised Pfam's coverage of UniProtKB by roughly a tenth. These predictions are distributed as **Pfam-N** ("N" for neural).

Pfam-N annotations are kept separate from the HMM-based ones, because they come with different evidence and different error properties. Curators also use them to extend the seed alignments of the standard families. This is part of a broader shift: recent Pfam releases also use AlphaFold-predicted structures to check and correct family boundaries, and to identify new families and clan relationships (Paysan-Lafosse et al. 2024).

1.9.5 InterPro

Pfam is one of several "signature" databases, each modelling families, domains or sites in its own way: regular expressions (PROSITE patterns), position-specific scoring matrices (CDD, PROSITE profiles), fingerprints (PRINTS) and profile HMMs (Pfam, SMART, TIGRFAMs/NCBIfam, PANTHER, CATH-Gene3D, SUPERFAMILY, PIRSF, HAMAP). **InterPro**, at EMBL-EBI, integrates these member databases into a single resource (Paysan-Lafosse et al. 2022). Signatures from different databases that describe the same family, domain or site are merged into one InterPro entry, with a common name, description and Gene Ontology terms. Entries are linked in parent–child relationships (for example, a family and its subfamilies) and classified by type (family, domain, repeat, site, homologous superfamily). InterPro precomputes matches for all of UniProtKB; more than 80% of its sequences have at least one match (Blum et al. 2020; Paysan-Lafosse et al. 2022). The InterProScan software lets users run all member databases on their own sequences. InterPro is now the standard starting point for annotating a new protein, and the databases are discussed further in Chapter 2.

1.9.6 Structural classification of domains

Because structure among homologues tends to be conserved much longer than sequence, many evolutionary relationships between domains can only be seen at the structural level. Several databases therefore classify domains of known three-dimensional structure. They are only introduced here; structure itself is the topic of Chapter 9.

1.9.6.1 SCOP

The **Structural Classification of Proteins (SCOP)** was created in 1994 by Alexey Murzin, Steven Brenner, Tim Hubbard and Cyrus Chothia at the MRC Laboratory of Molecular Biology and the Centre for Protein Engineering in Cambridge (Murzin et al. 1995). SCOP is largely manual: the classification was based on expert inspection of structures, supported by sequence comparison. Its unit is the structural domain, and its main levels are:

- **Class:** the overall secondary-structure content (all-α, all-β, α/β, α+β and some special classes).
- **Fold:** domains with the same major secondary structures in the same arrangement and with the same topological connections. A shared fold does *not* by itself imply common ancestry; similar folds can arise by convergence because only a limited number of arrangements are physically favourable.
- **Superfamily:** domains in the same fold that have low sequence identity but whose structural and functional features together indicate a probable common ancestor.

- **Family:** domains with clear sequence similarity (typically more than 30% identity), or lower identity combined with very similar structure and function. These are closely related homologues.

The human trypsin domain, for example, is classified as all-β class, trypsin-like serine protease fold, trypsin-like serine protease superfamily, eukaryotic protease family. The original SCOP was updated until version 1.75 (2009). It is continued as **SCOPe** at Berkeley (Fox et al. 2013), which adds new structures in a largely automated but compatible way, and as **SCOP2** from the Cambridge group (Andreeva et al. 2019), which replaces the strict tree with a more flexible network of relationships.

1.9.6.2 CATH

CATH was created in the mid-1990s by Christine Orengo, Janet Thornton and colleagues at University College London, and is still developed by the Orengo group (Sillitoe et al. 2020). Protein chains from the PDB are "chopped" into domains by a combination of algorithms and curation, and each domain is classified in four main levels, which give the database its name:

- **Class (C):** secondary-structure content (mainly α, mainly β, α–β, few secondary structures).
- **Architecture (A):** the overall arrangement of secondary structures in space, regardless of how they are connected (e.g. sandwich, barrel, three-layer sandwich).
- **Topology (T):** the fold, i.e. the arrangement *and* connectivity of the secondary structures.
- **Homologous superfamily (H):** domains with good evidence of a common ancestor.

Below the H level, CATH groups domains into sequence clusters and *functional families* (FunFams). Compared with SCOP, CATH relies more on automatic structure comparison, has an explicit architecture level, and does not use the α+β class. Through its sister resource **Gene3D**, CATH superfamilies are represented by HMMs that are used to assign domains to sequences without known structure, and Gene3D is one of the InterPro member databases.

1.9.6.3 ECOD

ECOD (Evolutionary Classification of Protein Domains), from Nick Grishin's group at UT Southwestern, puts evolutionary relationships first (Cheng et al. 2014). Its levels are *architecture* (A), *possible homology* (X), *homology* (H), *topology* (T) and *family* (F). The X level is the most distinctive: it groups domains for which homology is plausible but not established, instead of forcing a yes-or-no decision. Higher levels are defined by evidence of common ancestry rather than by shape alone, so domains with different topologies can still be placed in the same homology group if other evidence supports it. ECOD is updated weekly from the PDB, and its families map closely onto Pfam families, which is why Pfam uses it when defining clans.

1.9.6.4 TED: domains across the AlphaFold Database

Until recently, structural classifications covered only the roughly 200,000 experimentally determined structures in the PDB. The AlphaFold Protein Structure Database (Varadi et al. 2021) changed this by providing predicted structures for more than 200 million UniProt sequences. **The Encyclopedia of Domains (TED)** (Lau et al. 2024), from the Orengo and Jones groups at UCL together with others, used these models to segment and classify domains at the scale of the whole protein universe.

Chopping that many structures by hand is impossible. TED therefore combined three deep-learning domain-segmentation methods (Chainsaw, Merizo and UniDoc) and accepted domain boundaries on which they agreed. Applied to about 188 million unique AlphaFold models, this identified nearly 365 million domains. Using structure comparison (including Foldseek, Section 1.4), about 194 million of

these could be assigned to known CATH superfamilies, and a further 46 million matched known CATH topologies. The rest have structures not previously classified in CATH, and include many candidate new folds. TED shows both how much of protein space is covered by known folds, and how much remains unexplored.

1.9.6.5 Structure classifications and homology

The structural hierarchies connect directly to the definition of homology in 1. Homology means common ancestry; it is not a degree of similarity. Placing two domains in the same **superfamily** (SCOP, CATH) or **homology group** (ECOD) is a statement that there is enough evidence (structural similarity together with shared functional details, unusual structural features or weak sequence similarity) to conclude that they are homologous, even when their sequence identity is too low for sequence methods to detect it. Placing them only in the same **fold** or **topology** says that they have similar architectures, but leaves open whether this reflects common ancestry or convergence. The TIM barrel is the standard example: it is found in many enzyme families catalysing unrelated reactions, and it is still debated whether all TIM barrels share a common ancestor. The structure databases, in other words, help us infer homology, but similarity of structure, like similarity of sequence, is evidence for homology and not the same thing.

The same words have different meanings in different databases, which is a frequent source of confusion. Table 1.1 compares them.

Table 1.1: Domain-classification terms in different databases.

Term	Database	Meaning
Domain	SCOP, CATH, ECOD, TED	A structural unit, cut out of a structure (experimental or predicted).
	Pfam, InterPro	A region matched by a sequence model; in Pfam also one *entry type*, for units that occur in different protein contexts.
Family	SCOP	Domains with clear sequence similarity (often above 30% identity) or very similar structure and function.
	Pfam	The default entry type: any set of related sequences modelled by one HMM, which may be a domain, part of a domain or a whole protein.
	ECOD (F), CATH (FunFam)	ECOD: sequence-based families, close to Pfam families. CATH FunFams: functionally coherent subgroups within a superfamily.
Superfamily / homology group	SCOP, CATH (H), ECOD (H)	Domains judged to share a common ancestor from structural, functional and weak sequence evidence.
Possible homology	ECOD (X)	Homology plausible but not established.

Term	Database	Meaning
Clan	Pfam	Sequence families believed to share a common ancestor (from structure, function and HMM–HMM comparison). Roughly a superfamily, but built from Pfam families, so its boundaries and membership can differ.
Fold / topology	SCOP (fold), CATH (T)	Same secondary structures in the same arrangement and connectivity; *no* claim of common ancestry. In ECOD, T is instead a level *below* the homology group.

1.10 Protein language models

Every method in the previous sections compares sequences residue by residue, with scores that come from explicit models of evolution: substitution matrices, profiles, HMMs. Since about 2019 a different idea has spread from natural-language processing into biology. A large neural network is trained to *predict amino acids from their sequence context* on hundreds of millions of natural protein sequences, without any labels. To do this well, the network learns, implicitly, which substitutions are tolerated at which positions, which residues tend to be in contact and which sequence patterns belong to which families. Its internal representations, the *embeddings*, can then be used for prediction tasks and, more recently, to search for homologues. These networks are called **protein language models** (PLMs). This section describes where they come from, what they learn, and how they are being used for sequence searching and the detection of remote evolutionary relationships. The machine learning background is covered in Chapter 12.

1.10.1 From words to residues

1.10.1.1 The distributional hypothesis

In linguistics, the idea that "a word is characterised by the company it keeps" goes back to John Rupert Firth in 1957. This *distributional hypothesis* says that words occurring in similar contexts tend to have similar meanings. In natural-language processing it led to **word embeddings**: each word is represented by a real-valued vector, learned so that words that appear in similar contexts end up close together in the vector space. Early approaches reduced the dimension of word co-occurrence matrices, for example by latent semantic analysis in the late 1980s. From about 2000, neural probabilistic language models

learned distributed representations directly, and word2vec (2013) made this cheap enough to train on very large text collections.

A protein sequence can be read in the same way. The *tokens* are the twenty amino acids (plus a few special symbols), a protein is a "sentence", and the "corpus" is a sequence database such as UniProt or UniRef (Chapter 2). The analogy is useful but imperfect. The protein alphabet is tiny compared with a natural vocabulary, so a single residue carries little meaning on its own. What a residue "means" depends almost entirely on its context: the same leucine may be buried in a helix in one protein and exposed in a loop in another. A useful protein model therefore needs *contextual* embeddings, where the representation of a residue depends on the whole sequence around it. The evolutionary interpretation of the distributional hypothesis is also clear. The sequences in the corpus are the survivors of natural selection, so the patterns of co-occurring residues reflect structural and functional constraints. These are the same constraints that give rise to conserved columns in a multiple alignment (Section 1.6) and to correlated mutations between residues in contact (Chapter 9).

1.10.1.2 Language modelling objectives

A *language model* assigns probabilities to sequences. Two training objectives dominate.

- **Autoregressive (causal) language modelling.** The model predicts each residue from the residues before it, so that the probability of a sequence $x = x_1 \dots x_L$ factorises as

$$p(x) = \prod_{i=1}^{L} p(x_i \mid x_1, \dots, x_{i-1}).$$

  This is the objective of the GPT family in natural language. Such models can also generate new sequences, one residue at a time.
- **Masked language modelling.** This is the objective popularised by BERT (2018). A random subset M of positions (typically about 15%) is hidden, by replacing the residues with a mask token, and the model is trained to recover them from the remaining, unmasked context on *both* sides. The loss for one sequence is

$$\mathscr{L} = -\sum_{i \in M} \log p\left(x_i \mid x_{\setminus M}\right),$$

  where $x_{\setminus M}$ denotes the sequence with the masked positions hidden. The model never sees labels such as structure or function. This is *self-supervised* learning: the training signal is the sequence itself.

How well a model has learned is often summarised by its *perplexity*, the exponential of the average negative log-likelihood per residue. A model that knows nothing has a perplexity of about 20 (a uniform guess over the amino acids). Lower values mean the model predicts the hidden residues better.

1.10.1.3 Recurrent networks and transformers

The first protein language models used recurrent neural networks, in particular long short-term memory (LSTM) networks. These read the sequence one position at a time and carry information forward in a hidden state. They are hard to parallelise, and information from distant positions is easily lost.

The **transformer** (Vaswani et al. 2017) removed the recurrence. Each token is first converted into a vector by an embedding layer. Positional information is added, because attention by itself ignores order. Each layer then updates every token's vector by *self-attention*, a weighted combination of all the other

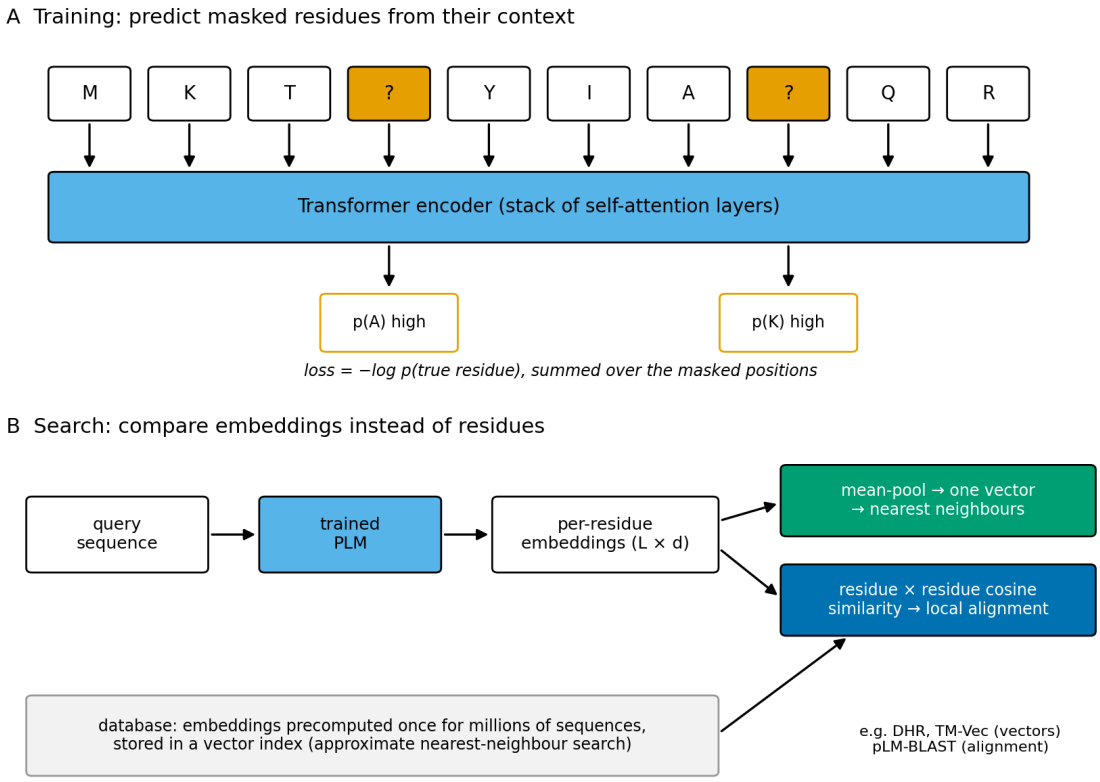

Figure 1.11: Protein language models. (A) In masked language modelling, some residues are hidden and the network is trained to predict them from the rest of the sequence. (B) After training, the per-residue embeddings can be compared directly, either as one pooled vector per protein (nearest-neighbour search) or residue by residue (alignment of embeddings).

tokens in the sequence. For a sequence represented as a matrix of token vectors, three learned linear maps give queries Q, keys K and values V, and attention is computed as

$$\mathrm{Attention}(Q, K, V) = \mathrm{softmax}\!\left(\frac{QK^{\top}}{\sqrt{d_k}}\right)V,$$

where d_k is the dimension of the keys. The matrix $\mathrm{softmax}(QK^{\top}/\sqrt{d_k})$ is an $L \times L$ table that says how much each position "looks at" every other position. Several such *attention heads* run in parallel in each layer, and many layers are stacked.

Two properties make transformers attractive for proteins. All positions are processed in parallel, so very large models can be trained on GPUs. And any position can interact directly with any other, which suits proteins, where residues far apart in sequence are often close in space. The price is that the cost of attention grows quadratically with sequence length. Most protein models are therefore trained on sequences cropped to around 1,000 residues.

1.10.2 A short history of protein language models

1.10.2.1 Early embeddings

Representing biological sequences with learned vectors predates the current models. In 2015 Asgari and Mofrad adapted word2vec to proteins ("ProtVec") (Asgari and Mofrad 2015), treating overlapping amino-acid 3-mers as words. These context-free embeddings carried some information about family membership and physico-chemical properties. However, they ignore the order and context of the 3-mers and were soon superseded.

1.10.2.2 Recurrent models: UniRep and SeqVec (2019)

The first models that learned contextual representations from large sequence collections appeared in 2019. **UniRep** (Alley et al. 2019) was a multiplicative LSTM trained autoregressively, to predict the next amino acid, on about 24 million UniRef50 sequences. Averaging its hidden states over the sequence gave a fixed-length vector per protein. Simple regression models on top of this vector could predict stability and the effects of mutations, and the authors used it to guide protein engineering. **SeqVec** (Heinzinger et al. 2019) adapted ELMo, a bidirectional LSTM language model from natural-language processing, to UniRef50. Per-residue embeddings from SeqVec, used as input to small supervised networks, predicted secondary structure and disorder. Per-protein embeddings predicted subcellular localisation and membrane association. These predictions approached, but did not reach, methods that used evolutionary information from multiple sequence alignments. They were, however, much faster, because no database search was needed.

Around the same time, the TAPE benchmark (Rao and colleagues, 2019) compared several architectures on a common set of tasks, such as secondary structure, contacts, remote homology, fluorescence and stability. It showed that self-supervised pre-training helps on almost all of them. On the structural tasks, however, it still did not reach features derived from alignments.

1.10.2.3 Transformers at scale: ESM-1b and ProtTrans (2020–2021)

The next step was to train much larger transformers on much more data. **ESM-1b** (Rives et al. 2021), from the group of Alexander Rives at Facebook AI Research, was a 33-layer transformer with about 650 million parameters. It was trained with masked language modelling on UniRef50, which the authors

drew from a collection of about 250 million sequences. The paper analysed what the model had learned without supervision:

- the embeddings of the amino acids themselves clustered by physico-chemical properties (hydrophobic, aromatic, charged and so on);
- per-protein embeddings separated orthologous groups and reflected phylogenetic relationships;
- per-residue embeddings contained information on secondary structure and on which residues are in contact;
- these signals improved as the model's perplexity decreased.

Shortly afterwards, Rao and colleagues showed that the attention maps of such models predict residue–residue contacts directly (Rao et al. 2020). A simple logistic regression on the attention weights recovered contacts with accuracy comparable to coevolution methods based on a full multiple alignment. The model had, in effect, learned something similar to the coupling analysis of Chapter 9, but from single sequences.

ProtTrans (Elnaggar et al. 2022), from the group of Burkhard Rost in Munich, trained several transformer architectures from natural-language processing on UniRef and on the metagenomic Big Fantastic Database (BFD), with billions of sequences in total. The models included ProtBERT, an encoder trained by masked language modelling, and ProtT5, an encoder–decoder model. The encoder of ProtT5-XL became one of the most widely used sources of embeddings. Using only its embeddings, without alignments, the authors predicted secondary structure about as well as the best alignment-based methods of the time. They also predicted localisation and membrane association well. A review by Bepler and Berger (2021) summarises this period and discusses how evolution, structure and function are encoded in the learned representations.

1.10.2.4 Structure from a language model: ESM-2 and ESMFold (2022–2023)

ESM-2 (Lin et al. 2023) scaled the masked-language-model approach to a series of models from 8 million to 15 billion parameters, trained on UniRef. As the models grew, their perplexity fell and the contact information in their attention maps increased. **ESMFold** attaches a structure module, similar to that of AlphaFold2 (Jumper, Evans, Pritzel, Green, Figurnov, Ronneberger, Tunyasuvunakool, Bates, Žídek, Potapenko, Bridgland, Meyer, Kohl, Ballard, Cowie, Romera-Paredes, Nikolov, Jain, Adler, Back, Petersen, Reiman, Clancy, Zielinski, Steinegger, Pacholska, Berghammer, Bodenstein, et al. 2021), to the ESM-2 language model. It predicts atomic structures from a *single sequence*, without searching for homologues or building an alignment. ESMFold is less accurate than AlphaFold2 on average, especially for proteins with few homologues. Because it skips the alignment step, however, it is roughly an order of magnitude faster. The authors used it to predict more than 600 million structures from metagenomic sequences (the ESM Metagenomic Atlas). An important observation was that ESMFold's accuracy is closely related to the language model's perplexity on the sequence. The model works well when it "understands" a protein, which in practice usually means that related sequences were well represented in its training data.

1.10.2.5 Generative and multimodal models (2024–)

The most recent models go beyond sequence. **ESM3** (Hayes et al. 2025) is a generative masked language model that reasons over three *tracks* at once: sequence, structure and function. Structure is encoded as discrete tokens, and function as keyword annotations. Any combination can be given as a prompt and the rest generated. The largest version has about 98 billion parameters. As a demonstration, the authors generated a functional green fluorescent protein, esmGFP, that is only distantly related to known fluorescent proteins. This illustrates a broader trend: language models are increasingly used to *design*

sequences (Chapter 9), not just to analyse them. Other models in this family include autoregressive models trained to generate protein families, and "bilingual" models that translate between amino-acid sequence and structural alphabets.

1.10.3 What do embeddings capture?

It is worth being precise about what a PLM provides. For a protein of length L, the last layer of the network (or a chosen intermediate layer) gives one vector of dimension d per residue, an $L \times d$ matrix. Typically d is between about 1,000 and 5,000. This **per-residue embedding** is used for tasks that need a prediction for each residue, such as secondary structure, disorder, binding sites, transmembrane segments or signal peptides (Chapter 10). Averaging the vectors over all positions (*mean pooling*) gives a **per-protein embedding** of fixed size d. This is used for tasks about the whole protein, such as localisation, enzyme class or family membership, and for fast comparison of proteins.

"The embedding of a protein" is therefore not a uniquely defined object. It depends on the model, on the layer it is taken from (intermediate layers are sometimes better than the last), and, for a per-protein vector, on the *pooling*: mean pooling, the vector of a special start token, maximum pooling, or a learned (attention-based) pooling. Long sequences may also be cropped or split into chunks, which changes the result. Pooling discards the order of the residues, so two proteins with similar composition and local environments but different domain order can get similar per-protein vectors. Embeddings are therefore only comparable when they were computed with the same model, layer and pooling.

Several lines of evidence show what these representations contain:

- **Structure.** Secondary structure and solvent accessibility can be read from per-residue embeddings with small supervised models. Contacts can be read from attention maps, and full 3D structures can be built from the representations (ESMFold).
- **Function.** Per-protein embeddings cluster by enzyme class, Gene Ontology terms and subcellular localisation. Simple nearest-neighbour annotation in embedding space ("embedding-based annotation transfer") often works where sequence similarity is too low for BLAST.
- **Evolution.** The likelihood a masked model assigns to a mutation correlates with the measured fitness effect of that mutation in deep mutational scanning experiments. This makes PLMs useful as unsupervised predictors of variant effects (Meier et al. 2021) (Chapter 10).
- **Family membership.** Proteins from the same family or superfamily are often close in embedding space, even when sequence identity is in the twilight zone (1). This is an empirical ability to recover family and structural relationships, not a direct inference of ancestry. Closeness in embedding space can also reflect shared structure class, composition or function, so on its own it is not evidence of common ancestry in the sense of a significant alignment score.

A common interpretation is that a large PLM acts as a *compressed multiple sequence alignment*. During training it sees many members of each family. The weights then store the conservation and covariation patterns that a profile or coevolution model would extract from an explicit alignment, and the model "retrieves" this information when it sees a new member of the family. This view explains both the strengths and the main weakness of PLMs. They are good for proteins from large, well-sampled families. For *orphan* proteins, or families with few sequences in the training data, they know little more than what is in the query itself.

1.10.4 Using language models to search for homologues

Classic homology search compares residues with a substitution matrix (Section 1.3) or a profile (Section 1.6). Embeddings offer two new possibilities. First, two proteins can be compared through their embeddings instead of their residues. Second, because an embedding summarises a sequence in context,

it may carry information about structure and family that the raw sequence only reveals through an alignment with many homologues. Several types of methods have appeared since 2021.

1.10.4.1 Embedding nearest-neighbour search

The simplest approach compares per-protein embeddings, for example with the cosine similarity

$$\cos(\mathbf{u}, \mathbf{v}) = \frac{\mathbf{u} \cdot \mathbf{v}}{\|\mathbf{u}\| \, \|\mathbf{v}\|}.$$

The embeddings for a whole database are computed once and stored in a *vector index*. Specialised libraries (for example FAISS (Johnson et al. 2021)) can then find the approximate nearest neighbours of a query among hundreds of millions of vectors in milliseconds, using clustering and quantisation of the vectors. Embedding the query is a single pass through the network, so the search itself costs almost nothing compared with dynamic programming against every database sequence.

Embeddings from a model trained only by masked language modelling are not optimised for this purpose. Better results come from *fine-tuning* the encoder with *contrastive learning*, so that homologous pairs end up close together and unrelated pairs far apart. This is the idea behind **dense retrieval** in information retrieval, where documents and queries are encoded into the same vector space. The **Dense Homolog Retriever** (DHR) (Hong et al. 2024) fine-tunes a protein language model contrastively, using homologous pairs taken from family alignments. It retrieves homologues with sensitivity comparable to or better than profile methods on the authors' benchmarks, at much higher speed. The authors also used it to build multiple sequence alignments for structure prediction quickly. This links PLM-based search to the alignment-building step of AlphaFold2 (Chapter 9).

1.10.4.2 Predicting structural similarity from sequence

Because structure among homologues tends to be conserved longer than sequence, structural similarity is the most sensitive sign of remote homology (1). It normally requires structures, which led to Foldseek and its 3Di alphabet (van Kempen et al. 2023) (Section 1.4). **TM-Vec** (Hamamsy et al. 2023) instead trains a network on top of PLM embeddings to predict the *TM-score* between two proteins, a measure of structural similarity (Chapter 9), directly from their sequences. The network is trained on pairs of proteins with known structures, so that the cosine similarity of the two output vectors approximates their TM-score. A database is again indexed once, and a query returns the proteins predicted to have similar structures, even when sequence identity is very low. The companion method DeepBLAST predicts a structural alignment between the two sequences.

A related idea uses language models to predict the 3Di structural alphabet directly from sequence (for example ProstT5 (Heinzinger et al. 2024), a "bilingual" model derived from ProtT5). This allows Foldseek-style structural search for proteins without any predicted structure.

1.10.4.3 Aligning embeddings

Pooling an $L \times d$ embedding into a single vector throws away the positional information needed for an alignment. An alternative keeps the per-residue embeddings and uses them in place of a substitution matrix. **pLM-BLAST** (Kaminski et al. 2023) computes the cosine similarity between every residue embedding of the query and every residue embedding of the target. This gives an $L_1 \times L_2$ similarity matrix specific to that pair of sequences, which is then used in a Smith–Waterman-like local alignment (Section 1.3). Since the embedding of a residue depends on its context, the matrix effectively contains a position-specific substitution score for each pair, much like a profile–profile comparison, but obtained from two single sequences. On benchmarks of distant homology, pLM-BLAST detects relationships

that BLAST misses and performs comparably to HMM–HMM comparison with HHsearch (Section 1.6), without building alignments for either sequence. Methods of this type also show where in two sequences the similarity lies, which pooled embeddings cannot.

1.10.4.4 Combined pipelines

Practical tools combine these ideas to balance speed and sensitivity, in the same way that BLAST and MMseqs2 combine a fast prefilter with a slower alignment step (Section 1.4). **PLMSearch** (Liu et al. 2024) first filters candidate pairs, using predicted family membership and embedding similarity. It then scores the remaining pairs with a model that predicts structural similarity from ESM embeddings, and finally aligns the hits with an embedding-based alignment method. The authors reported sensitivity for remote homologues similar to structure-based search, at a speed close to that of MMseqs2.

1.10.4.5 Deep learning for family annotation

Closely related to search is the assignment of sequences to known families. **ProtCNN** (Bileschi et al. 2022) is a deep convolutional network trained to classify sequence domains into Pfam families. It is not a transformer language model, but it rests on the same idea of learned sequence representations. Combined with profile HMMs, it was used to create *Pfam-N*, which added millions of new family assignments to UniProt sequences that the Pfam HMMs had missed. This is discussed in Section 1.9.

1.10.5 How good are they?

Remote-homology methods are usually evaluated on benchmarks derived from structural classifications such as SCOP or CATH (Section 1.9). Pairs in the same superfamily but in different families count as true remote homologues, and pairs in different folds count as non-homologues. Methods are compared by how many true pairs they rank above the first false one, or by the area under ROC-type curves. On such benchmarks, embedding-based methods are often more sensitive than BLAST and MMseqs2 in the twilight zone, and in several studies match or exceed HMMER and HHblits (Eddy 2011; Remmert et al. 2011). They usually remain below full structural comparison when structures are available.

These results have to be read carefully, for reasons that are directly relevant to the exam's emphasis on understanding the limitations of methods.

- **Leakage between training and test data.** A language model is trained on essentially all known sequences, including the test proteins and their relatives. A supervised model on top of it may be trained on pairs from the same families as the benchmark. Unless training and test sets are separated by family or superfamily, not just by sequence identity, reported performance is likely to be optimistic (the same issue as in any supervised learning in biology; 4).
- **No well-founded statistics.** The great strength of BLAST, HMMER and MMseqs2 is that their scores come with E-values derived from a model of random alignments (Section 1.4). A cosine similarity or a predicted TM-score has no such theory behind it. Thresholds are set empirically, and the false-positive rate on a new database is hard to predict. Some methods calibrate their scores against shuffled or unrelated sequences, but this is less mature than for classic tools.
- **Bias towards well-sampled families.** As discussed above, PLMs work best where training data are rich. Orphan proteins, rapidly evolving families, viral proteins and *de novo* designed proteins are often poorly represented, and these are precisely the cases where a sensitive remote-homology method is needed most.

- **Cost.** Searching an index is fast, but computing embeddings for hundreds of millions of sequences with a large model needs GPUs and a lot of storage. Each per-residue embedding is thousands of numbers per residue. The indexes must also be rebuilt when the model changes.
- **Interpretability.** An HMMER hit can be explained by the alignment and the profile columns that match. An embedding similarity is much harder to explain, although methods that align embeddings (pLM-BLAST) recover some of this.

1.10.6 Outlook

PLMs have not replaced classic sequence searching. They have added a new layer to it. Profile HMMs and fast *k*-mer-based tools remain the standard for routine annotation, because they are well understood, their statistics are reliable, and they run on ordinary computers. Language models are most useful at the edge of what these methods can detect: in the twilight zone, for building alignments quickly, for annotating metagenomic sequences at scale, and as cheap stand-ins for structural comparison. The classic and new approaches are also merging. Profile and alignment information is used to train language models, and language models are used to produce substitution scores, structural alphabets and alignments that feed into dynamic programming. It is therefore important to understand both: what the older methods assume, and why a model trained only to fill in missing amino acids ends up with representations from which evolutionary, structural and functional relationships can be recovered.

There is no Wikipedia article on protein language models. The rest of the section is based on the papers cited.

1.11 Benchmarking search methods

Each method in this chapter claims to be more sensitive, faster or more accurate than its predecessors. At the exam you should be able to say how such claims are tested, and what can go wrong. The central problem is that we need to know the right answer: which pairs of sequences are truly homologous and which are not. That knowledge must come from somewhere other than the method being tested.

1.11.1 Where does the truth come from?

The most widely used source of truth is a **structural classification** (Section 1.9). Because structure among homologues tends to be conserved much longer than sequence, two domains classified in the same SCOP or CATH superfamily are taken to be homologous, even if they have no detectable sequence similarity. Domains in different folds are taken to be unrelated. Pairs in the same fold but different superfamilies are ambiguous (they may be distant homologues or analogues) and are usually excluded. These labels are an *operational* gold standard: a convenient, independent definition of right and wrong answers, not a complete record of evolutionary history. Early benchmarks used curated sequence superfamilies instead (Pearson 1995). The SCOP-based benchmark of Brenner et al. (1998) became the template for later work. It showed that pairwise methods found only a small fraction of the homologous pairs with less than about 30% identity, and that well-computed E-values were reliable indicators of significance. Park et al. (1998) used the same approach to show that profile methods find about three

times as many remote homologues, and Lindahl and Elofsson (2000) measured performance separately at the family, superfamily and fold levels. Their results showed that methods which work well for close relationships can fail almost completely at the fold level, so a single overall number can hide large differences.

Other reference sets are used for other tasks: structural superpositions for multiple alignments (BAliBASE, Thompson et al. (1999)), and blind prediction experiments for structure and function (CASP and CAFA; Chapter 9 and Chapter 10).

1.11.2 What is measured?

A search method returns a ranked list of hits with scores or E-values. Performance is described by how true and false hits are ordered in that list.

- **ROC curves.** The *receiver operating characteristic* curve plots the number (or fraction) of true positives against false positives as the score threshold is lowered. The area under the curve (AUC) summarises it. In a database search almost all pairs are negatives, and only the top of the list is ever examined. The **ROC$_n$** score is therefore often used. It is the area under the curve up to the nth false positive, for example ROC$_1$ or ROC$_{50}$ (Gribskov and Robinson 1996).
- **Coverage versus errors per query.** Brenner et al. (1998) plotted the fraction of true relationships found (coverage) against the number of false positives per query. This shows directly how many homologues are found at an acceptable error rate.
- **Sensitivity up to the first false positive**, per query, averaged over all queries, is a common simple summary (used, for example, in the Foldseek and MMseqs2 papers; Section 1.4).
- **E-value calibration.** If E-values are correct, a search should produce on average E false positives with E-value at most E per query. Plotting the observed number of false positives against the reported E-value tests whether a method's statistics can be trusted. This is as important as sensitivity, because users choose thresholds based on E-values.
- **Speed**, in queries per hour or as a speed-up over BLAST, is always reported with a sensitivity measure. A faster method is only an improvement if it loses little sensitivity.

1.11.3 Pitfalls

Benchmarks are easy to design badly, and many published comparisons contradict each other for that reason.

- **Circularity.** If the reference set was built with one of the methods being compared, that method has an advantage. For example, Pfam families are defined by HMMER searches, so HMMER will look good on a benchmark based on Pfam membership.
- **Bias towards large families.** If every pair counts equally, a few very large superfamilies dominate the result. Results are usually weighted per query or per family, and redundant sequences are removed (for example, keeping only domains below 40% identity to each other).
- **"False" positives that are true.** Disagreement with a database classification is not automatically a biological false positive. Structural classifications are incomplete: relationships between superfamilies are still being discovered, and two superfamilies may later be merged or placed in the same ECOD homology group. Domain boundaries differ between SCOP, CATH and ECOD, and the schemes use different criteria for homology (Table 1.1). A hit counted as false may therefore be a real homologue classified in another superfamily, or a match to another domain in a multidomain protein. Ambiguous pairs should be excluded rather than counted as errors, and apparently false hits with very good scores are worth inspecting: some of them are discoveries.

- **Leakage in machine-learning methods.** A method that has been trained on sequences from the same families as the test set can appear to detect remote homologues while in fact recognising families it has seen. Training and test sets must be separated by superfamily or fold, not only by sequence identity. This is particularly important for deep-learning and language-model methods (Section 1.10), whose pre-training data may include the benchmark proteins themselves. Homology between training and test (or benchmark) sets is one of the most common reasons for inflated performance in bioinformatics, and it affects structure, function and interaction predictors as much as search methods; see 4.
- **Tuning on the test set.** Parameters chosen to maximise performance on a benchmark will overestimate how well a method works on new data. Independent test sets, or blind assessments such as CASP, avoid this.

When you read a claim that a new method "outperforms" existing ones, it is worth asking: what was the reference, how were true and false pairs defined, which measure was used, and could the method have seen the test data?

1.12 Key concepts

A checklist for revision. You should be able to explain each point, including the algorithm or argument behind it, and its limitations.

- **Homology:** definition as common ancestry (qualitative, not a percentage); orthologues, paralogues (in-/out-paralogues), xenologues, ohnologues; analogy and convergence; why significant similarity implies homology but not the reverse; the twilight and midnight zones; why proteins are compared rather than DNA
- **Dynamic programming:** principle of optimality; Needleman–Wunsch and Smith–Waterman recursions and traceback; semi-global, overlap and banded alignment; linear, affine and convex gap penalties; Gotoh's three-matrix algorithm; time and space complexity, Hirschberg/Myers–Miller linear space
- **Substitution matrices:** log-odds scores, target and background frequencies, relative entropy; how PAM and BLOSUM are derived and how their numbering differs; choosing a matrix
- **Heuristic search:** FASTA (k-tuples, diagonals, banded optimisation); BLAST (neighbourhood words, threshold T, X-drop, two-hit method, gapped extension); low-complexity filtering; the BLAST family and translated searches; DIAMOND, MMseqs2 and Linclust; Foldseek and the 3Di alphabet
- **Statistics:** why local scores follow a Gumbel distribution; Karlin–Altschul $E = Kmne^{-\lambda S}$; bit scores, E- and P-values; effective lengths, gapped and composition-based statistics; why E-values depend on database size while the score does not; per-query E-values versus multiple testing over many queries; query and target coverage
- **From hit to annotation:** checking the query (gene model, fragments, low complexity); identity with its denominator, coverage of both sequences and domain architecture; why the best (or reciprocal best) hit is not necessarily the orthologue; escalating to profiles, structure or embeddings without lowering the evidence standard; annotation statements that match the evidence; recording database release, program version and parameters

- **Exact matching:** suffix trees and arrays; the Burrows–Wheeler transform, LF mapping, FM-index and backward search; why they suit read mapping
- **Multiple alignment:** no single correct objective (SP, consistency, probabilistic and structure-aware surrogates); sum-of-pairs score and NP-hardness; progressive alignment and "once a gap, always a gap"; ClustalW, Clustal Omega, T-Coffee (consistency), MUSCLE and MAFFT (iterative refinement); benchmarks; alignment uncertainty, MUSCLE5 ensembles and trimming as a modelling choice
- **Motifs and profiles:** consensus, PROSITE patterns, PWMs with pseudocounts, information content and logos; Gibbs sampling and MEME; Gribskov profiles; sequence weighting and priors; computing a PSSM with background-weighted pseudocounts; PSI-BLAST and profile corruption (how to recognise and limit it); PSSM vs. profile HMM vs. pair HMM
- **Hidden Markov models:** states, transitions, emissions; Viterbi, forward, backward, posterior decoding and Baum–Welch; profile HMM architecture (match/insert/delete, Plan 7), local and glocal modes; HMMER3 filter pipeline and forward-score E-values; per-sequence vs. per-domain scores, independent vs. conditional E-values, reporting vs. inclusion thresholds; HHsearch/HHblits (HMM–HMM comparison); sequence–sequence < sequence–profile < profile–profile
- **Domains:** structural, folding and evolutionary definitions; multidomain proteins and architectures; why domains complicate annotation transfer; Pfam (seed/full alignments, gathering thresholds, clans), Pfam-N, InterPro; SCOP, CATH, ECOD and TED, and fold vs. superfamily; database-specific meanings of family, superfamily and clan
- **RNA homology search:** why structured RNA homologues often conserve structure better than sequence; compensatory mutations and covariation; Nussinov and Zuker folding algorithms; SCFGs and their relation to HMMs (CYK, inside–outside); covariance models, Infernal and its HMM filters; Rfam; limitations (pseudoknots, unstructured ncRNAs)
- **Whole-genome alignment and conservation:** why genomes are not aligned like genes (rearrangements, duplications, repeats, soft-masking); BLASTZ/LASTZ with spaced seeds; chains and nets; reference-based (MULTIZ) vs. reference-free (Enredo–Pecan, Progressive Cactus) multiple genome alignment and the Zoonomia alignment; Alignathon and the lack of ground truth; neutral models; phastCons (phylo-HMM), phyloP (conservation and acceleration, human accelerated regions) and GERP (rejected substitutions); use for non-coding elements and variant interpretation; caveats (alignment errors, branch length needed, lineage-specific function, biased gene conversion)
- **Alignment-free comparison:** k-mer statistics; MinHash and the Mash distance; ANI and Kraken; when alignment-free methods work and when they fail
- **Protein language models:** masked and autoregressive objectives; transformers and attention; UniRep, SeqVec, ESM, ProtTrans, ESMFold, ESM3; per-residue and per-protein embeddings and pooling; embedding search, TM-Vec, pLM-BLAST, PLMSearch; limitations (leakage, lack of statistics, bias towards well-sampled families)
- **Benchmarking:** structural classifications as an operational ground truth (and why disagreement is not always an error); ROC, ROC$_n$, coverage vs. errors per query, E-value calibration; circularity, family-size bias and train–test leakage

1.13 Recommended reading

These papers are recommended for reading in full:

- Smith and Waterman (1981) — The local alignment algorithm, in three pages.
- Altschul et al. (1997) — Gapped BLAST and PSI-BLAST; still the standard reference for heuristic search and profiles.

- Eddy (2011) — HMMER3; profile HMM search made as fast as BLAST, with a clear account of the statistics.
- Steinegger and Söding (2017) — MMseqs2; how sensitive search scales to billions of sequences.
- van Kempen et al. (2023) — Foldseek; searching with structure instead of sequence.

Titles, abstracts, links and the full texts are in Section A.1; a longer list of further papers is in Section B.1.

1.14 Background reading (open access)

- **Sequence homology (Wikipedia)** — Sequence homology is the biological homology between DNA, RNA, or protein sequences, defined in terms of shared ancestry in the evolutionary history of life.
  https://en.wikipedia.org/wiki/Sequence_homology
- **Sequence alignment (Wikipedia)** — In bioinformatics, a sequence alignment is a way of arranging the sequences of DNA, RNA, or protein to identify regions of similarity that may be a consequence of functional, structural, or evolutionary relationships between the sequences.
  https://en.wikipedia.org/wiki/Sequence_alignment
- **Needleman–Wunsch algorithm (Wikipedia)** — The Needleman–Wunsch algorithm is an algorithm used in bioinformatics to align protein or nucleotide sequences. It was one of the first applications of dynamic programming to compare biological sequences. The algorithm was developed by Saul B. Needleman and Christian D. Wunsch and published in 1970.
  https://en.wikipedia.org/wiki/Needleman%E2%80%93Wunsch_algorithm
- **Smith–Waterman algorithm (Wikipedia)** — The Smith–Waterman algorithm performs local sequence alignment; that is, for determining similar regions between two strings of nucleic acid sequences or protein sequences.
  https://en.wikipedia.org/wiki/Smith%E2%80%93Waterman_algorithm
- **Substitution matrix (Wikipedia)** — In bioinformatics and evolutionary biology, a substitution matrix describes the frequency at which a character in a nucleotide sequence or a protein sequence changes to other character states over evolutionary time.
  https://en.wikipedia.org/wiki/Substitution_matrix
- **BLOSUM (Wikipedia)** — In bioinformatics, the BLOSUM matrix is a substitution matrix used for sequence alignment of proteins. BLOSUM matrices are used to score alignments between evolutionarily divergent protein sequences. They are based on local alignments.
  https://en.wikipedia.org/wiki/BLOSUM
- **PAM (Wikipedia)** — A point accepted mutation — also known as a PAM — is the replacement of a single amino acid in the primary structure of a protein with another single amino acid, which is accepted by the processes of natural selection. This definition does not include all point mutations in the DNA of an organism.
  https://en.wikipedia.org/wiki/Point_accepted_mutation
- **BLAST (Wikipedia)** — In bioinformatics, BLAST is an algorithm and program for comparing primary biological sequence information, such as the amino-acid sequences of proteins, nucleotides of DNA and/or RNA sequences.
  https://en.wikipedia.org/wiki/BLAST_(biotechnology)
- **FASTA (Wikipedia)** — FASTA is a DNA and protein sequence alignment software package first described by David J. Lipman and William R. Pearson in 1985. Its legacy is the FASTA format which is now ubiquitous in bioinformatics.
  https://en.wikipedia.org/wiki/FASTA
- **NCBI: The Statistics of Sequence Similarity Scores** — Stephen Altschul's tutorial on the statistics of local alignment scores: the extreme value distribution, E-values, P-values and bit

scores, as used by BLAST.
https://www.ncbi.nlm.nih.gov/BLAST/tutorial/Altschul-1.html

- **Hidden Markov model (Wikipedia)** — In probability theory, a hidden Markov model (HMM) is a Markov model in which the observations are dependent on a latent Markov process. An HMM requires that there be an observable process whose outcomes depend on the outcomes of in a known way.
https://en.wikipedia.org/wiki/Hidden_Markov_model
- **Forward–backward algorithm (Wikipedia)** — The forward–backward algorithm is an inference algorithm for hidden Markov models which computes the posterior marginals of all hidden state variables given a sequence of observations/emissions , i.e. it computes, for all hidden state variables , the distribution . This inference task is usually called smoothing.
https://en.wikipedia.org/wiki/Forward%E2%80%93backward_algorithm
- **Additive smoothing ("pseudocounts") (Wikipedia)** — In statistics, additive smoothing, also called Laplace smoothing or Lidstone smoothing, is a technique used to smooth count data, eliminating issues caused by certain values having 0 occurrences.
https://en.wikipedia.org/wiki/Additive_smoothing
- **Multiple comparisons problem (Wikipedia)** — Multiple comparisons, multiplicity or multiple testing problem occurs when many statistical tests are performed on the same dataset. Each test has its own chance of a Type I error, so the overall probability of making at least one false positive increases as the number of tests grows.
https://en.wikipedia.org/wiki/Multiple_comparisons_problem
- **Family-wise error rate (Wikipedia)** — Family-wise error rate (FWER) is a term from statistics for the probability of making one or more false discoveries, or type I errors when performing multiple hypotheses tests. FWER is a metric that quantifies the risk caused by multiple testing.
https://en.wikipedia.org/wiki/Family-wise_error_rate
- **Multiple sequence alignment (Wikipedia)** — Multiple sequence alignment (MSA) is the process or the result of sequence alignment of three or more biological sequences, generally protein, DNA, or RNA. These alignments are used to infer evolutionary relationships via phylogenetic analysis and can highlight homologous features between sequences.
https://en.wikipedia.org/wiki/Multiple_sequence_alignment
- **A tutorial on Burrows–Wheeler indexing methods** — A step-by-step blog tutorial (The Grand Locus) on the Burrows–Wheeler transform, the FM-index and backward search, the data structures behind read mappers such as BWA and Bowtie.
http://blog.thegrandlocus.com/2016/07/a-tutorial-on-burrows-wheeler-indexing-methods

1.15 Student recommendations

Recommended by students preparing for the exam: papers, reviews, online lectures, tutorials and short explanations. To suggest something, use the suggestion form (SU login).

No recommendations yet.

1.16 Review problems

These problems are adapted from Matteo Tadiello, *Modern Bioinformatics: From Foundations to Frontiers* (CC BY 4.0), used with permission. For a longer treatment of this topic, see the chapters "Sequence Alignment and Search Foundations" and "Sequence Databases, BLAST, and Profile HMMs" of that book. In the HTML version, click a box to show the extensions, solution outline and common errors.

1.16.1 Derive global and local alignment

Derive the dynamic-programming recurrences for global and local pairwise sequence alignment. Explain which biological questions each formulation answers, and why neither recurrence gives a uniquely true evolutionary alignment.

Extensions, solution outline and common errors

Extensions:

- Give the optimal-substructure argument from the three possible final columns of an alignment.
- Compare initialisation, termination and traceback for global, local and semi-global alignment.
- Derive the time and memory complexity for sequences of lengths n and m.
- How would you test whether the result for a protein pair with uncertain terminal homology depends on the alignment mode?

Solution outline:

1. Define F_{ij} as the optimal score of the prefixes $A_{1:i}$ and $B_{1:j}$; the final column must be a residue pair or a gap in one of the two sequences.
2. Write the recurrence with a diagonal, a vertical and a horizontal move, using a substitution score and a linear gap cost.
3. For global alignment, penalise leading gaps and trace back from F_{nm}. For local alignment, add zero to the maximum, initialise the first row and column to zero, start the traceback at the highest cell and stop at a zero.
4. State $O(nm)$ time and $O(nm)$ memory for the traceback matrix; distinguish computing the score alone in linear memory from reconstructing the alignment (Hirschberg, Myers–Miller).
5. Use global alignment for sequences expected to correspond over most of their lengths, local alignment for a shared domain or a fragment, and semi-global alignment when terminal gaps should be free.
6. Conclude that the optimum depends on the substitution scores, the gap model, the boundary conditions and any masking.

Common errors:

- Describing the optimum under one scoring system as the biological truth.
- Changing only the traceback, without the zero and the boundary conditions of local alignment.
- Aligning proteins with different domain architectures globally without considering alternatives.

Connections: Section 1.3; insertions and deletions in evolution (Chapter 3); alignments as uncertain input to phylogeny (Section 4.4); structure-based alignment (Section 9.6).

1.16.2 Interpret substitution scores and affine gaps

Explain why empirical substitution matrices and affine gap costs are used in protein alignment. Derive their computational representations, and identify the evolutionary approximations that they make.

Extensions, solution outline and common errors

Extensions:

- Derive the log-odds interpretation of $s(a, b)$.
- Contrast the construction and intended use of PAM and BLOSUM matrices.
- Explain why affine gaps require separate match and gap states (Gotoh's algorithm).
- Predict how changing g_o and g_e affects the number and length of gaps in an alignment.

Solution outline:

1. Compare the frequency q_{ab} of the pair in alignments of related sequences with the frequency $p_a p_b$ expected by chance, giving $s(a, b) = \lambda^{-1} \log[q_{ab}/(p_a p_b)]$.
2. Positive scores favour the model of related sequences, negative scores the background model, under the assumed frequencies.
3. PAM matrices extrapolate a Markov model of accepted mutations from close relatives; BLOSUM matrices are estimated directly from conserved ungapped blocks after clustering sequences above a given identity.
4. Larger PAM numbers, but smaller BLOSUM numbers, are meant for more divergent sequences; the best matrix still depends on the task.
5. Define $g(k) = g_o + (k-1)g_e$ and show that separate dynamic-programming states are needed to distinguish opening a gap from extending one.
6. Gap penalties are a convenient approximation to insertion and deletion processes, not a mechanistic model of them.

Common errors:

- Calling a conservative, positive-scoring substitution an identity.
- Claiming that one substitution matrix is best for all purposes.
- Copying gap parameters between programs without checking whether a gap of length one costs g_o or $g_o + g_e$.

Connections: Section 1.3; divergence and protein evolution (Section 3.5); substitution models in phylogenetics (Section 4.3.6); likelihood ratios and model validation (4).

1.16.3 Interpret a database-search result

A BLAST hit has $E = 10^{-20}$, 35% identity and 60% query coverage. What may be concluded, what remains unresolved, and what further information is needed?

Extensions, solution outline and common errors

Extensions:

- Define the E-value and distinguish it from the probability that the sequences are homologous.
- Explain how the size of the database affects the E-value for a fixed raw score.
- Compare raw score, bit score, percent identity and the coverage of both sequences.
- Design the checks needed before transferring a molecular function.

Solution outline:

1. Ask for the alignment length, target coverage, query and target lengths, the gaps, the

composition of the aligned region, the database release and the search parameters.
2. Define the E-value as the expected number of chance alignments with at least this score, under the null model and in a search space of this size.
3. Use $E \approx Kmne^{-\lambda S} = mn\,2^{-S'}$ to relate the raw score S, the bit score S', the effective lengths m and n, and the parameters K and λ.
4. After checking for low complexity and masking, the hit is strong evidence of local similarity; decide whether the aligned segment covers a whole protein or only a domain.
5. Homology is then the most likely explanation for the aligned region; orthology cannot be inferred from the rank of a hit.
6. Before assigning a detailed function, require conserved functional residues, a compatible domain architecture, evolutionary context and, preferably, experimental evidence.

Common errors:

- Reading 10^{-20} as the probability that the sequences are not homologous.
- Reporting percent identity without saying over how many positions.
- Equating the lowest E-value with orthology or with the same function.

Connections: Section 1.4; database composition and annotation errors (Section 2.2); homology and orthology (1, Section 3.4); function prediction (Section 10.4).

1.16.4 Compare exact and heuristic search

Explain why BLAST is faster than running Smith–Waterman against every database sequence, and describe the true relationships that a seed-and-extend heuristic can miss.

Extensions, solution outline and common errors

Extensions:

- Divide seed-and-extend into seeding, extension, gapped alignment and statistics.
- Identify the parameters that control the trade-off between sensitivity and speed.
- Compare the overall strategies of BLAST and MMseqs2.
- How would you compare two search programs fairly?

Solution outline:

1. Smith–Waterman fills the whole dynamic-programming matrix for every pair; BLAST first finds short high-scoring words and extends only around them.
2. Gapped alignment is computed only for a small set of candidates, so most database sequences are never aligned; the scores of the alignments that are computed mean the same as before.
3. Word size, neighbourhood threshold T, substitution matrix, masking, composition correction, gap costs and the E-value threshold together determine sensitivity and speed.
4. A homologue is missed if no seed passes the filter, even if its optimal local alignment would be significant: typically short, gap-rich alignments without a conserved stretch.
5. MMseqs2 also uses a k-mer prefilter (with similar, not only identical, k-mers) followed by ungapped and gapped alignment, but is designed for very large data sets with vectorisation and parallelisation.
6. Compare methods on the same frozen database and hardware, with a benchmark of known relationships, and compare sensitivity at the same error rate as well as running time and memory.

Common errors:

- Assuming that a heuristic computes an approximate score for every target; most targets never reach the alignment step.
- Treating a named program as having one fixed sensitivity.
- Comparing running times without the same database, hardware and sensitivity.

Connections: Section 1.4; benchmarking search methods (Section 1.11); indexing for read mapping (Section 5.4).

1.16.5 Control an iterative profile search

Explain how PSI-BLAST can detect remote homologues, and describe controls that limit profile drift during the iterations.

Extensions, solution outline and common errors

Extensions:

- Define what a position-specific scoring matrix (PSSM) represents.
- Explain the roles of sequence weighting and pseudocounts.
- Distinguish an inclusion threshold from a reporting threshold.
- When should the iterations be stopped?

Solution outline:

1. Start with an ordinary BLAST search, align the hits below the inclusion threshold to the query, and estimate position-specific log-odds scores.
2. Weight sequences to reduce the influence of densely sampled subfamilies, and add pseudocounts to regularise columns with few sequences.
3. Search again with the PSSM, and include only hits that pass the inclusion threshold.
4. Check the new hits of each round: do they cover the whole domain, do they have a compatible architecture and composition, and do they keep the conserved residues?
5. Mask low-complexity regions, use composition-based statistics, and keep the profile and the list of included sequences from each round.
6. Stop at convergence or when new hits become doubtful, and confirm the final set with an independent method, such as a curated profile HMM, structure comparison or a phylogenetic analysis.

Common errors:

- Including every displayed hit in the next round.
- Letting one shared domain justify a full-length multiple alignment.
- Assuming that more iterations always give better results.

Connections: Section 1.6; redundancy and sampling bias in databases (Section 2.2); paralogy and orthology (Section 3.4); annotation transfer (Section 10.4).

1.16.6 Explain profile hidden Markov models

What does a profile hidden Markov model represent that a PSSM does not, and how does this difference affect remote-homology detection and the interpretation of hits?

Extensions, solution outline and common errors

Extensions:

- Define match, insert and delete states and what each emits.
- Contrast Viterbi and forward scores.
- Distinguish per-domain from per-sequence significance in HMMER output.
- How are family-specific thresholds such as Pfam's gathering threshold set?

Solution outline:

1. A PSSM represents position-specific residue preferences; a profile HMM also represents position-specific probabilities of insertions and deletions.
2. Match states emit residues in consensus columns, insert states emit extra residues, and silent delete states skip consensus columns.
3. The Viterbi algorithm finds the single most probable state path; the forward algorithm sums over all paths, which is more sensitive when the alignment of a remote homologue is uncertain.
4. Separate the evidence for one domain from the summed evidence over a multidomain target; independent and conditional domain E-values answer different questions.
5. The model depends on a curated, representative seed alignment, sequence weighting, priors and the alignment mode (local or glocal).
6. Thresholds are set by curators so that no known false positives are included; domain membership and specific function must still be validated separately.

Common errors:

- Saying that delete states emit gap characters.
- Treating a significant domain match as proof of the function of the whole protein.
- Treating a profile as objective while ignoring the curation of its seed alignment.

Connections: Section 1.6; Pfam and InterPro (Section 1.9); structural families (Section 9.6); domain-based function prediction (Section 10.4).

1.16.7 Diagnose low complexity and domain rearrangement

The strongest database hits to a query align only to a low-complexity region rich in coiled coils. How would you distinguish a biologically informative relationship from an artefact of composition?

Extensions, solution outline and common errors

Extensions:

- Explain why biased composition changes the distribution of scores expected by chance.
- Contrast hard masking, soft masking and composition-based score correction.
- When can masking remove a real signal?
- How does the domain architecture change what is being tested for homology?

Solution outline:

1. Treat the result as uncertain, since biased composition can give high scores between unrelated segments when the background model does not fit.
2. Map low-complexity regions, repeats, coiled coils, transmembrane helices, disordered segments and candidate globular domains before searching again.
3. Apply masking (for example SEG) and composition-based statistics, and compare masked with unmasked results.
4. Search the candidate domains separately, and report the coverage of both query and target for every hit kept.
5. Look for supporting evidence outside the biased region: profiles, structure, conserved gene order, phylogeny or functional residues.
6. If the biased region remains the only evidence, report the relationship as unresolved.

Common errors:

- Declaring every low-complexity match an artefact.
- Masking without recording what was masked and how.
- Inferring full-length homology from a repeat shared by proteins with different architectures.

Connections: Section 1.4, Section 1.9; repeats in genomes (Section 6.7); disorder and structure prediction confidence (Section 9.8); interactions through coiled coils (Chapter 11).

1.16.8 Combine sequence, structure and embedding search

Sequence searches fail to find a plausible relative of a protein with a predicted structure. Compare profile, Foldseek and protein-language-model embedding searches, and describe how you would combine their evidence.

Extensions, solution outline and common errors

Extensions:

- Explain how Foldseek turns a three-dimensional structure into a searchable sequence.
- When may structural similarity reflect convergence rather than common ancestry?
- Define an embedding nearest neighbour, and explain why an embedding distance is not an evolutionary distance.
- How should a remote-homology benchmark be designed to avoid information leakage?

Solution outline:

1. Choose the next method from the available evidence: a family alignment supports a profile search, a reliable structure supports a structure search, and embedding search can propose candidates for sequences alone.
2. Foldseek describes each residue by a 3Di letter for its tertiary interactions with a neighbour, then uses MMseqs2-style prefiltering and alignment; check the aligned fold coverage, topology and confidence (pLDDT) of the model.
3. Physical constraints and convergent evolution can give similar folds without detectable common ancestry.
4. An embedding is a vector produced by a model and a pooling rule; its neighbours depend on the model, the distance measure and the reference database.

5. Check all candidates with residue-level alignment, profiles, structure, phylogeny and functional residues.
6. Benchmark with splits by superfamily or cluster rather than at random, with frozen databases and a check for overlap with the training data.

Common errors:

- Treating a predicted structure as an experimental observation, ignoring confidence and disorder.
- Inferring homology from a shared fold alone.
- Reporting performance on random splits as evidence of generalisation to remote families.

Connections: Section 1.4, Section 1.10, Section 1.11; predicted structures and their confidence (Section 9.8); foundation models (Section 12.6); function prediction (Section 10.4).

1.16.9 Interpret conservation in a non-coding region

A patient carries a de novo variant 40 kb upstream of a developmental gene. The base has a high phyloP score and lies in a phastCons element in the 241-mammal alignment. Explain what these scores measure, and what they do and do not tell you about the variant.

Extensions, solution outline and common errors

Extensions:

- Why can a mammalian genome alignment not be computed like a Needleman–Wunsch alignment of two genes?
- What are chains and nets, and how do they separate orthologous from paralogous alignments?
- How do phastCons, phyloP and GERP differ in what they report?
- What would a strongly negative phyloP score on the human branch mean?

Solution outline:

1. A whole-genome alignment must handle rearrangements, duplications and repeats: local matches are found (for example with LASTZ), chained into collinear blocks and filtered into nets, and combined into a multiple alignment with MULTIZ or a reference-free method such as Progressive Cactus.
2. Conservation is measured against a neutral model estimated from, for example, fourfold degenerate sites: phyloP tests each base for fewer (or more) substitutions than expected, phastCons gives the posterior probability that a base lies in a conserved element from a phylo-HMM, and GERP counts rejected substitutions.
3. A high score means that the base has been under purifying selection across mammals, so some function is likely and a change is more likely to matter.
4. It does not show which gene the element regulates, whether the variant changes its activity, or that the function is the same in humans; experimental evidence (reporter assays, chromatin data, segregation, phenotype match) is needed.
5. Check the alignment locally: missing species, paralogous alignment or an assembly gap can create apparent conservation.

Common errors:

- Treating conservation as proof of pathogenicity.
- Treating lack of conservation as proof that a region has no function (lineage-specific elements).
- Ignoring the depth of the alignment: a few primates cannot give base-level resolution.

Connections: Section 1.8; synteny and rearrangements (Section 6.5); how much of the genome is functional (Section 6.9); variant effect prediction (Section 10.6).

2 Databases

> **From the exam description**
>
> Knowledge of bioinformatics' most important databases and understanding their hierarchy and relationships.

> **This chapter is an overview, and will date**
>
> Databases change constantly: new resources appear, others merge or close, and sizes grow (or, as for UniProt in 2025, shrink by design). The numbers in this chapter are snapshots from October 2026 and are given only to show orders of magnitude. What matters for the exam is *what kind* of data each resource holds, where the data come from, how reliable they are, and how the resources relate to each other, not the current number of entries. For up-to-date descriptions, see the latest *Nucleic Acids Research* database issue (Rigden and Fernández 2025).

2.1 Overview

Bioinformatics depends on public databases, and knowing what each one contains, where its data come from and how much to trust it is a core skill. This chapter starts with the general principles: primary and secondary databases, curation and error propagation, identifiers, releases, licences and FAIR data, and how data and literature are retrieved (Section 2.2). It then goes through the main groups of resources:

- sequence databases: the nucleotide archives, UniProt, metagenomic sequences and protein families (Section 2.3);
- genome databases and browsers, annotation formats and coordinate conventions, and taxonomy databases (Section 2.4);
- experimental and predicted structures (Section 2.5);
- function and pathways: GO, KEGG, Reactome, ontologies and knowledge graphs, and how function prediction is evaluated (Section 2.6);
- interactions and networks (Section 2.7);
- expression and proteomics repositories (Section 2.8);
- medical, variant and cancer data, and controlled access to personal data (Section 2.9).

2.2 How biological databases work

2.2.1 Primary and secondary databases

It is useful to divide databases into two kinds.

- **Primary (archival) databases** store data as submitted by the people who produced it: nucleotide sequences, sequencing reads, structures, expression measurements, mass spectra. Their job is to preserve the record. The submitter, not the database, is responsible for the content, and errors are corrected only if the submitter updates the entry.
- **Secondary (derived or curated) databases** build on the primary data. They remove redundancy, add annotation, classify, integrate and interpret. Examples are RefSeq and UniProtKB/Swiss-Prot for sequences, Pfam and InterPro for families, SCOP and CATH for structures, and Reactome for pathways.

The secondary databases are themselves of two kinds. **Curated knowledgebases**, such as UniProtKB/Swiss-Prot, Reactome and the model organism databases, are built by experts who read the literature and record the evidence for each statement. **Derived resources** are computed from the archives with little or no manual review: clustered sets such as UniRef, automatic annotation such as UniProtKB/TrEMBL, precomputed family matches, and collections of predicted structures. Two pairs are often confused. GenBank, ENA and DDBJ form the primary archive of submitted nucleotide sequences, while RefSeq is a secondary, NCBI-maintained selection built from them. Swiss-Prot and TrEMBL are both part of UniProtKB, but only Swiss-Prot is manually reviewed (Section 2.3). The word "database" covers all of these; what matters is who produced the content and how it was checked.

Most major journals require that new sequences, structures and many other data types are deposited in the appropriate primary archive before a paper is published. This rule, which began with nucleotide sequences and the PDB in the 1980s and 1990s, is the reason why these archives are close to complete.

Databases are also organised along the **central dogma**. There are separate, cross-referenced resources for DNA (genomes and their annotation), RNA (transcripts) and protein (sequences, families, structures), and for what proteins do (functions, pathways, interactions). Knowing which *level* you need is the first step of any search.

2.2.2 Curation, automatic annotation and error propagation

Only a small fraction of database entries has been examined by a person. In 2026, UniProtKB/Swiss-Prot contains about half a million manually reviewed proteins, while the automatically annotated part, TrEMBL, contains more than a hundred million (Section 2.3). For most sequences, the annotation has been transferred automatically from a similar entry, which itself may have been annotated automatically.

This creates the risk of **error propagation**. A wrong function assigned to one protein is transferred to its homologues, then to theirs, and soon appears in thousands of entries that seem to support each other. Errors of this kind are common for multidomain proteins, where a hit to one domain is taken as evidence for the function of the whole protein (Section 1.9), and for paralogues with different functions. Good practice is therefore to check the **evidence** behind an annotation: whether it comes from an experiment on that protein, from curated literature, or from an automatic method. Evidence codes in the Gene Ontology (Section 2.6) and the "reviewed" status in UniProt make this possible.

Redundancy is another problem. Some proteins and genomes are sequenced thousands of times (for example, strains of *E. coli* or SARS-CoV-2), while most organisms are represented by a single genome or not at all. Search results and statistics can therefore be dominated by a few well-studied groups. Clustered and non-redundant databases, such as UniRef or the reference proteomes of UniProt, reduce this effect.

2.2.3 Records as evidence

A useful way to read any database entry is as a **versioned claim**: a statement about a biological entity, made by an identifiable source, on the basis of some evidence, in a particular release. Three layers are mixed on a typical gene or protein page. The **data** are the observations themselves (bases, reads, spectra, atomic coordinates). The **metadata** describe the context needed to interpret them: organism, sample, assay, instrument, reference assembly, processing. **Knowledge assertions** connect entities to interpretations, such as "protein P catalyses reaction R" or "variant V is pathogenic for condition C". An experimentally determined sequence, a predicted gene model, a curated function and an automatically transferred GO term can all appear side by side, in the same font.

Before trusting a statement, it should therefore be traced back to where it came from: who submitted or curated it, what it was computed from, and which release it belongs to. Several consequences follow.

- **Agreement is not independence.** If three databases call a protein a kinase, but two of them copied the annotation from the third, or all three transferred it from the same characterised homologue, there is one piece of evidence, not three. What counts is the number of independent experimental sources.
- **Absence is not evidence of absence.** A missing record means "not represented under this query in this release", not that the molecule, interaction or variant does not exist. What is in the databases is strongly biased towards model organisms, abundant and easily studied proteins, and well-funded diseases.
- **"Primary" is not a quality label.** Archived data can contain submitter errors, contamination or wrong sample labels, and a derived resource can be more reliable than the archive it is built from. The roles describe where the data come from, not how good they are. One resource can also play several roles: UniProtKB stores sequences translated from the archives, computes automatic annotation, curates the literature and integrates cross-references.
- **Test the evidence policy.** A simple robustness check is to repeat an analysis under two defensible policies, for example with reviewed UniProtKB entries only and with all entries, or with experimental GO evidence only and with all evidence codes. If the conclusion changes, the choice of evidence is part of the result.

2.2.4 Identifiers: accession numbers and names

Four kinds of identifier are easily confused:

- An **accession number** is a stable identifier for a record, unique *within one database*. It is kept when the record is updated, and the same gene has different accessions in GenBank, RefSeq, Ensembl and UniProt. Old accessions are kept as secondary accessions when records are merged.
- A **versioned accession** (`accession.version`) identifies one exact sequence. The version increases when the sequence changes, but not when only the annotation changes. For example, `NM_000518.5` is version 5 of the RefSeq mRNA for human β-globin. Ensembl uses a similar convention, in which the version of a gene or transcript identifier (such as `ENSG00000244734` for β-globin) increases when its structure changes. A result should always cite the accession *with* its version, because the sequence behind an accession without a version can change. UniProt keeps the version separately, as the *sequence version* of an entry.
- Other **database-specific identifiers and names** are meant for people rather than for stable reference. The UniProt entry name `HBB_HUMAN` can change, while the accession `P68871` does not. The **official gene symbol** (for human genes, assigned by the HUGO Gene Nomenclature Committee, HGNC, which also gives each gene a stable `HGNC:` identifier) is shared across databases, but symbols can change, and the same symbol may have been used for different genes in the past.

- **Persistent identifiers** such as the **DOI** (digital object identifier) are designed to resolve to an object for the long term, wherever it is hosted. DOIs identify papers, but also data sets (for example deposits in Zenodo) and PDB entries.

Cross-references connect the records for the same molecule in different databases. The β-globin gene, for example, is NCBI Gene `3043` and HGNC `HGNC:4827`, lies on chromosome 11 (`NC_000011.10`), has the mRNA `NM_000518.5` and the protein `NP_000509.1` in RefSeq, the UniProt entry `P68871` (HBB_HUMAN), the InterPro family `IPR000971` (Globin), and the structure `2HHB` in the PDB. Mapping between identifier types, with services such as UniProt ID mapping or Ensembl BioMart, is a routine but error-prone step. The mapping is rarely one-to-one: a gene has several transcripts and protein isoforms, a UniProt entry may merge several nucleotide records, and some identifiers are retired or split between releases. Unmapped or multiply mapped identifiers should be counted and reported, not silently dropped.

It helps to think of identifier mapping as a *join* between two tables rather than as replacing one string with another (Figure 2.1). Every mapping has a direction and a type (a transcript *translates to* a protein, a gene *has* a transcript), comes from a particular mapping release, and falls into one of four classes: one-to-one (still dependent on versions), one-to-many (isoforms, paralogues, split records), many-to-one (redundant records, aggregation), or unmapped (retired identifiers, the wrong namespace, a release mismatch). The rule used to resolve ambiguous cases should depend on the question: summing transcripts to genes may be right for gene-level expression, but it destroys the object of study in an analysis of isoform-specific function. Taking the first hit is never a rule.

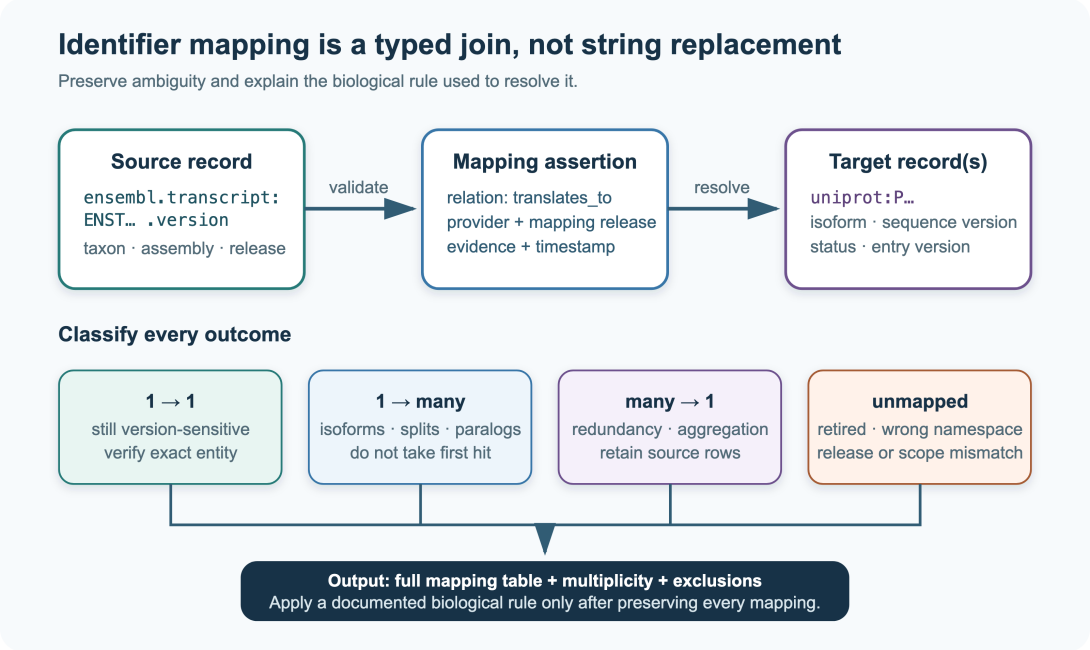

Figure 2.1: Identifier mapping as a typed join. A source record (here an Ensembl transcript with its version) is mapped through an explicit relation, with its provider and release, to one or more target records (here UniProt entries). Every outcome is classified, and the full mapping table, including multiple mappings and failures, is kept. Figure: Matteo Tadiello, *Modern Bioinformatics: From Foundations to Frontiers* (CC BY 4.0).

Three further pitfalls are common:

- An accession only means something within its **namespace**: `P04637` is a UniProt accession, `GO:0006915` a GO term. **Compact identifiers** of the form `prefix:accession` (for example

`uniprot:P04637`) make the namespace explicit and can be resolved by services such as Identifiers.org (Wimalaratne et al. 2018).

- A **genomic coordinate is not an identifier**. `chr7:117,559,590` is ambiguous without the assembly (GRCh37 or GRCh38), the contig accession, whether positions are counted from 0 or 1, and how the alleles are written (Section 2.4). Converting coordinates between assemblies is a transformation that can fail, not a lookup.
- **Spreadsheets corrupt identifiers.** Opened in a spreadsheet program, gene symbols such as *SEPT2* or *MARCH1* were silently converted into dates, and long numeric identifiers into floating-point numbers. A survey found such errors in about a fifth of the papers whose supplementary spreadsheets contained gene lists (Ziemann et al. 2016); HGNC has since renamed the affected genes (to *SEPTIN2* and *MARCHF1*). Identifiers should be kept as text, and ideally not handled in spreadsheets at all.

2.2.5 Retrieval: Entrez, EBI Search and APIs

The large data centres provide integrated search systems over all their databases.

- **Entrez** is NCBI's search system. It links some 40 databases (nucleotide, protein, gene, genome, structure, taxonomy, PubMed and others) so that one can move from a paper to the sequences it describes, and from a gene to its protein, variants and structures (Sayers et al. 2024).
- **EBI Search** plays the same role for the resources at EMBL-EBI (ENA, UniProt, InterPro, PDBe, Ensembl, Expression Atlas and many others).
- Almost every major database also has a **programmatic interface (API)**, usually a REST service that returns data in JSON or a standard file format. Examples are NCBI's E-utilities, the UniProt and Ensembl REST APIs, and the RCSB PDB search and data APIs. Programmatic access is how large analyses are done, and it makes them easier to reproduce, because the exact query and database release can be recorded (Programming and reproducible research).

Many resources can also be downloaded in full. For large analyses this is often the best option, since it fixes the database version used.

A programmatic query should be treated like any other method. Record the literal query, the filters and the date; check that the number of records retrieved matches the number the server reports (results usually come in pages, and an interrupted download is easy to miss); keep the raw responses; and respect the service's usage rules. NCBI's E-utilities, for example, allow three requests per second without an API key and ten with one. Documented APIs and bulk downloads are preferable to extracting data from web pages, whose layout can change at any time.

2.2.6 Releases, versions and reproducibility

Databases are not fixed objects. UniProt, Pfam, Ensembl, GENCODE and most other resources appear in numbered or dated **releases**, and between releases entries are added, corrected, merged and deleted. The same query can therefore give different answers a year apart. A BLAST E-value depends on the size of the database searched (1), a GO enrichment depends on the annotations in that release, and the 2025 reduction of UniProtKB (Section 2.3) changed the content of every search against it. The database release, or the download date for resources without releases, is therefore part of every computational result, in the same way as the software version and the parameters. Record it in the methods, and keep or deposit the exact files used when the analysis must be reproducible (Programming and reproducible research).

2.2.7 Licences, FAIR data and access

Most core resources are free to use, but their **licences** differ. INSDC data carry no restrictions on use, PDB data are released under CC0, and UniProt under CC BY 4.0, which requires attribution. Some resources, such as KEGG (Section 2.6), OMIM and COSMIC (Section 2.9), are free to browse but require a licence for bulk download or commercial use. The licence matters when data are redistributed, for example as part of a derived database or a training set for a machine-learning model.

The **FAIR principles** state that data should be *findable*, *accessible*, *interoperable* and *reusable* (Wilkinson et al. 2016). In practice this means persistent identifiers, rich metadata, standard formats and vocabularies (such as the ontologies in Section 2.6) and a clear licence. FAIR does not mean open: data can be FAIR and still be under controlled access. Human genetic and health data are the main example. They are deposited in controlled-access archives such as dbGaP and EGA, where use is limited by the consent of the participants (Section 2.9).

2.2.8 The literature: PubMed, PMC and preprints

The scientific literature is itself a database. **PubMed**, run by NCBI, indexes the biomedical literature from MEDLINE and other sources: about 41 million records in October 2026. Records are indexed with Medical Subject Headings (MeSH), and searches can be combined with Boolean operators (`AND`, `OR`, `NOT`) and exact phrases in quotation marks. **PubMed Central** (PMC) is the free full-text archive, with about 12.7 million articles, roughly a third of PubMed. **Preprint servers**, above all bioRxiv for biology, make papers available before peer review. Preprints are now a normal part of the literature in bioinformatics, but they have not been reviewed and should be read with that in mind.

Every January, *Nucleic Acids Research* publishes a **database issue** with papers on new and updated databases (182 papers in 2026), and maintains a collection of more than 2,000 molecular biology databases (Rigden and Fernández 2025). It is the best place to find the current description of nearly every resource in this chapter.

2.2.9 Choosing a resource for a question

The rest of this chapter goes through the resources by data type. In practice the choice starts from the question, and each question has its own pitfalls:

Question	Where to start	What to check
What sequence was submitted?	INSDC: GenBank, ENA, DDBJ (Section 2.3)	Accession and version, sample metadata, contamination
What is the reference transcript or protein?	RefSeq, Ensembl (Section 2.4)	Assembly and annotation release, transcript version, MANE status
What is known about a protein?	UniProtKB	Reviewed or not, which isoform, evidence for each statement
Which domains or families does it contain?	InterPro and its member databases	Which method, match coordinates and thresholds, architecture
Is there an experimental structure?	PDB (Section 2.5)	Method, resolution and validation, construct, biological assembly
Is there a predicted structure?	AlphaFold DB and other model archives	That it is a prediction; model version; pLDDT and PAE

Question	Where to start	What to check
What does it do, in which pathway?	GO, Reactome, KEGG (Section 2.6)	Evidence codes, ontology release, whether pathway membership was transferred from another species
What does it interact with?	IntAct, BioGRID, STRING (Section 2.7)	Physical interaction or functional association; evidence type
Where and when is it expressed?	GEO, Expression Atlas, GTEx (Section 2.8)	Study design, sample metadata, raw versus processed data
Is a variant common, and has it been interpreted?	gnomAD, ClinVar (Section 2.9)	Ancestry and coverage; review status, condition and conflicts

The same molecule is represented differently in each of these resources (Figure 2.2). A submitted genomic sequence can give several transcripts; the canonical UniProt sequence need not be the construct that was crystallised; a pathway assignment may have been inferred from another species. The organism, accession and version, assembly, isoform or construct, the type of each link and the release must therefore be carried along at every step. The question is not just "where is this protein?" but "which representation of this protein supports which claim?"

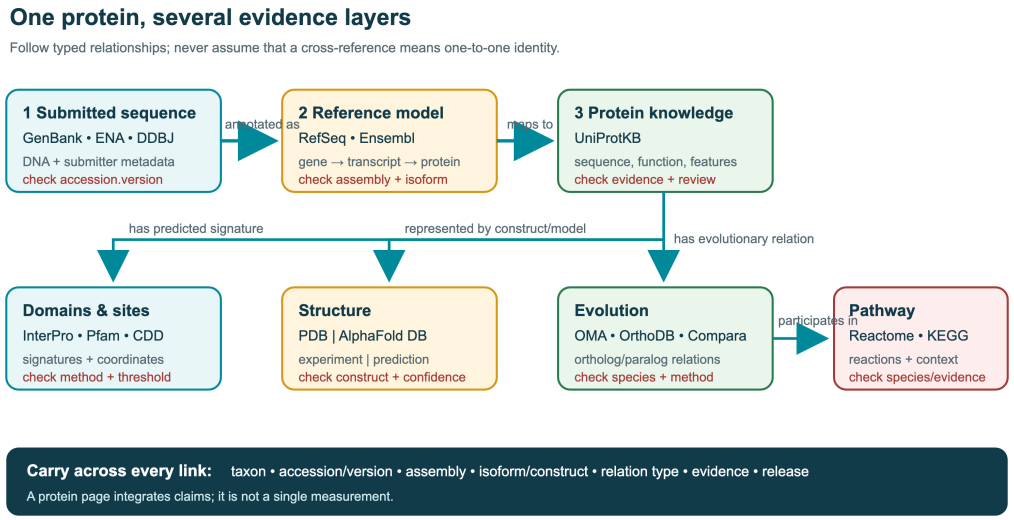

Figure 2.2: One protein seen through several evidence layers: the submitted sequence, the reference gene, transcript and protein models, the UniProtKB entry, and from there domains and sites, experimental or predicted structures, orthologues and pathways. The arrows are typed relationships, not statements that the records are identical. Figure: Matteo Tadiello, *Modern Bioinformatics: From Foundations to Frontiers* (CC BY 4.0).

Sources

Parts of this section are adapted from the Wikipedia articles Biological database, Accession number (bioinformatics), Entrez and PubMed (CC BY-SA 4.0, retrieved 2 October 2026). The structure and the β-globin example follow the database session of the KB8029 course book. Counts were

retrieved from the NCBI E-utilities on 2 October 2026. Parts of this section are adapted from Matteo Tadiello, *Modern Bioinformatics: From Foundations to Frontiers*, chapter "Biological Data, Databases, and Provenance" (CC BY 4.0), used with permission.

2.3 Sequence databases

2.3.1 The nucleotide archives: INSDC

All published nucleotide sequences are archived by the **International Nucleotide Sequence Database Collaboration (INSDC)** (Arita et al. 2020). It has three partners, which exchange their data every day so that the same records are available from all three:

- **GenBank** at NCBI in the USA, founded in 1982 at Los Alamos;
- the **European Nucleotide Archive (ENA)** at EMBL-EBI in the UK, whose predecessor, the EMBL Data Library, started in 1980;
- the **DNA Data Bank of Japan (DDBJ)**, founded in 1986.

INSDC is therefore one shared collection with three access points, not three independent databases: searching or counting all three gives the same records, not three times as many. Researchers submit to any of the three, and the record receives an accession number that is valid in all. The archives are not curated in the sense of being corrected by the database. An INSDC record is the submitter's sequence and annotation, and stays that way unless the submitter updates it. Data are free to use without restriction. The archives have grown with sequencing technology: GenBank release 271 (April 2026) contained more than 50 trillion bases in over six billion records, most of them from whole-genome shotgun and other bulk projects.

Raw sequencing data are kept separately, in the **Sequence Read Archive** (SRA) at NCBI and in ENA, which also mirror each other. A sequencing study is organised in a hierarchy of *study*, *sample*, *experiment* and *run* records, so that reads can be traced back to the biological samples they came from. Assembled genomes, transcriptome assemblies, and metadata about samples (BioSample) and projects (BioProject) are linked to the reads. Raw data are essential for reanalysis, but they are now so large that the archives store some of them in compressed or reduced forms.

2.3.2 Curated nucleotide and gene resources

Because the archives contain many redundant, partial and differently annotated records, curated resources have been built on top of them. **RefSeq** at NCBI, started in 2000, is such a secondary resource, not part of the INSDC archive. It provides a single, non-redundant, annotated record for each genomic sequence, transcript and protein of a selected organism (O'Leary et al. 2015). The accession prefix shows the type of molecule: `NC_` (complete chromosome), `NM_` (mRNA), `NR_` (non-coding RNA), `NP_` (protein), and `XM_`/`XP_` for transcripts and proteins predicted by the annotation pipeline but not yet supported by curated evidence. **NCBI Gene** collects information about each gene, and **Ensembl** provides the European counterpart for genomes and their annotation (Section 2.4).

2.3.3 Protein sequences: UniProt

Almost no protein sequences are determined directly any more. They are translated from genes predicted in sequenced genomes. **UniProt**, the Universal Protein Resource, is the central database for protein sequences and their functions (Bateman et al. 2024). It was formed in 2002 by combining

three older resources: **Swiss-Prot**, started by Amos Bairoch in 1986 in Geneva; its automatically annotated supplement **TrEMBL** (1996); and the **Protein Information Resource (PIR)**, the descendant of Margaret Dayhoff's *Atlas of Protein Sequence and Structure*. It is run by EMBL-EBI, the Swiss Institute of Bioinformatics and PIR. Its main parts are:

- **UniProtKB/Swiss-Prot**: manually reviewed entries. Curators read the literature, record function, catalytic activity, subcellular location, domains, post-translational modifications, variants and disease associations, and merge all sequences of the same protein from one species into one entry. About 576,000 entries (release 2026_03).
- **UniProtKB/TrEMBL**: unreviewed entries, annotated automatically by rule-based systems (UniRule, ARBA) that transfer annotation from reviewed entries to proteins of the same family. About 149 million entries (release 2026_03).
- **UniParc**: an archive in which every unique protein sequence from any source appears exactly once, under a stable identifier. It contains more than a billion sequences (2026).
- **UniRef**: clusters of UniProt and selected UniParc sequences at 100%, 90% and 50% identity (UniRef100, UniRef90, UniRef50) (Suzek et al. 2014). Searching UniRef instead of the full database removes most redundancy and is much faster. UniRef50 was, for example, used to train protein language models (Section 1.10).
- **Proteomes**: the set of proteins of each sequenced organism, with a selected **reference proteome** for each species or strain.

The difference in quality between the two sections of UniProtKB is large. A Swiss-Prot entry is a short review of what is experimentally known about a protein. A TrEMBL entry is a prediction: its sequence depends on an automatic gene model, and its annotation is inferred from homologues. The size of UniProtKB also depends on policy. To limit redundancy, UniProt decided in 2025 to keep only proteins from reference proteomes in UniProtKB, unless there is a specific reason to keep an entry, for example an experimental structure. This reduced UniProtKB from about 250 million to about 150 million entries during 2025–2026. The removed sequences remain available in UniParc.

2.3.4 Metagenomic sequences

A growing share of all known protein sequences comes not from cultured organisms but from **metagenomes**: DNA sequenced directly from environmental or host-associated samples. Most of these sequences are not in UniProtKB. **MGnify** at EMBL-EBI assembles and annotates metagenomic data and provides a protein database with billions of sequences (Richardson et al. 2022). Clustered collections of metagenomic and genomic proteins, such as the Big Fantastic Database (BFD) and the databases built with Linclust (Section 1.4), are used to build the deep multiple alignments needed for structure prediction (Chapter 9). Metagenomic proteins have also been predicted structurally on a massive scale (Section 2.5).

2.3.5 Protein families and domains

Family and domain databases classify sequences by homology. They are described in detail in Section 1.9 and are listed here only for completeness:

- **Pfam**: families and domains defined by curated seed alignments and profile HMMs, now including deep-learning annotations (Pfam-N) (Mistry et al. 2020; Paysan-Lafosse et al. 2024).
- **InterPro**: integrates Pfam and about a dozen other signature databases (PROSITE, SMART, PANTHER, CDD, NCBIfam, CATH-Gene3D, SUPERFAMILY and others) into a single classification. Its matches are precomputed for all of UniProtKB (Blum et al. 2024).

- **SCOP, CATH, ECOD and TED**: classifications of domains of known or predicted three-dimensional structure (Section 2.5).
- **Rfam**: the corresponding database for families of non-coding RNAs (Section 1.7).

See also: further explanation in Section D.2.2; related Wikipedia articles in Section E.2.2.

>
> Parts of this section are adapted from the Wikipedia articles International Nucleotide Sequence Database Collaboration, GenBank, European Nucleotide Archive, Sequence Read Archive, RefSeq and UniProt (CC BY-SA 4.0, retrieved 2 October 2026). UniProt counts were retrieved from the UniProt REST API (release 2026_03) on 2 October 2026.

2.4 Genome databases and browsers

A genome sequence becomes useful when it is annotated: genes, transcripts, regulatory elements, variants and comparisons with other species have to be placed on the sequence and kept up to date as assemblies improve. **Genome browsers** present this information graphically, as tracks along a chromosome, and are among the most used tools in biology.

- **Ensembl** was started in 1999 by EMBL-EBI and the Sanger Institute to annotate the human genome automatically as it was being sequenced (Dyer et al. 2024). It now covers hundreds of vertebrate genomes, with gene models built by an automatic pipeline from aligned transcripts and proteins, combined with manual annotation (GENCODE) for human and mouse. It also provides comparative genomics (orthologues, paralogues and whole-genome alignments), variation data and the Variant Effect Predictor. **Ensembl Genomes** extends the system to bacteria, fungi, plants, protists and invertebrates. Ensembl is moving to a new browser and data model designed for many more genomes.
- The **UCSC Genome Browser**, from the University of California, Santa Cruz, displayed the first working draft of the human genome in 2000 (Perez et al. 2024). It is known for its large collection of annotation tracks contributed by many projects (conservation, regulatory elements, expression, variation, repeats), its fast display, and tools such as BLAT (Section 1.4) and the Table Browser. Users can upload their own data as custom tracks.
- **NCBI** provides the Genome, Gene and RefSeq resources and its own Genome Data Viewer, together with the annotation pipelines that produce the RefSeq gene models for eukaryotes and prokaryotes (Sayers et al. 2024).

Ensembl, UCSC and NCBI annotate the human genome independently. Their gene sets largely agree, and the **MANE** project (Matched Annotation from NCBI and EMBL-EBI) now defines one agreed reference transcript per human protein-coding gene, which is important for reporting clinical variants consistently. The coordinates of features depend on the **genome assembly** (for example GRCh37/hg19 or GRCh38/hg38 for human), so the assembly version must always be stated. Converting coordinates between assemblies (“liftover”) is a common source of errors. The first complete telomere-to-telomere human genome (T2T-CHM13) and the human pangenome reference are gradually being added to these resources (Chapter 5).

2.4.1 Annotation formats and coordinates

Features on a genome, such as genes, exons, peaks or variants, are exchanged as tables of coordinates. Two families of formats dominate, and they count positions differently.

- **BED** (Browser Extensible Data), from UCSC, has three required columns (chromosome, start, end) and up to nine optional ones (name, score, strand, the coding region, colour, and the sizes and starts of blocks such as exons). It is compact and is the input of tools such as BEDTools (Quinlan and Hall 2010), which intersect, merge and compare sets of intervals.
- **GFF3** (General Feature Format) has nine columns: sequence, source, feature type, start, end, score, strand, phase (the reading frame of a CDS) and free-form attributes. Feature types are terms from the Sequence Ontology, and the `ID` and `Parent` attributes link exons and CDSs to transcripts and transcripts to genes, so that a whole gene model can be described. **GTF** is an older dialect (GFF version 2) with mandatory `gene_id` and `transcript_id` attributes, still used by Ensembl and GENCODE and by most RNA-seq quantification tools (Chapter 7).

The two families also use different **coordinate conventions**. BED is **0-based, half-open**: the first base of a chromosome is position 0, and the interval $[s, e)$ includes the start but not the end, so its length is $e - s$. GFF3, GTF, VCF and SAM are **1-based, closed**: the first base is 1, and $[s, e]$ includes both ends, so the length is $e - s + 1$. The same single base, the 100th of chromosome 1, is therefore written `chr1 99 100` in BED and as start = end = 100 in GFF. Converting between the two means subtracting 1 from the start and leaving the end unchanged. The UCSC browser displays 1-based coordinates but stores 0-based ones, and BAM files store 0-based positions that are displayed as 1-based SAM. Forgetting a conversion gives **off-by-one errors**: features shifted by one base, zero-length or one-base-too-long intervals, and variants assigned to the wrong base or the wrong codon. Such errors are silent: the files still parse, and the results are almost right. A related source of silent failure is chromosome naming (`chr1` at UCSC, `1` at Ensembl), which can make two files that describe the same genome share no features at all.

Coordinates also only mean something together with the **genome build**, the assembly version they refer to (Section 2.2). Human GRCh37 is the same assembly as UCSC's hg19, and GRCh38 the same as hg38; the positions of most features differ between them, sometimes by megabases. **Liftover** converts coordinates from one build to another using a whole-genome alignment of the two assemblies, stored as chain files (Section 1.8), with UCSC liftOver or CrossMap (Zhao et al. 2013). Liftover is a transformation, not an identity: some regions cannot be converted because they were changed, added or removed in the new assembly, others are split or map to several places, and alleles may differ when the reference base has changed. For important analyses it is better to map the original reads to the new assembly than to lift over the results.

2.4.2 Organism-specific databases

For each major model organism there is a dedicated **model organism database**, curated by experts who follow the literature on that organism. Examples are SGD (budding yeast), PomBase (fission yeast), FlyBase (*Drosophila*), WormBase (*C. elegans*), ZFIN (zebrafish), MGI (mouse), RGD (rat), TAIR (*Arabidopsis*) and EcoCyc (*E. coli*). They hold gene nomenclature, mutant phenotypes, genetic and physical interactions, and detailed functional annotation that the general databases often import. Several of them are federated in the Alliance of Genome Resources. For prokaryotes, collections of genomes and taxonomies such as NCBI's prokaryotic RefSeq and the Genome Taxonomy Database (GTDB), which classifies bacteria and archaea by genome phylogeny, are the most important resources (Chapter 6).

2.4.3 Taxonomy databases

Almost every database record carries the organism it came from, and the taxonomy is the key that links them. **NCBI Taxonomy** (Schoch et al. 2020) holds the names and classification of all organisms with sequences in INSDC (Section 2.3), each identified by a numerical **taxid** (9606 for *Homo sapiens*, 562 for *Escherichia coli*). The taxid, not the name, is what UniProt, RefSeq, Ensembl, the PDB and many other resources use to say which organism an entry belongs to, and it is how searches can be

restricted to a clade (for example, BLAST against Metazoa only). Names change and can be ambiguous; taxids are stable, although they can be merged or deleted when the classification is revised. The NCBI database explicitly states that it is not an authoritative source for nomenclature or classification: it is a curated working classification that follows the literature and taxonomic experts, and it contains many provisional names for unclassified and environmental organisms.

For bacteria and archaea, the **Genome Taxonomy Database** (GTDB) (Parks et al. 2018, 2021) offers an alternative: a classification derived entirely from a phylogeny of conserved single-copy proteins of genomes, including metagenome-assembled genomes, with ranks normalised by evolutionary divergence. It reclassified many groups and renamed many taxa, so the same genome can have different names in NCBI and GTDB. The principles behind the two approaches are discussed in Section 4.5.

>
> Parts of this section are adapted from the Wikipedia articles Ensembl genome database project, UCSC Genome Browser and Model organism database (CC BY-SA 4.0, retrieved 2 October 2026). The subsections on annotation formats and taxonomy databases were written for this book from the primary literature cited in the text.

2.5 Structure databases

Structure resources fall into two groups that should not be confused: the PDB, an archive of structures determined by experiment, and collections of computationally predicted models, such as the AlphaFold database.

2.5.1 The Protein Data Bank: experimental structures

The **Protein Data Bank** (PDB), founded in 1971 at Brookhaven National Laboratory with seven structures, is the single global archive of experimentally determined structures of proteins, nucleic acids and their complexes (Berman et al. 2000; Burley et al. 2018). Since 2003 it has been managed by the **worldwide PDB (wwPDB)**: RCSB PDB in the USA, PDBe in Europe, PDBj in Japan, the Biological Magnetic Resonance Data Bank (BMRB) and, since 2021, the Electron Microscopy Data Bank (EMDB). Depositions are processed and validated by curators, and the data are freely available under a CC0 licence. In October 2026 the PDB contained about 260,000 experimental structures.

Each entry contains the atomic coordinates, the experimental data (such as structure factors for X-ray crystallography or restraints for NMR), information about the sample and the method, and a **validation report** that compares the model with the data and with expected geometry. Quality varies a lot between entries. For crystal structures, the resolution and the R and R-free values are the first things to check (Brünger 1992). Note also that the deposited *asymmetric unit* is not necessarily the biologically relevant assembly, which is given separately. The standard file format is now PDBx/mmCIF, which has replaced the old fixed-column PDB format because that format cannot represent very large structures. **Integrative** (or hybrid) structures, which combine data from several experimental methods with computational modelling, use an extension of PDBx/mmCIF and are archived through PDB-IHM (formerly PDB-Dev), now part of the wwPDB. They are experimentally based, but their precision is often lower than that of a crystal or cryo-EM structure.

EMDB archives the three-dimensional density maps from cryo-electron microscopy and tomography (Turner et al. 2023). The atomic models built into the maps are deposited in the PDB. With the rapid

growth of cryo-EM, an increasing share of new structures, especially of large complexes and membrane proteins, comes from EMDB/PDB pairs.

Structures are classified into domains, folds and superfamilies by **SCOP**, **CATH** and **ECOD**, and the domains of predicted structures by **TED** (Section 1.9).

2.5.2 Predicted structures: model databases

Since 2021, predicted structures have become a resource in their own right, much larger than the PDB. These are prediction resources, not archives of experimental data, and purely computational models are not accepted in the PDB. They are models, not measurements, and must always be used together with their confidence estimates (pLDDT and predicted aligned error, PAE; Chapter 9).

- The **AlphaFold Protein Structure Database** (AFDB), built by DeepMind and EMBL-EBI, was released in July 2021 with the proteomes of humans and 20 model organisms, and expanded in 2022 to more than 200 million proteins, almost all of UniProt (Varadi et al. 2021, 2023). In 2025 it was updated to a recent UniProt release, with a redesigned interface, isoforms and domain annotations (Bertoni et al. 2025). In 2026 it started to include predicted **complexes**: about 80,000 high-confidence heterodimers and 1.7 million homodimers, mainly from about 20 well-studied species and priority pathogens, with millions of lower-confidence predictions available for download.
- The **ESM Metagenomic Atlas** contains more than 600 million structures of metagenomic proteins, predicted with ESMFold (Lin et al. 2023). Most of these proteins are from organisms that have never been cultured.
- AFDB does not cover viral proteins. The **Big Fantastic Virus Database** (BFVD), from Martin Steinegger's group, fills this gap with structures of viral proteins predicted with ColabFold (Kim et al. 2024). Its first version contained about 350,000 structures of representative sequences. Many of them have no structural similarity to anything in the PDB or AFDB, and later versions cover almost all viral proteins in UniProt.
- Other collections of models (ModelArchive, SWISS-MODEL Repository) are linked to the PDB and AFDB through the **3D-Beacons** network, so that experimental and predicted models of a protein can be found in one place.

These collections are only searchable at this scale because of fast structure-search tools such as Foldseek, which also made it possible to cluster the whole AFDB and discover new folds (van Kempen et al. 2023; Barrio-Hernandez et al. 2023) (Section 1.4).

>
> Parts of this section are adapted from the Wikipedia articles Protein Data Bank, EM Data Bank and AlphaFold (CC BY-SA 4.0, retrieved 2 October 2026). The PDB count was retrieved from the RCSB Search API on 2 October 2026; the 2026 AFDB complexes are described in an EMBL announcement.

2.6 Function and pathways

2.6.1 The Gene Ontology

The **Gene Ontology** (GO), started in 1998 by the model organism databases for fly, yeast and mouse, provides a shared, controlled vocabulary for describing what genes and proteins do in any organism

(Ashburner et al. 2000; The Gene Ontology Consortium et al. 2023). It has three independent parts:

- **Molecular function**: the activity of the gene product at the molecular level, such as "protein kinase activity" or "ATP binding";
- **Biological process**: the larger biological programme that the activity contributes to, such as "DNA repair" or "cell division";
- **Cellular component**: where the gene product is located or acts, such as "mitochondrial inner membrane" or "ribosome".

Terms are organised as a **directed acyclic graph** rather than a strict tree: a term can have several parents, linked by relations such as *is_a* and *part_of*. An annotation to a specific term implies all of its ancestors (the "true path rule"). This structure is what makes GO useful for computation, for example for **enrichment analysis**, where one asks whether a list of genes is annotated to some term more often than expected by chance (Section 7.4.1, Chapter 7).

Every annotation of a gene to a GO term carries an **evidence code**. Annotations based on experiments (for example IDA, *inferred from direct assay*) are distinguished from those inferred from phylogeny or sequence similarity (IBA, ISS) and from fully automatic electronic annotations (IEA), which are the large majority. As discussed in Section 2.2, the evidence code tells you how much to trust an annotation, and whether it is independent evidence or a copy of another annotation. Other classification systems used alongside GO are the **Enzyme Commission (EC) numbers** for enzymatic reactions and the reaction database Rhea.

2.6.2 Pathway databases

- **KEGG** (Kyoto Encyclopedia of Genes and Genomes) was started in 1995 by Minoru Kanehisa at Kyoto University (Kanehisa et al. 2024). Its best-known part is a set of manually drawn **pathway maps** for metabolism, signalling, cellular processes and diseases. Genes are linked to the maps through **KEGG Orthology** (KO) groups, so that the pathways can be reconstructed automatically for any sequenced genome. KEGG also contains modules, compounds, reactions, drugs and diseases. The website is free for academic use, but bulk downloads require a licence, which is why some open tools use other resources.
- **Reactome** is an open, expert-curated database of human pathways and reactions, developed by OICR, EMBL-EBI, NYU and OHSU (Milacic et al. 2023). Pathways are built from individual reactions with defined inputs, outputs, catalysts and regulators, each supported by literature references. Pathways for other species are inferred by orthology. Reactome is widely used for pathway enrichment analysis.
- Other important resources are MetaCyc and BioCyc for metabolic pathways across organisms, WikiPathways for community-curated pathways, and BioModels for quantitative, computational models of pathways.

2.6.3 Ontologies and knowledge graphs

GO is one of many biomedical **ontologies**, controlled vocabularies whose terms are linked by defined relations. Others describe chemical entities (ChEBI), sequence features (Sequence Ontology), anatomy (Uberon), cell types (Cell Ontology), human phenotypes (Human Phenotype Ontology) and diseases (Mondo). Many are developed together in the OBO Foundry, so that they use compatible identifiers and relations. When databases annotate their records with the same ontology terms, the records can be combined across resources.

A **knowledge graph** takes this integration further. Genes, proteins, GO terms, pathways, compounds, diseases and phenotypes become nodes, and relations from many databases (a protein *participates in* a

Reactome reaction, a gene *is associated with* a disease, a drug *targets* a protein) become typed edges. Several resources, UniProt among them, also distribute their data in this form (as RDF, queried with SPARQL). Knowledge graphs are used for queries across databases, for prioritising disease genes and for drug repurposing (Himmelstein et al. 2017), often with graph machine-learning methods (Chapter 12). They inherit the biases of their sources: well-studied genes have many more edges, and a missing edge usually means "not studied" rather than "no relation".

2.6.4 Evaluating function prediction: CAFA

Because most annotations are predictions, it matters how good the prediction methods are. The **Critical Assessment of Functional Annotation** (CAFA) evaluates them prospectively. Participants predict GO terms for thousands of proteins without experimental annotation, and the predictions are scored against the experimental annotations that accumulate in the following months (Radivojac et al. 2013; Zhou et al. 2019). The fifth round (CAFA5) was run as a Kaggle competition with a much larger number of participants. It showed clear improvements, attributed to protein language models, predicted structures and the growth of experimental annotations (De Paolis Kaluza et al. 2026). CAFA also highlights a general problem of the field: annotations are incomplete, so a "false" prediction may simply be one that has not yet been tested (Chapter 10).

> **i** Sources
>
> Parts of this section are adapted from the Wikipedia articles Gene Ontology, KEGG and Reactome (CC BY-SA 4.0, retrieved 2 October 2026).

2.7 Interaction databases

Interaction databases differ in *what kind* of relationship they record, and this matters for how they can be used (Chapter 11).

- **Curated physical interactions. IntAct** at EMBL-EBI curates molecular interactions from the literature in fine detail: the experimental method, the participants, their roles and any binding regions (Toro et al. 2021). It is the main member of the **IMEx** consortium, which shares a common curation standard. **BioGRID**, started in 2003, curates protein–protein and genetic interactions, chemical interactions and post-translational modifications for the major model organisms and human, and includes many large screens (Oughtred et al. 2020). The **Complex Portal** describes curated stable complexes with their composition and stoichiometry, for example the haemoglobin tetramer of two α and two β chains (Meldal et al. 2021).
- **Functional association networks. STRING** combines experimental interactions with evidence from genomic context (gene neighbourhood, fusion, co-occurrence), co-expression, curated pathways and text mining, and transfers associations between organisms by orthology. Each link has a confidence score, and the network covers thousands of organisms (Szklarczyk et al. 2022, 2024). The 2025 version also distinguishes directed, regulatory links. **FunCoup**, developed by Erik Sonnhammer's group in Stockholm, builds networks with a naive Bayesian framework that integrates many types of evidence, and recent versions include directed gene-regulatory links for human and many other species (Buzzao, Persson, et al. 2024; Guala et al. 2019). A link in these networks means that two proteins probably *work together*. It does not necessarily mean that they bind each other.

- **Maps of complexes from proteomics. hu.MAP** integrates thousands of affinity-purification and co-fractionation mass-spectrometry experiments with machine learning to predict human protein complexes. Version 3.0 combined more than 25,000 experiments and identified more than 15,000 complexes covering about 70% of the human proteome (Fischer et al. 2025). The complexes are also imported into the Complex Portal.
- **Predicted structures of complexes.** Large sets of AlphaFold-predicted complexes are now available, including in the AlphaFold database (Section 2.5). They add a structural model and a confidence to a predicted interaction.

When using interaction data, ask what type of evidence a link is based on. High-throughput screens and text mining have different error rates, and interactions between very well-studied proteins are over-represented simply because more experiments have been done on them.

2.8 Expression and proteomics repositories

Functional genomics experiments are archived in their own primary repositories, again usually as a condition of publication.

- **GEO** (Gene Expression Omnibus), at NCBI since 2000, archives microarray, RNA-seq, single-cell and epigenomics data sets, with processed data and descriptions of the samples, while the raw reads are stored in the SRA (Clough et al. 2023).
- **ArrayExpress**, at EMBL-EBI since 2002, is the European counterpart. It is now part of **BioStudies**, a general archive for data that belong to one study, with the raw reads in ENA.
- Curated, reanalysed views of these data are provided by, for example, the **Expression Atlas** and **Single Cell Expression Atlas** at EMBL-EBI, **GTEx** (gene expression across about 50 human tissues from around a thousand donors), and the **Human Protein Atlas**, a Swedish project started in 2003 that maps human proteins in tissues, cells and organs with antibodies, transcriptomics and other methods (Uhlén et al. 2015).
- **PRIDE** at EMBL-EBI is the largest repository of mass-spectrometry proteomics data (Perez-Riverol et al. 2024). It is part of the **ProteomeXchange** consortium, which coordinates submission and data sharing between proteomics repositories (Chapter 8).

The value of these archives depends heavily on the **metadata**: which samples were compared, how they were treated and how the data were processed. Reanalysing public data is a powerful approach, but incomplete or inconsistent sample descriptions are a common obstacle. Standards such as MIAME (for microarrays) and MINSEQE (for sequencing) define the minimum information that should be provided.

2.9 Medical and variant data

Human genetic and clinical data raise two issues that the databases above do not have: the interpretation of variants for health, and the protection of personal data. The resources therefore fall into two groups: open databases of variants and their interpretation, and controlled-access archives of individual-level data.

2.9.1 Variants and their interpretation

- **dbSNP** at NCBI, started in 1998, catalogues short genetic variants (single-nucleotide variants, small insertions and deletions) and gives each a stable identifier, the `rs` number. The **European Variation Archive** (EVA) plays a similar role at EMBL-EBI for variants from all species.
- **gnomAD** (Genome Aggregation Database) aggregates exome and genome sequences from large studies to provide allele frequencies in different populations. Version 4 contains data from more than 800,000 individuals (Chen et al. 2023). Its main use is to tell whether a variant is rare or common, and which genes tolerate loss-of-function variants (*constraint*), which is essential when judging whether a variant could cause a rare disease. The **1000 Genomes Project** produced an earlier, openly accessible reference of human genetic variation.
- **ClinVar** at NCBI collects interpretations of variants submitted by clinical laboratories and researchers, classified on a scale from *benign* to *pathogenic*, together with the supporting evidence (Landrum et al. 2017). Most clinical laboratories classify variants with the ACMG/AMP guidelines, which combine population frequency, segregation, functional data and computational predictions (Richards et al. 2015). A ClinVar classification is therefore a submitter's interpretation, not an experimentally established fact. Conflicting interpretations between submitters are common and are shown explicitly, and each record has a **review status** (zero to four stars), from a single submitter without stated criteria to an expert panel or practice guideline. Classifications also change over time, often from *uncertain significance* to benign or pathogenic. When ClinVar is used as a ground truth, for example to train or evaluate variant effect predictors, the review status should be filtered, the release recorded, and circularity with computational evidence kept in mind (Section 10.6, 4).
- **OMIM** (Online Mendelian Inheritance in Man) is the classic curated catalogue of human genes and genetic disorders, going back to Victor McKusick's *Mendelian Inheritance in Man* from the 1960s (Amberger et al. 2018).
- The **GWAS Catalog** (NHGRI and EMBL-EBI) collects the associations between variants and traits reported in genome-wide association studies (Sollis et al. 2022).
- Computational predictions of variant effects, for example AlphaMissense predictions for all possible human missense variants (Cheng et al. 2023), are integrated into several of these resources (Chapter 10).

These resources answer different questions, and mixing them up is a common error. An `rs` number in dbSNP shows that a variant has been *observed* before, not that it is benign. gnomAD gives its *frequency* in the sampled populations; it is not a collection of healthy controls (its cohorts include people with common diseases), and a variant's absence from gnomAD is weak evidence if coverage at that position is poor or the relevant ancestry is under-represented. ClinVar records *interpretations* for a stated condition and mode of inheritance, which should be read together with their review status and dates rather than counted as votes. All three depend on the reference assembly and on the transcript used to describe the variant: the same genomic change can have different consequences in different transcripts, and GRCh37 and GRCh38 coordinates must never be mixed.

2.9.2 Cancer genomics

- **The Cancer Genome Atlas** (TCGA), a project of the US National Cancer Institute and NHGRI from 2006, characterised more than 11,000 tumours from 33 cancer types with genome, exome, transcriptome, methylation and protein data (Weinstein et al. 2013). Its data, and those of later projects, are distributed through the NCI **Genomic Data Commons** (GDC). The International Cancer Genome Consortium (ICGC) coordinated similar projects worldwide.
- **COSMIC** (Catalogue of Somatic Mutations in Cancer), at the Sanger Institute since 2004, is an expert-curated database of somatic mutations in cancer, including the Cancer Gene Census of genes with a documented role in cancer (Sondka et al. 2023).

2.9.3 Controlled access to personal data

Sequences and clinical data from individual people can identify them, so they are not openly published. They are deposited in **controlled-access archives**, such as dbGaP at NCBI and the **European Genome-phenome Archive** (EGA) at EMBL-EBI and CRG in Barcelona. Researchers must apply to a data access committee and agree to conditions on how the data are used and stored. The permitted uses follow from the consent the participants gave: a data set may be restricted to research on a particular disease, to non-commercial use, or to approved projects only. These restrictions travel with the data and also apply to any derived data set. In Europe, the use of such data is regulated by the General Data Protection Regulation (GDPR); in Sweden, research on personal data also requires ethical approval (Programming and reproducible research). Large biobanks, such as the UK Biobank with genetic and health data from about half a million participants, are accessed in the same way, increasingly through secure analysis environments where the data never leave the provider.

Controlled access is compatible with the FAIR principles (Section 2.2): the existence and description of a data set can be open even when the data themselves are not. The **CARE principles** (*collective benefit*, *authority to control*, *responsibility* and *ethics*) complement FAIR for Indigenous data governance (Carroll et al. 2020). They stress that the peoples and communities from which data come should have a say in how the data are used and should benefit from that use.

This area changes particularly quickly, and many national resources (for example for Swedish health data) are not covered here. For a current picture, start from the NAR database issue (Rigden and Fernández 2025) and the websites of the resources themselves.

2.10 Key concepts

A checklist for revision.

- **Principles:** primary archives vs. curated knowledgebases vs. derived resources (GenBank vs. RefSeq, Swiss-Prot vs. TrEMBL); the DNA–RNA–protein organisation; curation vs. automatic annotation; error propagation and evidence codes; redundancy and non-redundant sets; records as versioned claims (data, metadata, knowledge assertions); why agreeing databases are not independent evidence; absence of a record is not absence; testing robustness to the evidence policy
- **Identifiers and retrieval:** stable accessions vs. versioned accessions vs. names and symbols; persistent identifiers (DOI); cross-references and identifier mapping as a typed join (one-to-one, one-to-many, many-to-one, unmapped); namespaces and compact identifiers; why a genomic coordinate is not an identifier; spreadsheet corruption of gene symbols; Entrez, EBI Search and REST APIs; recording queries and checking that retrieval is complete; choosing a resource from the question; PubMed, MeSH, PMC and preprints; the NAR database issue
- **Releases and reuse:** the database release as part of every result; licences (CC0, CC BY, restricted bulk download); the FAIR principles; FAIR is not the same as open
- **Sequences:** INSDC (GenBank, ENA, DDBJ): one shared collection, exchanged daily; SRA and the study–sample–experiment–run hierarchy; RefSeq and its accession prefixes; UniProtKB/Swiss-Prot vs. TrEMBL, UniParc, UniRef and reference proteomes; metagenomic sequence collections (MGnify); family databases (Pfam, InterPro)
- **Genomes:** Ensembl, UCSC and NCBI; gene models and MANE; BED vs. GFF3/GTF; 0-based half-open vs. 1-based closed coordinates and off-by-one errors; chromosome naming; genome builds (GRCh37/hg19, GRCh38/hg38) and liftover with chain files, and why it can fail; model organism databases
- **Taxonomy:** NCBI Taxonomy and taxids as the organism key across databases (and not an authoritative nomenclature); GTDB's genome-based, rank-normalised classification of bacteria and archaea; why the same genome can have different names
- **Structures:** the PDB and wwPDB as the archive of *experimental* structures (integrative structures in PDB-IHM); what an entry contains, validation, resolution and R-free, asymmetric unit vs. biological assembly; mmCIF; EMDB; *predicted* models in AlphaFold DB (including complexes), ESM Atlas and BFVD; confidence measures of predicted models
- **Function and pathways:** the three GO aspects, the GO graph and the true path rule, evidence codes; EC numbers; KEGG (pathway maps, KO) and Reactome (reactions); other ontologies (OBO Foundry) and knowledge graphs; CAFA and why function prediction is hard to evaluate
- **Interactions:** curated physical interactions (IntAct/IMEx, BioGRID, Complex Portal) vs. functional association networks (STRING, FunCoup) vs. complex maps (hu.MAP); what a link means
- **Expression and proteomics:** GEO, ArrayExpress/BioStudies, Expression Atlas, GTEx, Human Protein Atlas; PRIDE and ProteomeXchange; the importance of metadata
- **Medical data:** dbSNP, gnomAD, ClinVar (submitted interpretations, review status, conflicts); observation vs. frequency vs. interpretation, and why gnomAD is not a set of healthy controls, OMIM, GWAS Catalog; TCGA/GDC and COSMIC; controlled access (dbGaP, EGA) and consent-based use restrictions, GDPR and ethical approval; the CARE principles

2.11 Recommended reading

These papers are recommended for reading in full:

No recommendations yet.

2.14 Review problems

These problems are adapted from Matteo Tadiello, *Modern Bioinformatics: From Foundations to Frontiers* (CC BY 4.0), used with permission. For a longer treatment of this topic, see the chapter "Biological Data, Databases, and Provenance" of that book. In the HTML version, click a box to show the extensions, solution outline and common errors.

2.14.1 Archival, derived and integrated resources

Distinguish the archival, curated, derived and integrated roles of biological databases. Explain why these roles are not a ranking of how reliable the data are.

Extensions, solution outline and common errors

Extensions:

- Classify the different kinds of information in UniProtKB, RefSeq and Ensembl, rather than giving each resource a single label.
- What happens when an integrated database copies an annotation from another integrated database?

Solution outline:

1. Define the labels as roles: archival (primary) resources preserve submitted observations; curated and derived resources select, transform, predict or interpret them; integrated resources link many kinds of entities and evidence.
2. One resource can play several roles. UniProtKB stores sequences translated from the nucleotide archives, computes automatic annotation (TrEMBL), curates the literature (Swiss-Prot) and integrates cross-references.
3. Contrast submission to GenBank, ENA and DDBJ with the selection and curation of RefSeq and the computed, integrated genome annotation of Ensembl.
4. "Primary" is not a quality label: archived data can contain submitter errors and contamination, while derived data add value but also assumptions.
5. Trust depends on tracing the specific claim back through its evidence, transformations and versions. Copying between resources does not create independent support.

Common errors:

- Treating "archival" as meaning "experimentally proven".
- Forcing every resource into one category.
- Counting three database pages that show the same annotation as three independent observations.

Connections: Section 2.2; annotation by similarity (Section 1.4); evidence for protein function (Section 10.4).

2.14.2 Identifiers, versions and mappings

Explain why a gene symbol is not enough for reproducible bioinformatics, and describe how identity can be preserved across resources and releases.

Extensions, solution outline and common errors

Extensions:

- Distinguish an accession from a versioned accession.
- Map an Ensembl transcript to a UniProt entry while keeping one-to-many results.
- Explain why a genomic coordinate is not a stable identifier.

Solution outline:

1. Gene symbols are labels for people. They can be ambiguous, have aliases, be reused or change, and an identifier means something only within its namespace.
2. A stable accession identifies a record; the version identifies one particular sequence. Record the database release and the retrieval date as well.
3. A coordinate needs the assembly, the contig accession, the coordinate convention (0- or 1-based) and the allele representation. Liftover between assemblies is a transformation, not an identity.
4. Treat mapping as a typed join: source accession and version, the relation, target accession and version, organism, and the source and release of the mapping.
5. Keep one-to-many and many-to-one mappings, find out whether they reflect isoforms, paralogues, merges or splits, and choose a rule that fits the question. Never silently take the first result.
6. Report how many identifiers mapped multiply or not at all.

Common errors:

- Removing version suffixes without recording it.
- Assuming that the "canonical" transcript is the dominant one in every tissue.
- Using gene symbols as keys in spreadsheets.
- Treating every cross-reference as an equivalence.

Connections: Section 2.2; gene models and assembly versions (Section 2.4, Section 5.6); summing transcripts to genes in RNA-seq (Section 7.3).

2.14.3 Selecting sequence and protein resources

You need a protein sequence for a functional analysis. How would you choose it, and justify the choice in terms of the biological entity, the evidence and the version?

Extensions, solution outline and common errors

Extensions:

- Why is the first BLAST hit not enough?
- Compare GenBank, RefSeq, UniProtKB/Swiss-Prot, UniProtKB/TrEMBL, UniParc, UniRef and InterPro.
- State exactly what "reviewed" does and does not guarantee.

Solution outline:

1. Start from the biological entity: organism or strain, gene, isoform, and whether the submitted, the reference or an experimentally characterised sequence is needed.

2. Use the INSDC archives for submitted nucleotide records and their provenance, and RefSeq or Ensembl for versioned reference gene, transcript and protein models.
3. Use UniProtKB for protein sequences and functional annotation. Swiss-Prot entries are manually reviewed; TrEMBL entries are annotated automatically.
4. Use UniParc to follow the history of a sequence, UniRef when redundancy-reduced clusters are useful, and InterPro for family and domain signatures, which are predictions, not proof of biochemical activity.
5. "Reviewed" means that a curator has examined the entry, not that every statement has been demonstrated experimentally for that exact protein or isoform; check the evidence for each statement.
6. Check organism, sequence version, isoform, evidence, domain coverage and date, and record the accession and retrieval date.

Common errors:

- Treating sequence similarity as enough evidence to transfer a function.
- Assuming that a protein family can be defined by one identity threshold.
- Mixing a gene-level claim with an isoform-specific sequence.

Connections: Section 2.3; orthology and paralogy (Section 3.4); search statistics (Section 1.4); function prediction (Section 10.4).

2.14.4 Structure databases and evidence

A database shows a three-dimensional structure for a protein. What biological conclusions does the record support?

Extensions, solution outline and common errors

Extensions:

- Distinguish the PDB archive from portals such as RCSB PDB and PDBe.
- Compare experimental and predicted structures.
- Does a high resolution establish biological relevance?

Solution outline:

1. Establish the provenance: the PDB, run by the wwPDB, is the archive of experimentally determined structures, and RCSB PDB, PDBe and PDBj give access to it with their own added services. AlphaFold DB and similar resources contain computed models.
2. Compare the sequence of the construct with the biological protein: mutations, truncations, tags, missing residues, isoform, ligands and oligomeric state.
3. Check the quality measures for the method: resolution, R-free and geometry for crystallography; local resolution and model–map fit for cryo-EM; agreement with restraints for NMR.
4. Distinguish the asymmetric unit from the biological assembly.
5. For a predicted model, check the model version and its confidence (pLDDT per residue, PAE for the relative position of domains). A prediction is not experimental evidence of a conformation, an interaction or ligand binding.
6. The quality of the coordinates and their biological relevance are separate questions.

Common errors:

- Calling an AlphaFold model an experimental structure.
- Choosing the highest-resolution entry without checking the construct and state.
- Assuming that every ligand in a structure is physiological.
- Interpreting missing coordinates as missing sequence.

Connections: Section 2.5; structure determination and prediction (Section 9.4, Section 9.8); complexes (Chapter 11).

2.14.5 Variant databases

A sequencing study finds a human variant. Describe how databases can be used to assess it, keeping apart the evidence that it has been observed before, its population frequency, its molecular consequence and its clinical interpretation.

Extensions, solution outline and common errors

Extensions:

- Compare the questions answered by dbSNP, gnomAD and ClinVar.
- How should absence from gnomAD and conflicting ClinVar submissions be interpreted?
- Why are assembly and transcript versions needed?

Solution outline:

1. Keep the original call, with the reference assembly, contig, position, alleles and representation convention.
2. Use dbSNP (or study archives) to find identifiers and earlier observations, not pathogenicity.
3. Use gnomAD for population frequency, ancestry, coverage and gene constraint. Absence is weak evidence if coverage is poor or the relevant population is under-represented.
4. Use ClinVar for submitted interpretations of the variant for a specific condition, and check review status, submitter, criteria, date, mode of inheritance and conflicts.
5. Map the variant to versioned transcripts and protein isoforms; different transcripts can give different consequences.
6. Databases support, but do not replace, a clinical classification that combines segregation, phenotype, functional data and population evidence (for example under the ACMG/AMP guidelines).

Common errors:

- Taking an `rs` number as evidence that a variant is benign.
- Calling gnomAD participants healthy controls.
- Counting votes among ClinVar classifications.
- Mixing GRCh37 and GRCh38 coordinates.

Connections: Section 2.9; variant calling (Section 5.4); predicting the effects of mutations (Section 10.6).

2.14.6 Ontologies and enrichment

Explain why an ontology is a better computational representation than an unstructured list of biological terms, and what follows for functional enrichment analysis.

Extensions, solution outline and common errors

Extensions:

- Explain how GO annotations propagate in the graph, and the role of evidence codes.
- May all edges of an ontology be treated the same way?
- How do the ontology release and the choice of background affect an enrichment analysis?

Solution outline:

1. A controlled vocabulary standardises labels; an ontology adds stable identifiers, definitions and typed relations that can be used in computation.
2. A GO annotation links a gene product to a term, with an evidence code, a reference and sometimes qualifiers.
3. By the true path rule, an annotation to a term implies its ancestors, but only along relations that allow this inference; negations (NOT) must not be propagated.
4. Evidence codes show how an annotation is supported (experimental, phylogenetic, computational or electronic) and allow analyses to be repeated with stricter evidence.
5. Terms and the graph change between releases; record the ontology and annotation releases.
6. In enrichment analysis, the background should be the genes that could have been measured or selected, not every annotated gene, and annotation bias towards well-studied genes must be kept in mind.

Common errors:

- Treating GO terms as independent labels.
- Propagating annotations over every edge.
- Excluding electronic annotations without discussing what is lost.
- Using the whole genome as background for an assay that measured only part of it.

Connections: Section 2.6; gene-set analysis (Section 7.5); multiple testing (Section 7.4); evaluating function prediction (Section 10.7).

2.14.7 FAIR and controlled human data

Do the FAIR principles require all biomedical data to be openly downloadable? Describe how controlled-access human genomic data can be FAIR.

Extensions, solution outline and common errors

Extensions:

- What is the role of a data access committee?
- What obligations does a researcher take on when given access to data in dbGaP or EGA?

Solution outline:

1. FAIR means findable, accessible, interoperable and reusable: rich, machine-readable metadata, persistent identifiers, standard protocols and vocabularies, provenance and a clear licence.
2. "Accessible" can mean accessible after authentication and authorisation. FAIR is not the same as open, and it is not a privacy or ethics framework.

3. Controlled-access archives make the metadata public, while a data access committee decides whether a proposed use is compatible with the participants' consent and the restrictions on the data set.
4. Approved users must follow the data use agreement: secure storage, use only by approved people for the approved purpose, no attempts at re-identification, reporting of incidents, and deletion at the end of the project.
5. Data protection law (in Europe the GDPR) and ethical approval apply throughout the analysis and publication.

Common errors:

- Equating FAIR with free of charge or open.
- Assuming that de-identified data cannot be re-identified.
- Moving controlled data to an unapproved computer or cloud service.

Connections: Section 2.2, Section 2.9; human expression cohorts (Section 2.8); responsible use of data in machine learning (Section 12.7).

2.14.8 Reproducible programmatic retrieval

Describe a reproducible way to retrieve all records that match a biological criterion from an online database, keeping the provenance and detecting incomplete retrieval.

Extensions, solution outline and common errors

Extensions:

- What should be recorded about a query?
- How can an incomplete download be detected?
- Why should web pages not be scraped?

Solution outline:

1. Define the entity, the population, the type of evidence and the exclusion criteria before choosing the resource.
2. Use a fixed release or bulk download where possible; otherwise record the endpoint, date, literal query, filters, fields and API version.
3. Use the documented API, send requests in batches, follow the usage limits (for example the request rates of NCBI's E-utilities) and log errors.
4. Check that the number of records retrieved equals the number reported, handle pagination, and look for duplicates; keep the raw responses.
5. Check the biology: organism, assembly, sequence versions and controlled terms. Keep the mapping from raw to processed identifiers and all exclusions.
6. Archive the query record, the code and its environment, and cite the sources. For a live resource, repeat a sample of the query later to see how much it changes.

Common errors:

- Reporting only a download date.
- Scraping a web interface that may change at any time.
- Ignoring pagination and missing values.
- Assuming that a checksum proves that the data are biologically correct.
- Including controlled-access data in a public reproducibility package.

Connections: Section 2.2; data leakage and validation in machine learning (4).

2.14.9 Coordinates, formats and genome builds

A collaborator sends a BED file of enhancer peaks on hg19 and asks you to intersect it with variants from a VCF file on GRCh38 and with a GENCODE GTF annotation. List the checks you need, and the errors that can occur.

Extensions, solution outline and common errors

Extensions:

- A single-base variant at position 1,000 of chromosome 7 is written how in VCF and in BED?
- How is the length of an interval computed in each convention?
- Why may some peaks fail to lift over, or map to several places?

Solution outline:

1. Bring everything to the same genome build: lift the peaks from hg19 to GRCh38 with chain files (UCSC liftOver or CrossMap), and record how many fail or split; for important data, re-map the original reads instead.
2. Harmonise chromosome names (`chr7` vs 7) and check that contigs and patches match.
3. Handle coordinates: BED is 0-based, half-open (`chr7 999 1000`, length $e-s$), while VCF and GTF are 1-based, closed (position 1000, length $e-s+1$); use tools that know the conventions (BEDTools) rather than ad hoc arithmetic.
4. Check strand and feature type (gene, transcript, exon, CDS) in the GTF, and which annotation release was used.
5. Verify on a few known examples in a genome browser before trusting the full intersection.

Common errors:

- Mixing builds without noticing, because coordinates on both are plausible numbers.
- Off-by-one shifts that move a variant into the neighbouring base or out of a one-base feature.
- Silently getting zero overlaps because of chromosome naming.

Connections: Section 2.4, Section 2.2; whole-genome alignment and chains (Section 1.8); variant calling (Section 5.4).

3 Evolution

> **From the exam description**
>
> How does evolution affect the current genomes? Gene duplication, evolutionary pressure.

3.1 Overview

Dobzhansky's remark that "nothing in biology makes sense except in the light of evolution" is particularly true for bioinformatics. Almost every method that transfers information from one sequence to another assumes common descent, and sequence data are in turn our richest source of information about evolution. This chapter is largely historical: it follows how the main ideas of molecular evolution developed, and connects them with what has been learned from the analysis of genomes (Chapter 6) and protein structures (Chapter 9).

- the origin of life: prebiotic chemistry, the RNA world, metabolism-first scenarios and astrobiology (Section 3.2);
- the basic concepts: mutation, selection, drift, effective population size, hitchhiking, the neutral theory and the molecular clock (Section 3.3);
- homologues, orthology inference, orthology databases and gene duplication (Section 3.4); other routes to new genes, including *de novo* gene birth, and pseudogenes and small proteins are covered in Section 6.8;
- protein evolution: domains, repeats, disorder, coevolution, alternative splicing, structural constraints and ancestral sequence reconstruction (Section 3.5);
- detecting selection with dN/dS and related tests, and testing molecular convergence (Section 3.6);
- genome evolution: horizontal gene transfer, the power laws of gene family sizes, and gene-family expansion and contraction (Section 3.7).

Phylogeny, the reconstruction of evolutionary trees, including gene trees versus species trees, reconciliation and the tree of life, has its own chapter (Chapter 4).

3.2 The origin of life

All the processes described in this chapter assume a population of replicating organisms. How the first such system arose from chemistry is one of the great open questions in science. There is no agreed answer, but experiments, the geological record and comparative genomics constrain the possibilities. This section gives a short overview, starting with the history of the question. It helps to keep two kinds of statement apart. Some are established observations: amino acids and nucleobases form under plausible prebiotic conditions, RNA can catalyse reactions, and the catalytic centre of the ribosome is made of RNA. Others are hypotheses that try to connect these observations into a history, such as the RNA world, metabolism first or an origin in hydrothermal vents. None of the hypotheses has been demonstrated.

3.2.1 From spontaneous generation to prebiotic chemistry

For most of history it was assumed that life arose continually from non-living matter (*spontaneous generation*), for example maggots from meat. Experiments by Francesco Redi in the 17th century and Louis Pasteur in the 1860s showed that this does not happen under present conditions. The question then became how life arose once, under very different conditions on the early Earth.

In the 1920s Alexander Oparin and J. B. S. Haldane independently proposed that the early atmosphere contained no oxygen and was *reducing*, and that energy from lightning or ultraviolet light could drive the formation of organic molecules, which accumulated in the oceans as a "primordial soup". In 1953 Stanley Miller, a student of Harold Urey, tested the idea. The **Miller–Urey experiment** passed electric sparks through a mixture of methane, ammonia, hydrogen and water, and within a week produced several amino acids (Miller 1953). A reanalysis of Miller's stored samples with modern methods in 2008–2011 found more than 20 amino acids (Parker et al. 2011). Soon after, Joan Oró showed that adenine forms from ammonium cyanide (Oró 1960), so the building blocks of both proteins and nucleic acids could be made abiotically. Geochemists later concluded that the early atmosphere was probably less reducing than Miller assumed, which gives lower yields, but organic molecules could also have formed near volcanoes and hydrothermal vents, or been delivered by meteorites: the Murchison meteorite, which fell in Australia in 1969, contains dozens of amino acids.

3.2.2 When did life appear?

The Earth formed about 4.54 billion years ago. Its early history included a giant impact that formed the Moon, and possibly a period of heavy bombardment, but liquid water was present by about 4.4 billion years ago. The oldest generally accepted fossils, stromatolites (layered mats built by microbes) and microfossils, are about 3.5 billion years old. Older evidence, such as isotopically light carbon in a 4.1 billion-year-old zircon crystal (Bell et al. 2015) or possible microfossils in hydrothermal vent deposits that are at least 3.77 billion years old (Dodd et al. 2017), is debated. Molecular clocks calibrated with fossils place the last universal common ancestor (LUCA) at around or before 4 billion years ago, with wide uncertainty (Betts et al. 2018; Moody et al. 2024). Life therefore probably appeared early, soon after the Earth became habitable. LUCA was already a complex cell with a genetic code, ribosomes and hundreds of protein families; its reconstruction is discussed in Section 4.5. Everything between the first chemistry and LUCA must be inferred indirectly.

3.2.3 The RNA world

Modern life depends on a chicken-and-egg cycle: DNA stores the information, proteins catalyse its replication, and the instructions for making proteins are in DNA. In the 1960s Carl Woese, Francis Crick and Leslie Orgel independently suggested a way out: RNA can both store information and, in principle, catalyse reactions, so the first life could have used RNA for both. The idea became much more plausible when Thomas Cech and Sidney Altman discovered catalytic RNAs, **ribozymes**: a self-splicing intron (Kruger et al. 1982) and the RNA subunit of ribonuclease P (Guerrier-Takada et al. 1983). Walter Gilbert named the hypothesis the **RNA world** in 1986 (Gilbert 1986).

Several observations are consistent with it, although none proves it (Joyce 2002; Orgel 2004; Higgs and Lehman 2014):

- the ribosome is a ribozyme: the peptidyl transferase centre, where peptide bonds are formed, consists only of RNA (Ban et al. 2000), so protein synthesis itself is catalysed by RNA;
- many coenzymes, such as ATP, NAD, FAD and coenzyme A, contain nucleotides, perhaps as relics of RNA catalysis;

- deoxyribonucleotides are made from ribonucleotides in all organisms, consistent with DNA being a later invention;
- *in vitro* evolution has produced ribozymes that catalyse many reactions, including RNA ligases that replicate each other exponentially (Lincoln and Joyce 2009).

The main problem is how RNA itself could have formed. Ribose is unstable, and joining ribose to the bases is inefficient. In 2009 Powner, Gerland and Sutherland showed that activated pyrimidine ribonucleotides can form by a different route from simple precursors, without free ribose (Powner et al. 2009). This led to *cyanosulfidic* scenarios in which hydrogen cyanide, hydrogen sulfide and ultraviolet light produce precursors of nucleotides, amino acids and lipids in the same environment (Sutherland 2015). Most researchers today see the RNA world as a stage, not necessarily the first one, and many think RNA and peptides coevolved from the start. Whether an RNA world existed at all remains a hypothesis.

3.2.4 Metabolism first and the role of compartments

An alternative view is that self-sustaining networks of chemical reactions came before genetic information. Günter Wächtershäuser proposed that metabolism began on the surfaces of iron–sulfur minerals, driven by the formation of pyrite (Wächtershäuser 1988). William Martin and Michael Russell developed a related scenario in alkaline **hydrothermal vents**, where natural proton and redox gradients across thin mineral walls could have driven carbon fixation, and where the mineral pores could have served as the first compartments (Martin and Russell 2003). This is consistent with one reconstruction of LUCA as an anaerobic organism that used hydrogen and the acetyl-CoA pathway (Weiss et al. 2016) (a reconstruction that is itself debated), and with the fact that all life uses proton gradients to make ATP. These are scenarios, not demonstrated pathways: parts of such pathways have been reproduced with metal and mineral catalysts, but a complete, self-sustaining metabolic cycle without enzymes has not been shown, and critics point out that metabolic networks without a genetic system have limited ability to evolve. A third component that all scenarios need is a **compartment**: fatty acids form vesicles spontaneously, and in laboratory experiments such protocells can grow and divide, keeping replicating molecules together so that selection can act on them.

3.2.5 Astrobiology

Astrobiology studies the origin, evolution and distribution of life in the universe (Des Marais et al. 2008). It combines the origin-of-life research described above with the search for habitable environments and signs of life elsewhere. Since Michel Mayor and Didier Queloz discovered the first planet orbiting a Sun-like star in 1995 (Mayor and Queloz 1995), thousands of exoplanets have been found, many of them in the *habitable zone* where liquid water could exist. Within the Solar System, the main targets are Mars, which had liquid water early in its history, and the ice-covered oceans of Jupiter's moon Europa and Saturn's moon Enceladus. Astrobiology also studies *extremophiles* on Earth, organisms that live at high temperature, pressure, acidity or salinity, as models for life elsewhere. Two ideas from the field are relevant for biology on Earth. *Panspermia* proposes that life, or its building blocks, was transported between planets by meteorites. It does not solve the origin problem, but moves it elsewhere. The search for *biosignatures*, chemical or isotopic traces that only life produces, has also sharpened the debate about how to recognise the earliest life on Earth.

3.3 Basic evolutionary concepts

Evolution at the molecular level is the result of a few processes acting together: mutation creates variation, and selection and random genetic drift decide which variants are lost and which spread through the population until they are *fixed*. Much of bioinformatics can be read as the analysis of the traces these processes leave in sequences. This section summarises the concepts and the history behind them.

3.3.1 A short history

Darwin's *On the Origin of Species* (1859) proposed descent with modification by natural selection, but without a theory of heredity. Mendel's laws (1866, rediscovered in 1900) provided the particulate inheritance that Darwin lacked. In the 1920s and 1930s Ronald Fisher, J. B. S. Haldane and Sewall Wright combined the two into **population genetics**, a mathematical theory of how allele frequencies change under mutation, selection, drift and migration. This was the core of the *modern synthesis* of the 1940s.

Molecular data entered in the 1950s and 1960s, when protein sequences such as haemoglobin, cytochrome *c* and fibrinopeptides could be compared between species. Two observations surprised many evolutionists: there was far more variation within species than expected, and proteins seemed to change at a roughly constant rate. These observations led to the neutral theory and the molecular clock (below), and to the **neutralist–selectionist debate** of the 1970s and 1980s. Today, genome-scale data are analysed with the same population-genetic framework, which provides the null models for detecting selection (Section 3.6).

3.3.2 Mutation

A **mutation** is any heritable change in the DNA sequence. The main kinds are:

- **point substitutions**, divided into *transitions* (purine ↔ purine, pyrimidine ↔ pyrimidine), which are about twice as frequent as *transversions*, partly because of the deamination of methylated cytosines in CpG dinucleotides;
- **insertions and deletions** (indels), often caused by replication slippage in repeats;
- **larger rearrangements**: duplications, deletions, inversions and translocations of chromosome segments, and the movement of transposable elements;
- duplication of whole chromosomes or genomes (Section 3.4).

In a protein-coding gene, a substitution can be **synonymous** (silent), changing the codon but not the amino acid, or **non-synonymous** (missense or nonsense). This distinction is the basis of the dN/dS test for selection.

Mutation rates are low. In humans there are about $1–1.5 \times 10^{-8}$ new point mutations per site per generation, or roughly 60–70 new mutations in each child, most of them from the father. Per generation and per genome, rates differ much less between species than per site, and Lynch has argued that the mutation rate itself evolves until further improvement in replication fidelity is too small to be seen by

selection, the *drift-barrier hypothesis* (Lynch et al. 2016). Mutations are not uniformly distributed: rates vary with sequence context, replication timing, chromatin state and position in the genome.

3.3.3 Selection

Natural selection changes allele frequencies because carriers of different alleles leave different numbers of descendants. Its strength is measured by the **selection coefficient** s, the relative difference in fitness. Three kinds are important in molecular evolution:

- **Purifying (negative) selection** removes harmful mutations. It is by far the most common, and it is why functionally important sequences are conserved, the basis of homology search (Chapter 1).
- **Positive (directional) selection** increases the frequency of beneficial mutations, which may then sweep to fixation.
- **Balancing selection** keeps several alleles in the population, for example through heterozygote advantage (sickle-cell haemoglobin in malaria regions) or frequency-dependent selection (immune genes such as the MHC).

3.3.4 Genetic drift and effective population size

In a finite population, allele frequencies also change by chance, because each generation is a random sample of the gametes of the previous one. This is **genetic drift**. In the simplest model (Wright–Fisher, with N diploid individuals), a new neutral mutation has a probability $1/(2N)$ of eventually becoming fixed, and when it does, fixation takes on average about $4N$ generations. Drift is therefore strong in small populations and weak in large ones.

The N in these formulas is not the census number of individuals but the **effective population size** N_e: the size of an idealised population that would show the same amount of drift. N_e is reduced by fluctuations in population size (bottlenecks), unequal sex ratios and variation in offspring number, and it is usually far smaller than the census size. Long-term estimates are of the order of 10^4 for humans, 10^5–10^6 for *Drosophila*, and 10^8 or more for many bacteria (Charlesworth 2009).

The interplay between selection and drift is governed by the product $N_e s$. When $|N_e s| \ll 1$, a mutation behaves as if it were neutral: drift decides its fate. When $|N_e s| \gg 1$, selection dominates. The same mutation can thus be effectively neutral in a small population and clearly selected in a large one. This is the key idea behind both the nearly neutral theory and Lynch's explanation for why genome complexity differs between prokaryotes and multicellular eukaryotes (Lynch and Conery 2003; Lynch et al. 2016) (Chapter 6).

The fixation probability of a selected mutation also depends on $N_e s$ (Kimura's diffusion approximation). In the simplest case, a new beneficial mutation with a small advantage s in a large population is fixed with a probability of only about $2s$: a mutation with a 1% advantage is lost by drift in about 98% of cases. The fixation probability of a slightly harmful mutation falls steeply once $N_e|s|$ exceeds about one. Because N_e differs by orders of magnitude between lineages, so does the efficacy of selection. In lineages with small N_e, such as large mammals or endosymbiotic bacteria, more slightly harmful mutations are fixed, which is seen, for example, as higher genome-wide dN/dS (Section 3.6) and weaker codon usage bias.

3.3.5 Genetic hitchhiking and linked selection

Selection on one site also affects nearby neutral sites, because they are inherited together until recombination separates them. When a beneficial mutation sweeps to fixation, linked neutral variants are dragged along: **genetic hitchhiking**, a term coined by Maynard Smith and Haigh in 1974 (Smith and Haigh 1974). A *selective sweep* reduces genetic diversity in the surrounding region, and the size of the region depends on the local recombination rate. The removal of harmful mutations has a similar but weaker effect on linked sites, called **background selection**. Because of these effects, levels of diversity along a genome are not set by drift alone, and regions of low recombination tend to have low diversity. Patterns of reduced diversity and skewed allele frequencies are used to find recent sweeps in population genomic data.

3.3.6 The neutral theory and the molecular clock

In 1968 Motoo Kimura (Kimura 1968), and independently Jack King and Thomas Jukes in 1969 (King and Jukes 1969), proposed the **neutral theory of molecular evolution**. It holds that most of the differences between species at the molecular level, and most of the variation within species, are caused not by positive selection but by the random drift of mutations that are selectively neutral. Harmful mutations occur but are quickly removed; beneficial ones are rare. The theory does not deny that adaptation happens. It claims that adaptive changes are a small minority of all molecular changes.

The neutral theory makes a simple prediction. The rate at which neutral mutations are *substituted* (fixed) in a lineage is the number of new mutations per generation, $2N\mu$, times their probability of fixation, $1/(2N)$:

$$k = 2N\mu \cdot \frac{1}{2N} = \mu.$$

The substitution rate equals the neutral mutation rate and does not depend on population size. If the mutation rate and the fraction of neutral mutations stay constant, neutral sequences therefore diverge at a constant rate. These conditions hold only approximately (see below), but the result explains why functionally less constrained sequences (synonymous sites, pseudogenes, introns, fibrinopeptides) evolve fastest: a larger fraction of their mutations are neutral.

The observation that came first was the **molecular clock**. In 1962 Zuckerkandl and Pauling noted that the number of amino acid differences between haemoglobins of different species increases roughly linearly with the time since divergence estimated from fossils (Pauling and Zuckerkandl 1963). Margoliash made the same observation for cytochrome *c*: all mammalian sequences are about equally different from all bird sequences, and both are equally different from fish. The clock made it possible to date divergences that left no fossils, and to build trees from sequences alone (Chapter 4). Tests showed that the clock is only approximate (Langley and Fitch 1974). Rates differ between genes, between sites and between lineages, for example with generation time and metabolic rate, and they can change over time within a lineage; rates measured over short time spans are often higher than those measured over long ones, partly because slightly harmful mutations have not yet been removed (Ho et al. 2005). A **strict molecular clock**, a single constant rate, is therefore a model to be tested, not a general law. Modern dating methods use **relaxed clocks** that allow the rate to vary across the tree, calibrated with several fossils.

Tomoko Ohta extended the theory in 1973 with the **nearly neutral theory** (Ohta 1973). Many mutations are only slightly harmful, with $|s|$ close to $1/N_e$. In small populations these behave as neutral and can be fixed by drift; in large populations they are removed. The theory explains why protein clocks tick at roughly constant rates per *year* rather than per generation: species with long generation times tend to have small populations, in which more slightly harmful mutations are fixed, and the two

effects partly cancel. Today the neutral and nearly neutral theories serve as the **null hypothesis** of molecular evolution. Adaptive explanations are invoked when the data deviate from neutral expectations (Section 3.6).

3.4 Homologues, orthologues and gene duplication

3.4.1 Kinds of homology

The definitions were introduced in 1 and are only summarised here. Two genes are **homologous** if they descend from a common ancestral gene; homology is a yes-or-no statement, not a degree of similarity. Homologues are classified by the event that separated them (Fitch 1970, 2000; Koonin 2005):

- **orthologues** diverged by *speciation*;
- **paralogues** diverged by *gene duplication*. Relative to a given speciation, **in-paralogues** arose by duplication *after* it (and are together co-orthologous to genes in the other species), while **out-paralogues** arose *before* it (Remm et al. 2001);
- **xenologues** have a history that includes *horizontal gene transfer*;
- **ohnologues** are paralogues created by whole-genome duplication.

These definitions describe only the event that separated two genes. They say nothing about function: an orthologue can change function and a paralogue can keep it.

Similar features that evolved independently are **analogous** (convergent); the classic molecular example is the catalytic triad of chymotrypsin and subtilisin, which share a mechanism but not an ancestor. Convergence also occurs at the level of sequence, but on a small scale. Short linear motifs of a few residues (Section 3.5) arise independently many times, and the same amino acid replacements can be selected independently in different lineages, for example substitutions in the Na^+/K^+-ATPase that make insects feeding on toxic plants resistant to cardiac glycosides (Zhen et al. 2012). A shared short motif, or a few identical residues at functional sites, is therefore weak evidence of homology. Homology is inferred from significant similarity over a longer region (1), and even then convergent changes at a few sites can mislead tree inference.

The distinction between orthologues and paralogues matters for function prediction. A widely used heuristic, the *ortholog conjecture*, holds that orthologues are more likely to keep the same function than paralogues, which are freer to diverge after duplication. It underlies the transfer of functional annotation between species (Chapter 10), but it is a statistical tendency, not part of the definition. It has been tested and debated. One study using Gene Ontology annotations concluded that paralogues in the same species are *more* similar in function than orthologues (Nehrt et al. 2011); a reanalysis showed that this was largely a bias in how annotations are made, and that orthologues are on average somewhat more similar (Altenhoff et al. 2012). The difference is smaller than often assumed.

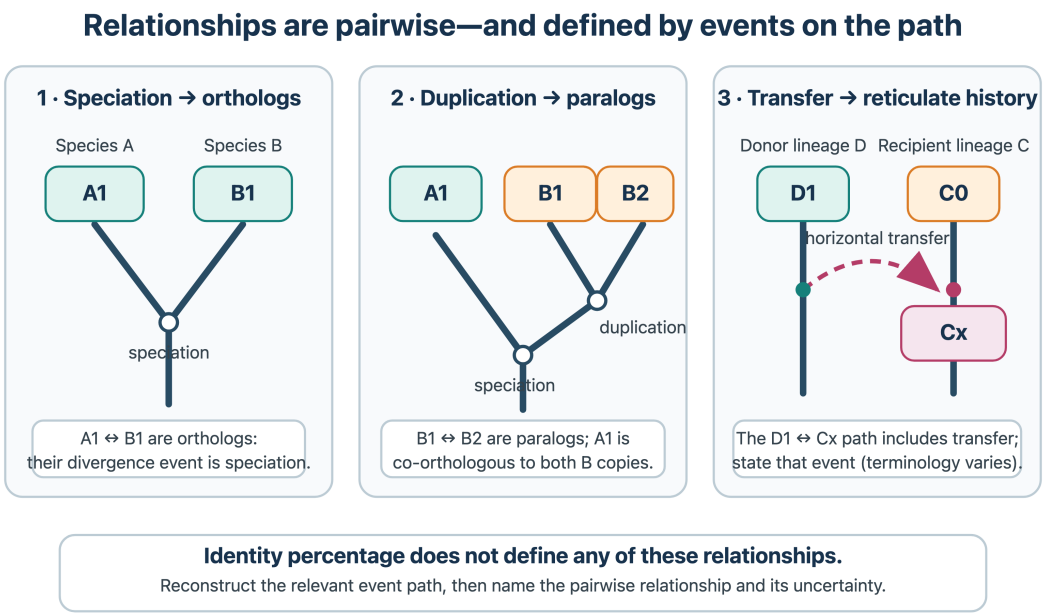

Figure 3.1: Homology relationships are defined by the event at which two genes diverged, not by their similarity. Genes separated by a speciation are orthologues, genes separated by a duplication are paralogues, and a gene in one species can be co-orthologous to two in-paralogues in another. A history that includes horizontal transfer gives xenologues; because that terminology is used less consistently, the transfer itself should be described. Figure: Matteo Tadiello, *Modern Bioinformatics: From Foundations to Frontiers* (CC BY 4.0).

3.4.2 Inferring orthology

Orthology is defined by the gene tree and the species tree, but building and reconciling trees for every gene family is expensive. Methods therefore fall into two groups (Altenhoff et al. 2019):

Graph-based methods compare all proteins of all genomes with each other and cluster them using sequence similarity.

- **Reciprocal best hits (RBH).** Genes *a* in genome A and *b* in genome B are predicted to be orthologues if *b* is the best hit of *a* in B and *a* is the best hit of *b* in A. RBH is simple and fast and gives *candidate* one-to-one orthologues; it does not establish orthology by itself. It cannot handle in-paralogues (one gene in one genome is orthologous to several in the other). It fails when the true orthologue has been lost in one genome, because the best hit is then a paralogue, and when rates differ after a duplication, so that a slowly evolving paralogue scores higher than a fast-evolving orthologue.
- **COGs** (Clusters of Orthologous Groups), introduced by Tatusov, Koonin and Lipman in 1997, extend RBH to many genomes. Groups are built from triangles of reciprocal best hits in three genomes, which are merged when they share sides (Tatusov et al. 1997). COGs and their successors (KOGs, arCOGs, eggNOG; Huerta-Cepas et al. (2018)) are widely used for functional annotation of prokaryotic genomes.
- **InParanoid**, from Erik Sonnhammer's group in Stockholm, starts from reciprocal best hits between two genomes as "seed" orthologues, and then adds in-paralogues: genes in the same genome that are more similar to the seed than to any gene in the other genome (Remm et al. 2001).
- **OrthoMCL** clusters a graph of reciprocal best hits and in-paralogues from many genomes with the Markov clustering algorithm (Li et al. 2003).

Tree-based methods build a gene tree for each family and reconcile it with the species tree (Section 4.4). Duplication nodes separate paralogues and speciation nodes orthologues. Examples are Ensembl Compara, PhylomeDB and PANTHER. They are more accurate in principle, especially for complex families with many duplications and losses, but slower and sensitive to errors in the gene trees.

OrthoFinder (Emms and Kelly 2019) combines the two: it first clusters genes into *orthogroups* (all genes descended from one gene in the last common ancestor of the species considered) with a graph method, then infers a gene tree for each orthogroup, a rooted species tree from all of them, and finally the orthologues, paralogues and duplication events from the reconciled gene trees.

Methods disagree considerably, so the **Quest for Orthologs** consortium has developed shared reference proteomes and standardised benchmarks (Altenhoff et al. 2016). These show a trade-off between precision and recall: methods that find more true orthologues also report more false ones.

3.4.3 Orthology is not transitive

Orthology is a relationship between *pairs* of genes, and it is not transitive. If a is orthologous to b and b to c, a and c need not be orthologues. The simplest case is a pair of in-paralogues: if a gene duplicated in the human lineage after the split from mouse, both human copies are orthologous to the single mouse gene, but they are paralogues of each other. The same happens across species. Suppose a gene duplicated in the common ancestor of species A and C, after that lineage had separated from species B, and A and C then lost different copies. The gene a in A and the gene c in C are both orthologous to the gene b in B, but they diverged at the duplication, so they are paralogues, and a tree built from them would mislead (hidden paralogy; Section 4.4).

Relationships are therefore reported as *one-to-one*, *one-to-many* or *many-to-many*, and groups of orthologues in many species have to be defined relative to a point in the species tree. A **hierarchical orthologous group** (HOG) is the set of genes descended from a single gene in the last common ancestor of a chosen clade (Altenhoff et al. 2013). The orthogroups of OrthoFinder are HOGs at the root of the species analysed. A HOG defined at a deep level, for example vertebrates, contains all the copies made by later duplications, and splits into several HOGs at a shallower level, such as mammals, if the gene duplicated in between. A group of orthologues is therefore meaningful only together with its taxonomic level. The COGs and the deepest eggNOG groups are broad groups of this kind, and can contain ancient paralogues with different functions (Gabaldón and Koonin 2013).

3.4.4 Orthology databases

Most users do not infer orthologues themselves but take them from a database. The main resources differ in method, species and output:

- **OMA** (Roth et al. 2008; Altenhoff et al. 2020) infers pairwise orthologues from evolutionary distances estimated from all-against-all Smith–Waterman alignments. It removes hidden paralogues with *witnesses of non-orthology*: if a third genome contains two genes, one closer to each of the candidates a and b, the candidates probably descend from an older duplication, and their true orthologues have been lost. OMA reports pairwise orthologues, *OMA groups* (sets of genes, at most one per species, that are all orthologous to each other, which are conservative and useful as markers for phylogenomics) and HOGs.
- **OrthoDB** (Kuznetsov et al. 2022) provides HOGs at every major node of the taxonomy for many thousands of eukaryotes, prokaryotes and viruses. Its single-copy groups are the basis of the BUSCO sets used to assess the completeness of genome assemblies (Section 5.3).
- **eggNOG** (Huerta-Cepas et al. 2018) provides groups at many taxonomic levels together with functional annotations, which eggNOG-mapper transfers to new sequences (Chapter 10).

- **Tree-based resources** build a gene tree for each family and reconcile it with the species tree. *Ensembl Compara* (Vilella et al. 2008) does so for vertebrates and other eukaryotes in Ensembl, and assesses each predicted orthologue also by conserved gene order and whole-genome alignment. *PANTHER* (Mi et al. 2018) combines family trees with curated functional annotations, *TreeFam* (Li 2006) covered animal families, and *PhylomeDB* (Huerta-Cepas et al. 2013) stores the complete collection of gene trees (the *phylome*) of each genome.
- **Extensions of InParanoid** from Stockholm include Hieranoid, which applies InParanoid hierarchically along the species tree (Schreiber and Sonnhammer 2013), and Domainoid, which infers orthology for individual domains, so that proteins with rearranged domain architectures can be handled (Persson et al. 2019).
- **Meta-methods** such as MetaPhOrs combine the predictions of several phylogeny-based databases and score their consistency (Pryszcz et al. 2010). Agreement between databases is reassuring, but they are not independent if they share proteomes, trees or algorithms.

Databases disagree for several reasons that do not imply carelessness: different species sets and genome releases, the choice of one protein isoform per gene, gene models that are split or fused, thresholds, tree methods and the taxonomic level of the groups. A practical consequence is to record which resource, release and relationship type were used, and to check important cases with a gene tree, the domain architecture and conserved gene order (Section 6.5).

3.4.5 Gene duplication

Gene duplication is the main source of new genes, a view championed by Susumu Ohno in a 1968 paper (Ohno et al. 1968) and his 1970 book *Evolution by Gene Duplication.* Duplications arise in several ways:

- **unequal crossing-over** between misaligned chromosomes produces *tandem* duplications, which explains clusters of related genes such as the globins, olfactory receptors and Hox genes;
- **retrotransposition** of an mRNA produces an intronless copy (*retrocopy*) elsewhere in the genome, which usually lacks a promoter and becomes a processed pseudogene, but occasionally becomes a functional *retrogene* (Section 6.8);
- **segmental duplications** copy larger chromosomal regions;
- **whole-genome duplication** (polyploidy) copies everything at once.

Duplication is not the only source of new genes: genes also arise by fusion and fission, by horizontal transfer, by domestication of transposable elements and *de novo* from non-coding sequence. These mechanisms, together with the types of pseudogenes and the small proteins that classical annotation missed, are described in Section 6.8.

Duplications are frequent. Lynch and Conery estimated from genome sequences that a typical gene duplicates at a rate of the order of 0.01 per gene per million years, comparable to the point-mutation rate per site, but that most copies are lost again within a few million years (Lynch and Conery 2000).

3.4.5.1 The fates of duplicated genes

Immediately after duplication, the two copies are at least partly redundant, so the selective constraints on one or both of them may be relaxed, although both can also remain under purifying selection (Innan and Kondrashov 2010).

- **Nonfunctionalisation.** The usual fate is that one copy accumulates disabling mutations and becomes a pseudogene, which eventually decays beyond recognition.

- **Neofunctionalisation.** Ohno's classic model: one copy keeps the ancestral function, and the other acquires a new, beneficial function by mutation. The evolution of new enzyme specificities, or of the colour vision opsins in primates, are examples.
- **Subfunctionalisation.** In the *duplication–degeneration–complementation* model of Force and colleagues (Force et al. 1999), an ancestral gene with several functions or expression domains is duplicated, and each copy loses a different subset by degenerative mutations. Both copies are then needed to perform the original set of functions, and both are preserved, without any new function. Subfunctionalisation can be followed by specialisation of each copy.
- **Dosage effects.** Some duplicates are kept because more gene product is beneficial (for example rRNA genes). Others are sensitive to the balance between interacting proteins: duplicating one subunit of a complex can be harmful, which is why such genes are rarely retained after small duplications but often kept together after whole-genome duplication, when the balance is preserved (Papp et al. 2003).

3.4.5.2 Gene conversion and concerted evolution

Duplicated genes do not always evolve independently. **Gene conversion** is the non-reciprocal copying of a stretch of sequence from one gene onto a similar one during recombinational repair (Chen et al. 2007). Between paralogues it *homogenises* the copies, so that members of a family stay more similar to each other within a species than to their orthologues in other species. This is called **concerted evolution**; the tandem arrays of ribosomal RNA genes are the classic example. For sequence analysis, gene conversion has two consequences. Converted paralogues look younger than they are, which distorts the dating of duplications and can make paralogues appear as lineage-specific in-paralogues in orthology inference. Different parts of a gene can also have different histories, which violates the assumption of a single tree (Section 4.4). GC-biased gene conversion, which favours G and C alleles in heterozygotes, also affects base composition and can mimic positive selection.

3.4.5.3 Whole-genome duplication

Ohno also proposed that the vertebrate genome had been duplicated twice early in vertebrate evolution, providing the raw material for vertebrate complexity: the **2R hypothesis** (Ohno et al. 1968). It was controversial for decades because the signal had been eroded by gene loss and rearrangement. Genome sequences eventually settled the question. In yeast, Wolfe and Shields found duplicated blocks of genes in *Saccharomyces cerevisiae* and proposed an ancient genome duplication (Wolfe and Shields 1997). Kellis and colleagues proved it by comparison with *Kluyveromyces waltii*, which had not duplicated: each region of *K. waltii* corresponded to two regions in *S. cerevisiae*, and in most cases only one of the two copies of each gene had been kept (Kellis et al. 2004). For vertebrates, the analysis of the distribution of paralogous regions across the human genome provided strong support for two rounds of duplication in the ancestor of jawed vertebrates (Dehal and Boore 2005). Further duplications occurred in the ancestor of teleost fish (3R) and again in salmonids, and polyploidy is extremely common in plants, where most lineages show several ancient duplications.

After a whole-genome duplication most duplicates are lost, but the retained ohnologues are strongly biased towards genes involved in signalling, transcriptional regulation and development, consistent with the dosage-balance hypothesis. The duplicated *Hox* clusters of vertebrates are a classic example.

3.5 Protein evolution

Genes evolve, but selection acts on what the protein does. The structure, stability and interactions of a protein therefore shape how its sequence can change. This section collects what has been learned about protein evolution from comparisons of sequences, structures and genomes.

3.5.1 Domain evolution: combination, fusion and fission

Most proteins, especially in eukaryotes, consist of several domains, and domains are the units of protein evolution (Section 1.9). New proteins are mostly made by rearranging existing domains rather than by inventing new ones. Comparisons across genomes show several regularities (Apic et al. 2001; Björklund et al. 2005):

- The number of distinct domain *combinations* is small compared with what would be possible, and most domains have only one or two partners. A few promiscuous domains (for example SH3, SH2, PH and immunoglobulin domains) combine with very many others (Basu et al. 2008).
- Domain architectures change mainly by gaining or losing domains at the N- or C-terminus, rather than by insertions in the middle (Björklund et al. 2005).
- **Gene fusion** joins domains that previously formed separate proteins, and **gene fission** splits them. Both occur (Snel et al. 2000), but in a comparison of more than a hundred genomes fusion was about four times as frequent as fission (Kummerfeld and Teichmann 2005). Because fused domains usually work together, fusion events are used to predict functional links between proteins that are separate in other species (the "Rosetta stone" method; Chapter 10).
- Multidomain proteins are more common in eukaryotes than in prokaryotes, and animals have invented many new domain combinations, particularly in signalling and cell adhesion.
- The order in which subunits of a protein complex assemble often mirrors the order in which they were added during evolution (Levy et al. 2008).

3.5.2 Repeat proteins

Many proteins contain **tandem repeats**: the same unit, from a few residues to a whole domain, repeated many times. Repeats of short motifs of about 20–40 residues often stack into elongated *solenoid* structures, such as ankyrin repeats, leucine-rich repeats (LRR), tetratricopeptide repeats (TPR) and HEAT/armadillo repeats. Others close into rings, such as the β-propellers of WD40 proteins. Larger repeats consist of whole domains, for example the immunoglobulin and fibronectin domains of titin. Kajava classified repeat proteins by the length of the unit and the resulting structure (Kajava 2012).

Repeats evolve quickly by internal duplication and loss of units, through unequal crossing-over or replication slippage. Comparative analyses show that repeated domains are much more common in eukaryotes, especially in animals, and that repeat number often differs even between close homologues (Björklund et al. 2006). Because each unit adds a binding surface, repeat proteins are well suited for protein–protein interactions, and their modular nature has made them popular scaffolds for protein

design. For sequence analysis, repeats are a challenge: they cause ambiguous alignments, inflated scores and difficulties in defining homologous positions.

3.5.3 Evolution of intrinsically disordered proteins

Many proteins, or long regions of them, do not fold into a single stable structure. These **intrinsically disordered regions** (IDRs) are common in eukaryotes, where a substantial fraction of all residues is predicted to be disordered, and rarer in prokaryotes (Lee et al. 2014). They often act as flexible linkers, or bind other proteins through **short linear motifs** (SLiMs) of a few residues, as in many signalling and regulatory proteins.

Disordered regions evolve differently from folded domains (Brown et al. 2011):

- Their sequences change much faster, and insertions and deletions are frequent. When homologous proteins differ in length, the extra residues are mostly found in disordered regions, which suggests that disordered regions are the main place where proteins can grow or shrink (Light et al. 2013).
- What is conserved is often not the sequence but *properties*: the amino acid composition, net charge, the fact of being disordered, or the presence of short motifs at varying positions. Such regions are therefore hard to align, and standard substitution matrices and alignment methods, designed for folded domains, fit them poorly.
- Short motifs can appear and disappear quickly by a few mutations, which makes disordered regions a rapid source of new interactions and regulation.

3.5.4 Coevolution

Residues that interact in a structure cannot change independently. If a mutation at one position destabilises a contact, a compensating mutation at the interacting position can restore it. Over many homologues, this produces **correlated mutations** between positions in a multiple sequence alignment. The idea was tested in the 1990s (Göbel et al. 1994), but simple correlation measures gave poor predictions of contacts because they cannot separate direct couplings from indirect, transitive correlations. Global statistical models, notably **direct coupling analysis** (DCA), largely solved this problem (Weigt et al. 2009; Marks et al. 2011). Given deep enough alignments, the strongest couplings predict residue contacts accurately, which made the first accurate *de novo* structure predictions of large proteins possible and is part of the information used by AlphaFold (Chapter 9). The same principle applied to concatenated alignments of two interacting protein families predicts which proteins interact and how (Cong et al. 2019) (Chapter 11). Coevolution is also the basis of comparative RNA structure analysis, where it appears as compensatory base pair changes (Section 1.7).

3.5.5 Alternative splicing and its evolution

In eukaryotes, the exons of one gene can be combined in different ways, producing several mRNA and protein **isoforms**. RNA-seq showed that almost all human multi-exon genes, about 95%, are alternatively spliced (Pan et al. 2008; Wang et al. 2008). Comparisons between species show that splicing patterns evolve fast: within the same tissue, splicing differs more between species than gene expression does, and many alternative exons are specific to one lineage (Barbosa-Morais et al. 2012; Merkin et al. 2012). Alternatively spliced segments often lie in disordered regions and contain binding motifs, so tissue-specific splicing can rewire protein interactions (Buljan et al. 2012).

How much of this is functional is debated. Proteomics experiments detect only a small fraction of the predicted isoforms, most genes have one dominant isoform, and alternative isoforms are often poorly conserved. This suggests that much alternative splicing is noise from an imprecise splicing machinery,

which is tolerated because it has little effect (Tress et al. 2017). Alternative splicing is therefore an example of a general question in evolutionary genomics: whether a widespread molecular activity is an adaptation or a by-product (Chapter 6).

3.5.6 Structural and functional constraints on protein evolution

Comparing sequences with structures has shown that the rate of evolution varies systematically, both between sites in a protein and between proteins (Echave et al. 2016).

- **Between sites.** Buried residues in the hydrophobic core evolve slowly, and surface residues fast. The rate of a site correlates with its relative solvent accessibility and, even more, with how many contacts it makes (*packing density*). Active sites and binding interfaces are conserved, which is how functional sites are recognised in alignments. The exchanges allowed at a site depend on its environment: hydrophobic for hydrophobic in the core, and much freer exchanges on the surface.
- **Between proteins.** The strongest predictor of how fast a protein evolves is not its functional importance but its **expression level**: highly expressed proteins evolve slowly (Drummond et al. 2005). One explanation is that mistranslated or misfolded copies of an abundant protein are costly to the cell, so there is strong selection for sequences that fold robustly.
- **Stability.** Most proteins are only marginally stable, and most mutations are destabilising. Neutral evolution under a requirement for minimal stability alone reproduces this marginal stability and the robustness of proteins to mutation (Taverna and Goldstein 2002). A destabilising but beneficial mutation can often only be accepted after a stabilising one, which makes evolutionary paths depend on the order of mutations (*epistasis*).
- **Structure is conserved longer than sequence.** Homologous proteins keep the same fold long after sequence similarity has disappeared, and the structural divergence of the core increases slowly as identity falls (Chothia and Lesk 1986). This is why structure is used to detect remote homology (1), and why the number of distinct folds in nature is limited (Holm and Sander 1996).

3.5.7 Ancestral sequence reconstruction

The same substitution models used to build trees (Section 4.3.6) can be used to infer the sequences of extinct ancestors at the internal nodes of a tree. Early methods used parsimony; modern methods use maximum likelihood or Bayesian inference. Given an alignment, a tree and a model, they compute for each site and each node the posterior probability of every amino acid or nucleotide (Yang et al. 1995; Williams et al. 2006). The reconstructed gene can then be synthesised and the "resurrected" protein studied in the laboratory. This has been used to test hypotheses about how new functions and specificities arose, which mutations were needed and in which order (epistasis), the temperature of ancient environments from the thermostability of ancestral proteins, and as a starting point for protein engineering (Thornton 2004).

A reconstruction is an estimate, not an observation, and its uncertainty should be taken into account:

- The posterior probabilities are conditional on the alignment, the tree and the substitution model. Errors in any of them propagate, and insertions and deletions are usually handled crudely.
- Uncertainty grows with the depth of the node and with the rate of the site. Deep ancestors may have many sites where two or more residues are almost equally likely.
- The common practice of taking the most probable residue at every site is biased. It systematically picks the most frequent and often stabilising residues, so such reconstructions tend to overestimate stability. Robustness is therefore tested by also making alternative ancestors with the second most probable residues, or by sampling sequences from the posterior distribution, and checking that the conclusions do not change.

3.6 Detecting selection

The neutral theory provides a null model (Section 3.3): if a sequence evolves neutrally, all kinds of mutations are fixed at the rates at which they occur. Selection shows up as a deviation from this expectation. For protein-coding genes, the most widely used comparison is between two kinds of sites in the same gene.

Selection acts on organisms: individuals with different phenotypes leave different numbers of offspring. The methods in this section do not observe this. They detect *statistical signatures* in sequence data that deviate from a neutral null model, and they attribute the deviation to selection under the assumptions of that model. A statement such as "this residue is under positive selection" is shorthand for "a codon model assigns this site to a class with $\omega > 1$ with high posterior probability". It is an inference that can be wrong if the model is wrong, and it says nothing directly about which phenotype was selected.

3.6.1 dN/dS (Ka/Ks)

Synonymous mutations do not change the protein and are, to a first approximation, neutral. Non-synonymous mutations change an amino acid and are exposed to selection on the protein. The ratio

$$\omega = \frac{d_N}{d_S} \quad \text{(also written } K_a/K_s\text{)}$$

compares the number of non-synonymous substitutions per non-synonymous site (d_N) with the number of synonymous substitutions per synonymous site (d_S) between two sequences or along a branch of a tree. Normalising *per site* is essential, because only about a quarter of random point mutations in coding sequence are synonymous. The interpretation is:

- $\omega < 1$: **purifying selection** predominates. Most amino acid changes are harmful and removed. This is the norm; typical genes have ω around 0.1–0.3, and highly constrained genes much lower.
- $\omega \approx 1$: consistent with **neutral evolution**, as in pseudogenes.
- $\omega > 1$: evidence for **positive (diversifying) selection** under the model. Amino acid changes have been favoured, for example in genes involved in immunity, host–pathogen conflicts or reproduction.

These are statements about an *average* over all the sites and branches compared. A gene-wide $\omega < 1$ does not mean that every site is under purifying selection, and it can coexist with positive selection at a few sites or on a few branches (next section). A value near one can also be an average of constrained and positively selected sites. Conversely, $\omega > 1$ is evidence of positive selection only if the model's assumptions hold: neutral synonymous sites, a correct alignment, and a single tree without recombination (see Pitfalls below).

The first methods estimated d_N and d_S by counting sites and differences between two sequences, with corrections for multiple substitutions (Nei and Gojobori 1986). Modern methods use **codon models**,

Markov models of substitution between the 61 sense codons in which ω is an explicit parameter, fitted by maximum likelihood on a phylogeny (Goldman and Yang 1994; Yang and Bielawski 2000).

3.6.2 Site, branch and branch-site models

Averaged over a whole gene and a whole tree, ω is almost always below one, even when positive selection has acted, because a few adaptive changes are swamped by the many conserved sites. Codon models therefore let ω vary:

- **Site models** allow ω to differ between codons. A model that includes a class of sites with $\omega > 1$ (for example M2a or M8) is compared with a nested model that does not (M1a or M7) by a likelihood ratio test, and Bayesian methods then identify the sites that most probably belong to the class with $\omega > 1$ (Nielsen and Yang 1998). A classic example is the peptide-binding groove of the MHC molecules.
- **Branch models** let ω differ between branches of the tree, for example to test whether a gene evolved faster after a duplication or in a particular lineage.
- **Branch-site models** test for positive selection on a few sites along a specified (*foreground*) branch (Zhang 2005).

These models are implemented in programs such as PAML (codeml) and HyPhy (Yang 2007; Pond et al. 2004).

3.6.3 Tests based on polymorphism and divergence

dN/dS was developed for comparing species. Within a population, polymorphisms include slightly harmful mutations that have not yet been removed, so ω computed between closely related sequences behaves differently and is hard to interpret (Kryazhimskiy and Plotkin 2008). The **McDonald–Kreitman test** (McDonald and Kreitman 1991) uses both kinds of data. Under neutrality, the ratio of non-synonymous to synonymous changes should be the same for polymorphisms within a species and for fixed differences between species. An excess of non-synonymous fixed differences indicates adaptive evolution, and its size can be used to estimate the fraction of amino acid substitutions driven by positive selection. McDonald and Kreitman first applied it to the alcohol dehydrogenase gene of *Drosophila*. Population genomic data are also scanned for the signatures of selective sweeps (Section 3.3): local reductions in diversity, skewed allele frequencies and long haplotypes.

3.6.4 Molecular convergence

The same amino acid change in independent lineages with a similar way of life is tempting evidence of adaptation. Parker and colleagues compared the genomes of echolocating bats and dolphins and reported convergent substitutions in many genes, including some involved in hearing (Parker et al. 2013). Reanalyses showed that comparable levels of convergence occur between lineages that do not echolocate, so that most of the signal was not specific to echolocation (Thomas and Hahn 2015; Zou and Zhang 2015). Convergence is common by chance because each site accepts only a few amino acids, and because related lineages share substitution tendencies.

A test of adaptive convergence therefore needs:

- a species tree and a reconstruction of ancestral states (Section 3.5), to show that the same *derived* state arose independently on the lineages concerned. A shared ancestral state, or a state shared through introgression or incomplete lineage sorting (Section 4.4), is not convergence;

- a null expectation, estimated from control branches matched for length or from simulations with a model that keeps site-specific amino acid preferences;
- functional evidence that the change affects the phenotype. The substitutions in the Na^+/K^+-ATPase of insects that feed on toxic plants are a convincing case because their effect on toxin resistance was tested experimentally (Zhen et al. 2012).

3.6.5 Pitfalls

Tests for selection are powerful but easy to misuse.

- **Saturation.** When sequences are very divergent, synonymous sites have changed many times and d_S cannot be estimated reliably. When they are very similar, there are too few changes for a meaningful test.
- **Alignment and annotation errors** create apparent non-synonymous changes and are a common source of false positives.
- **Recombination** violates the assumption of a single tree.
- **Synonymous sites are not always neutral.** Codon usage bias, splicing signals and mRNA structure constrain them, and biased gene conversion can mimic selection.
- **Multiple testing.** Genome-wide scans test thousands of genes and many branches, and need correction for multiple testing (Section 7.4.1).

3.7 Genome evolution

The structure of genomes, how many genes they contain, how they are organised and how they differ between the domains of life, is covered in Chapter 6. This section discusses evolutionary questions that genome sequences made it possible to answer.

3.7.1 Horizontal gene transfer

Horizontal (lateral) gene transfer (HGT) is the movement of genetic material between organisms other than from parent to offspring. In prokaryotes it occurs through three main mechanisms:

- **transformation**, the uptake of free DNA from the environment;
- **transduction**, transfer by bacteriophages;
- **conjugation**, transfer of plasmids or integrative elements through direct cell-to-cell contact.

HGT was first recognised through the spread of antibiotic resistance between bacterial species in the 1950s. Complete genome sequences showed how common it is (Ochman et al. 2000; Koonin et al. 2001). Transferred genes can be recognised in several ways:

- **phylogenetic incongruence**: the gene tree conflicts strongly with the species tree (Section 4.4);

- **phyletic patterns**: a gene is present in a species but absent from all its close relatives, and present in distantly related organisms;
- **composition**: recently transferred genes often have a GC content or codon usage that differs from the rest of the genome. This signal fades as the gene adapts to its new host.

Each method has false positives (for example, gene loss can mimic a patchy distribution), and estimates of the amount of HGT vary. It is clear, however, that in bacteria and archaea gene content changes rapidly. Strains of the same species can differ in a large fraction of their genes, which led to the concept of the **pan-genome**: a *core* of genes shared by all strains and an *accessory* part present in only some of them (Tettelin et al. 2005). Transfer, rather than duplication, is the main way prokaryotic gene families expand (Treangen and Rocha 2011). Transferred genes are often involved in adaptation to new niches: antibiotic resistance, virulence, metabolism of new compounds.

HGT challenges the idea of a single tree of life. Doolittle argued in 1999 that, if genes are transferred frequently, the history of prokaryotes is better described as a network than a tree (W. F. Doolittle 1999). In practice, a core of genes that are rarely transferred, such as those for ribosomal proteins, still gives a consistent tree that is used to classify prokaryotes (Section 4.5), but many other genes do not follow it. In eukaryotes, HGT is much rarer, with an important exception: the transfer of genes from the endosymbionts that became mitochondria and plastids to the nuclear genome (*endosymbiotic gene transfer*).

3.7.2 Power laws and the statistics of gene families

When the first complete genomes were compared, a striking regularity appeared. The number of protein families (or folds, or domains) of a given size n falls off approximately as a **power law**,

$$P(n) \propto n^{-\gamma},$$

rather than exponentially. In every genome, a few families are very large (protein kinases, ABC transporters, zinc fingers), and most families have only one or a few members. This was shown for gene families by Huynen and van Nimwegen (Huynen and Nimwegen 1998), and for domain and fold occurrence by Qian, Luscombe and Gerstein (Qian et al. 2001). The exponent differs between genomes: larger genomes have flatter distributions, with relatively more large families.

These distributions are interesting because they can be explained by simple models of evolution. In **birth–death–innovation models**, families grow by duplication of one of their members (with a probability proportional to the family size, as in "rich get richer" models), shrink by gene loss, and new families are created by innovation, such as horizontal transfer or the origin of new genes. Such models reproduce the observed distributions without assuming selection for particular family sizes (Koonin et al. 2002). A related regularity is that the number of genes in certain functional categories scales with genome size as a power law: the number of transcription regulators grows faster than linearly with the number of genes, and the number of genes for basic functions such as translation grows slower (Nimwegen 2003). Similar power laws are found in other biological networks (Chapter 11). Together with other statistical regularities, they have been called the "laws" of genome evolution (Koonin 2011).

The power laws also have practical consequences for bioinformatics. A few very large families dominate databases and search results, and an appreciable fraction of the genes in any newly sequenced genome belongs to small families or is unique to the lineage ("orphan" genes), for which homology-based annotation has nothing to offer (Chapter 10). Some orphans are genuinely new genes born *de novo* from non-coding DNA, while others are old genes whose homologues have diverged beyond detection; how the two are told apart is discussed in Section 6.8.

3.7.3 Gene-family expansion and contraction

A family with 20 members in one species and five in its relatives may have expanded in that lineage, but the counts alone do not show it. Family sizes change all the time by duplication and loss, so a count must be compared with what is expected along the species tree. The usual approach models family size as a **birth–death process** on a dated species tree: each copy duplicates at rate λ and is lost at rate μ, the likelihood of the observed counts at the leaves is computed, and families whose changes are improbable under the genome-wide rates are flagged. The program CAFE introduced this approach (Hahn et al. 2005; De Bie et al. 2006), and CAFE5 allows the rates to vary between families (Mendes et al. 2020). Applied to mammals, it showed rapid turnover of gene families: humans and chimpanzees differ by at least 6% of their genes in copy number (Demuth et al. 2006).

The analysis is only as good as the counts. Collapsed repeats in an assembly hide copies, while uncollapsed haplotypes, fragmented gene models and pseudogenes add false ones, and differences in assembly and annotation quality between genomes easily dominate the signal (Section 5.3). An unusual change in family size is a statement about history, not about adaptation. Linking an expansion to a phenotype requires further evidence, such as expression, biochemical divergence of the copies and repeated expansions in independent lineages with the same phenotype.

3.8 Key concepts

A checklist for revision.

- **Origin of life:** established observations versus hypotheses; spontaneous generation and Pasteur; Oparin–Haldane; the Miller–Urey experiment and its reanalysis; the age of the Earth and the earliest evidence of life; the RNA world and the evidence for it (ribozymes, the ribosome, coenzymes); prebiotic synthesis of nucleotides; metabolism-first and hydrothermal-vent scenarios; protocells; astrobiology, exoplanets and biosignatures
- **Population genetics:** types of mutation and mutation rates; purifying, positive and balancing selection; genetic drift and fixation probability (neutral $1/(2N)$, beneficial about $2s$); effective population size and why $N_e s$ matters for the efficacy of selection; hitchhiking, selective sweeps and background selection
- **Neutral theory:** Kimura and King–Jukes; why the neutral substitution rate equals the mutation rate; the molecular clock (Zuckerkandl and Pauling, Margoliash) and its limits (rate variation between lineages, genes, sites and over time; strict versus relaxed clocks); Ohta's nearly neutral theory; the neutralist–selectionist debate
- **Homology:** orthologues, paralogues (in-/out-), xenologues, ohnologues, analogues; relationship type versus functional outcome; convergent sequence evolution of short motifs and single sites; the ortholog conjecture and the debate about it
- **Orthology inference:** reciprocal best hits as candidate one-to-one orthologues and their failure modes; COGs, InParanoid, OrthoMCL, eggNOG; tree-based methods; OrthoFinder; Quest for Orthologs benchmarks; orthology is not transitive; one-to-one, one-to-many and many-to-many

relationships; hierarchical orthologous groups and their taxonomic level; orthology databases (OMA and witnesses of non-orthology, OrthoDB, eggNOG, Ensembl Compara, PANTHER, PhylomeDB, Hieranoid, Domainoid, MetaPhOrs) and why they disagree
- **Gene duplication:** mechanisms (tandem, retrotransposition, segmental, whole-genome); non-, neo- and subfunctionalisation (DDC model); dosage balance; gene conversion and concerted evolution; whole-genome duplications in yeast, vertebrates (2R), fish and plants, and how they were proven
- **Other origins of new genes** (see Section 6.8): retrogenes, fusion and fission, HGT, TE domestication, *de novo* gene birth and proto-genes; orphan genes versus homology detection failure; pseudogenes as the usual fate of duplicates and retrocopies
- **Protein evolution:** domain combinations, fusion and fission; repeat proteins; how disordered regions evolve; coevolution and direct coupling analysis; alternative splicing and the noise-versus-function debate; site-specific rates and structure, expression level and rate, marginal stability and epistasis; ancestral sequence reconstruction and its uncertainty
- **Selection:** selection on fitness versus statistical signatures in sequences; dN/dS and its interpretation (an average over sites and branches; model assumptions); counting methods and codon models; site, branch and branch-site models (PAML, HyPhy); the McDonald–Kreitman test; molecular convergence, null models and the echolocation debate; pitfalls
- **Genome evolution:** mechanisms and detection of HGT; pan-genomes; tree versus network of life; power-law distributions of family sizes and birth–death–innovation models; scaling of functional categories with genome size; birth–death models of gene-family size (CAFE) and why an expansion is not evidence of adaptation

3.9 Recommended reading

These papers are recommended for reading in full:

- Kimura (1968) — the neutral theory in two pages; why most molecular change may be neutral.
- Koonin (2005) — orthologues, paralogues and evolutionary genomics; the definitions and why they matter.
- Lynch and Conery (2000) — how often genes duplicate and what happens to the copies.
- Echave et al. (2016) — why rates of evolution vary among protein sites; the link between structure and evolution.
- Treangen and Rocha (2011) — horizontal transfer, not duplication, drives gene family expansion in prokaryotes.
- Emms and Kelly (2019) — OrthoFinder; how orthology is inferred from gene trees at genome scale.

Titles, abstracts, links and the full texts are in Section A.3; a longer list of further papers is in Section B.3.

3.10 Background reading (open access)

- **Abiogenesis (Wikipedia)** — Abiogenesis or the origin of life is the natural process by which life arises from non-living matter, such as simple organic compounds.
  https://en.wikipedia.org/wiki/Abiogenesis
- **RNA world (Wikipedia)** — The RNA world is a hypothetical stage in the evolutionary history of life on Earth in which self-replicating RNA molecules proliferated before the evolution of DNA and proteins. The term also refers to the hypothesis that posits the existence of this stage.
  https://en.wikipedia.org/wiki/RNA_world

- **Astrobiology (Wikipedia)** — Astrobiology is a scientific field within the life and environmental sciences that studies the origins, early evolution, distribution, and future of life in the universe by investigating its deterministic conditions and contingent events.
  https://en.wikipedia.org/wiki/Astrobiology
- **Genome evolution (Wikipedia)** — Genome evolution is the process by which a genome changes in structure (sequence) or size over time. The study of genome evolution involves multiple fields such as structural analysis of the genome, the study of genomic parasites, gene and ancient genome duplications, polyploidy, and comparative genomics.
  https://en.wikipedia.org/wiki/Genome_evolution
- **Neutral theory of molecular evolution (Wikipedia)** — The neutral theory of evolution holds that most of the genetic variation within and between species is due to random genetic drift of mutant alleles that are selectively neutral. A neutral mutation is one that does not affect an organism's ability to survive and reproduce.
  https://en.wikipedia.org/wiki/Neutral_theory_of_molecular_evolution
- **Molecular clock (Wikipedia)** — The molecular clock is a figurative term for a technique that uses the mutation rate of biomolecules to deduce the time in prehistory when two or more life forms diverged. The biomolecular data used for such calculations are usually nucleotide sequences for DNA, RNA, or amino acid sequences for proteins.
  https://en.wikipedia.org/wiki/Molecular_clock
- **Genetic drift (Wikipedia)** — Genetic drift is the change in the frequency of an existing allele in a population due to chance.
  https://en.wikipedia.org/wiki/Genetic_drift
- **Genetic hitchhiking (Wikipedia)** — Genetic hitchhiking, also called genetic draft or the hitchhiking effect, is when an allele changes frequency not because it itself is under natural selection, but because it is near another gene that is undergoing a selective sweep and that is on the same DNA chain.
  https://en.wikipedia.org/wiki/Genetic_hitchhiking
- **Sequence homology (Wikipedia)** — Sequence homology is the biological homology between DNA, RNA, or protein sequences, defined in terms of shared ancestry in the evolutionary history of life.
  https://en.wikipedia.org/wiki/Sequence_homology
- **Gene duplication (Wikipedia)** — Gene duplication is a mechanism through which new genetic material is generated during molecular evolution. It can be defined as any duplication of a region of DNA that contains a gene.
  https://en.wikipedia.org/wiki/Gene_duplication
- **Intrinsically disordered proteins (Wikipedia)** — In molecular biology, an intrinsically disordered protein (IDP) is a protein that lacks a fixed or ordered three-dimensional structure, typically in the absence of its macromolecular interaction partners, such as other proteins or RNA.
  https://en.wikipedia.org/wiki/Intrinsically_disordered_proteins
- **Ka/Ks ratio (Wikipedia)** — In genetics, the Ka/Ks ratio, also known as ω or dN/dS ratio, is used to estimate the balance between neutral mutations, purifying selection and beneficial mutations acting on a set of homologous protein-coding genes.
  https://en.wikipedia.org/wiki/Ka/Ks_ratio
- **Horizontal gene transfer (Wikipedia)** — Horizontal gene transfer (HGT) or lateral gene transfer (LGT) is the movement of genetic material between organisms other than by the ("vertical") transmission of DNA from parent to offspring (reproduction). HGT is an important factor in the evolution of many organisms.
  https://en.wikipedia.org/wiki/Horizontal_gene_transfer
- **Pan-genome (Wikipedia)** — In the fields of molecular biology and genetics, a pan-genome is the entire set of genes from all strains within a clade. More generally, it is the union of all the genomes of a clade.

https://en.wikipedia.org/wiki/Pan-genome

3.11 Student recommendations

Recommended by students preparing for the exam: papers, reviews, online lectures, tutorials and short explanations. To suggest something, use the suggestion form (SU login).

No recommendations yet.

3.12 Review problems

These problems are adapted from Matteo Tadiello, *Modern Bioinformatics: From Foundations to Frontiers* (CC BY 4.0), used with permission. For a longer treatment of this topic, see the chapters "Evolution and Comparative Genomics" and "Orthology: Concepts, Algorithms, and Databases" of that book. In the HTML version, click a box to show the extensions, solution outline and common errors.

3.12.1 Mutation, selection and drift

Explain how mutation, natural selection and genetic drift together shape molecular evolution.

Extensions, solution outline and common errors

Extensions:

1. What is the difference between a mutation and a substitution?
2. Why does the neutral substitution rate equal the mutation rate in an ideal model?
3. Does a larger population experience less drift?
4. What does "nearly neutral" mean?
5. Is mutation random?

Solution outline:

- Mutation creates heritable variants. It is not directed towards future usefulness, although its rate and spectrum vary between sites, sequence contexts and organisms.
- Selection changes the expected reproductive success associated with variants. Drift is random sampling in finite populations, and acts even when selection is present.
- A mutation is a new change; a substitution is a change that has become fixed along a lineage. For neutral mutations in a diploid population, $2N\mu$ new copies arise per generation and each has fixation probability $1/(2N)$, so the substitution rate is $K = \mu$ (Kimura 1968).
- Compare selection with drift through the product $N_e s$. A weakly deleterious mutation behaves as effectively neutral when its effect is small relative to drift, the central idea of the nearly neutral theory (Ohta 1973).
- The effective population size is usually much smaller than the census size, and differs between parts of the genome.

Common errors:

- Saying that drift acts only at neutral sites.

- Treating every fixed difference as adaptive.
- Saying that "random mutation" means that all mutations are equally likely.
- Treating $|N_e s| \approx 1$ as a sharp boundary rather than a rough scale.
- Confusing allele-frequency change within a population with substitution between lineages.

Connections: Section 3.3; branch lengths in Section 4.2; population variation in Section 6.6.

3.12.2 Sequence identity and orthology

Two proteins from different species are 40% identical. What can be inferred about homology and orthology, and what further evidence is needed?

Extensions, solution outline and common errors

Extensions:

1. Does similarity prove homology?
2. Can paralogues occur in different species?
3. What are co-orthologues?
4. How would you infer the relationship?
5. Does orthology imply the same function?

Solution outline:

- Identity is a property of an alignment. What it means depends on the length and coverage of the alignment, the composition of the sequences, their domains and a statistical significance estimate. Homology is common ancestry, and orthology is defined by the event that separated the genes.
- Orthologues diverged at a speciation and paralogues at a duplication. A duplication followed by a speciation gives paralogues in different species, and a duplication after a speciation makes two copies co-orthologous to one gene in the other lineage (Fitch 1970).
- Collect the gene family with suitable species and outgroups, align the homologous regions, infer a gene tree with support values, reconcile it with an independent species tree, and check conserved gene order and domain architecture.
- Report the relationship as one-to-one, one-to-many or many-to-many, with its uncertainty.
- Orthology supports, but does not prove, transfer of function; check conserved functional residues, expression and direct experimental evidence.

Common errors:

- Defining homology or a gene family by a universal identity threshold.
- Calling the proteins "40% homologous".
- Assuming that genes in different species are orthologues and genes in the same species are paralogues.
- Treating reciprocal best hits as proof of orthology after a duplication.
- Ignoring matches that cover only one domain.

Connections: 1; Section 3.4; gene trees and reconciliation in Section 4.4; annotation transfer in Section 10.4.

3.12.3 Inferring duplication and loss

A gene occurs twice in species A, once in species B, and is not found in species C. Suggest and compare plausible evolutionary histories.

Extensions, solution outline and common errors

Extensions:

1. Is one duplication plus one loss the answer?
2. Why is the species tree needed?
3. How does the choice of species change the reconstruction?
4. What does conserved synteny add?
5. How would you confirm the absence in species C?

Solution outline:

- Several histories fit the counts: a duplication in the lineage of A; an older duplication with different losses; horizontal transfer; or technical errors. The counts alone cannot decide between them.
- Check the assemblies and annotations, search the genome sequence itself, look for pseudogenes and uncollapsed haplotypes, and choose outgroups.
- Infer a gene tree and reconcile it with an independently supported species tree under a duplication–loss or duplication–transfer–loss model. Parsimony minimises a weighted number of events, while probabilistic methods model the rates of events.
- Use conserved gene order: the corresponding position in another genome can reveal a missed gene, or ancient duplicates after their sequences have diverged.
- Vary the species sampled, the tree topology, the family boundaries and the event costs or rates, and report ambiguous nodes rather than forcing one history.

Common errors:

- Treating the absence of an annotation as a biological loss.
- Inferring the history from a table of counts without a tree.
- Assuming that the history with the fewest events is the true one.
- Building the species tree from the gene of interest, and then treating the agreement as independent support.
- Ignoring whole-genome duplication and the subsequent loss of most duplicates.

Connections: Section 3.4; reconciliation in Section 4.4; synteny in Section 6.5; assembly and annotation in Section 5.3 and Section 5.6.

3.12.4 Interpreting d_N/d_S

A gene has an estimated $d_N/d_S = 1.4$. Does this support positive selection, and which analyses are needed before drawing that conclusion?

Extensions, solution outline and common errors

Extensions:

1. How are d_N and d_S estimated?

2. How do branch, site and branch-site models differ?
3. Can positive selection occur when the ratio for the whole gene is below one?
4. What if d_S is close to zero or saturated?
5. Why do recombination and GC-biased gene conversion matter?

Solution outline:

- The estimate indicates an excess of non-synonymous substitutions under its codon model, alignment and tree, averaged over sites and branches; on its own it is not sufficient.
- Codon models account for the genetic code, multiple substitutions, codon frequencies, the transition–transversion bias and the phylogeny (Goldman and Yang 1994).
- A ratio for the whole gene averages over sites and branches. Episodic selection at a few residues can coexist with purifying selection on the rest of the protein; branch-site models test this alternative.
- Test a pre-specified alternative against the appropriate null model with a likelihood-ratio test, check that the optimisation has converged, correct for multiple testing, and identify candidate sites only after the model-level test is significant.
- Check the codon alignment, non-homologous regions, sequencing errors, saturation of d_S, recombination, tree uncertainty, selection on synonymous sites, mutation bias and GC-biased gene conversion. Recombination can give false positives in site models (Anisimova et al. 2003).
- Confirm the functional effect experimentally, and use polymorphism data if the claim concerns recent adaptation.

Common errors:

- Calling $\omega = 1$ proof of neutrality.
- Interpreting $\omega < 1$ as absence of any positive selection.
- Dividing raw counts of differences without correcting for multiple substitutions.
- Treating the posterior probability of a single site as an independent hypothesis test.
- Equating selection on a coding sequence with a specific phenotype.

Connections: Section 3.6; substitution models and likelihood in Section 4.3.6; multiple testing in Section 7.4.1.

3.12.5 Testing gene-family expansion

A desert plant has 20 annotated copies of a gene family involved in water stress, while related plants have five. Design an analysis that distinguishes unusual copy-number evolution from an adaptive expansion.

Extensions, solution outline and common errors

Extensions:

1. Why is 20 against five not enough?
2. What does a birth–death model do?
3. How can assembly quality inflate the size of a family?
4. What evidence connects an expansion to adaptation?
5. How should the phylogeny enter an association with a trait?

Solution outline:

- Check that the copies are distinct loci, with read depth, flanking sequence, intact domains and complete gene models; separate pseudogenes, fragments, alleles and uncollapsed haplotypes.
- Define the family at an explicit evolutionary depth, sample species and outgroups, infer a gene tree and reconcile duplications and losses.
- Model copy number along a dated species tree. A birth–death model, as in CAFE, tests whether the change is unusual compared with the normal turnover of families; recent versions allow rates to differ between families (Mendes et al. 2020).
- Repeat the analysis with alternative family definitions and allowing for errors in the counts, and correct for testing many families.
- An expansion is a statement about history, not adaptation. Connect the copies to stress-responsive expression, biochemical differences, phenotypes after perturbation, and repeated expansions in independent lineages with the same ecology.

Common errors:

- Calling every BLAST hit a functional gene.
- Ignoring differences in annotation quality between the focal genome and its relatives.
- Equating a statistically unusual expansion with positive selection.
- Treating species as independent observations without correcting for phylogeny.
- Assuming that all duplicates share one function.

Connections: Section 3.7; gene duplication in Section 3.4; assembly errors in Section 5.3; expression in Chapter 7.

3.12.6 Detecting horizontal gene transfer

A metabolic gene occurs in one bacterium and in several distantly related archaea, but not in the close relatives of the bacterium. Assess the hypothesis of horizontal transfer.

Extensions, solution outline and common errors

Extensions:

1. Which signals would you combine?
2. Why can GC content fail?
3. Does conflict between gene tree and species tree prove transfer?
4. How do contamination and gene loss compete as explanations?
5. Can you infer the direction of transfer and the donor?

Solution outline:

- A patchy distribution motivates the hypothesis but can also result from gene loss, incomplete assemblies or missed annotations.
- Collect a broad, quality-controlled family, infer a gene tree with support values and reconcile it with the species tree under a duplication–transfer–loss model. Compare alternative roots and models.
- Inspect GC content, codon usage, mobile elements, the boundaries of the insertion, association with plasmids and the conservation of the neighbouring genes. Composition detects mainly recent transfers from compositionally different donors; the signal fades as the gene adapts to its new genome.
- Check the raw reads, coverage, the contig context and independent assemblies to exclude contamination.

- Infer the direction only when rooting, taxonomic distribution and genomic context support it. The true donor may be unsampled or extinct.
- Describe the transfer explicitly, since the terminology for xenologues is less uniform than for orthologues and paralogues.

Common errors:

- Using unusual GC content as proof.
- Calling every conflict between gene tree and species tree a transfer.
- Assuming that the closest sampled sequence comes from the actual donor.
- Ignoring incomplete lineage sorting and introgression in eukaryotes.
- Failing to rule out contamination.

Connections: Section 3.7; conflicting trees in Section 4.4; pan-genomes in Section 6.6; metagenomic binning in Section 5.7.

3.12.7 Testing molecular convergence

Two distantly related marine mammals share the same amino acid at one site of a protein. Formulate a test of the hypothesis that this is adaptive convergence.

Extensions, solution outline and common errors

Extensions:

1. What counts as an independent origin?
2. Which null model is appropriate?
3. Why reconstruct ancestral sequences?
4. Could introgression or ancestral polymorphism explain the pattern?
5. What functional evidence is needed?

Solution outline:

- First establish, with a species tree and probabilistic ancestral reconstruction, that the same derived state arose independently on the branches concerned. A shared ancestral state, or one shared through gene flow, is not convergence.
- Count or score the convergent substitutions and compare them with a null expectation that keeps the branch lengths, the substitution tendencies and, preferably, site-specific constraints. Matched control branches are more informative than arbitrary species without the phenotype.
- Consider alignment, tree, recombination, incomplete lineage sorting, introgression, mutation bias and uncertainty in the ancestral states.
- Show an excess over the expectation. In the echolocation debate, apparent genome-wide convergence depended strongly on the choice of control branches (Thomas and Hahn 2015).
- Link the substitution to a biochemical or organismal phenotype by mutagenesis or structural analysis, and ideally show it in several independent origins.
- State a graded conclusion: a repeated state; an excess of molecular convergence; an association with the phenotype; or an experimentally supported adaptive mechanism.

Common errors:

- Treating similar phenotypes as proof of the same molecular route.

- Counting species instead of independent evolutionary transitions.
- Using a null model that ignores site-specific amino acid preferences.
- Calling identical states adaptive without functional evidence.
- Ignoring gene flow.

Connections: Section 3.6; ancestral sequence reconstruction and structural constraints in Section 3.5; incomplete lineage sorting in Section 4.4.

4 Phylogeny

> **From the exam description**
>
> Advantages and limitations of different methods.

4.1 Overview

Phylogenetics reconstructs the evolutionary history of genes and species from their sequences. It is one of the oldest areas of bioinformatics, and many of its ideas, such as dynamic programming on trees, explicit probabilistic models of sequence change, the bootstrap and Markov chain Monte Carlo, have spread to the rest of the field. The problem is both computational, because the number of possible trees is astronomically large, and statistical, because the data are noisy and the models approximate. This chapter covers

- the history of the field and the vocabulary of trees: rooting, clades and the number of possible trees (Section 4.2);
- the main families of methods: distance methods, parsimony, maximum likelihood and Bayesian inference (Section 4.3), the substitution models they depend on, the choice between nucleotide, codon and protein data, and tests of the molecular clock (Section 4.3.6), and measures of support (Section 4.3.9);
- alignment uncertainty, phylogenomics, gene trees versus species trees, consensus trees and concordance factors, reconciliation, phylogenomic function prediction and phylogenetic networks (Section 4.4);
- what has been learned about the tree of life, its root and the origin of eukaryotes, how taxonomy relates to phylogeny, and about the evolution of humans and the other great apes (Section 4.5).

The evolutionary processes that trees describe are covered in Chapter 3, and the use of trees to infer orthology in Section 3.4.

4.2 Basic definitions

A phylogenetic tree is a hypothesis about how a set of sequences or species descend from common ancestors. Trees are used to classify organisms, infer orthology (Section 3.4), date divergences, reconstruct ancestral sequences, detect selection (Section 3.6) and track the spread of pathogens. This section introduces the history of the field and the vocabulary used for trees. The methods for building them follow in Section 4.3.

4.2.1 From morphology to molecules

Darwin's only figure in the *Origin of Species* (1859) was a branching tree, and Ernst Haeckel drew elaborate "trees of life" in the 1860s, but these were based on anatomy and intuition. Two developments in the 1950s and 1960s turned phylogeny into a quantitative science.

The first was **cladistics**. Willi Hennig argued that classification should reflect phylogeny only, and that groups should be *clades*, an ancestor and all its descendants (Hennig 1965). Clades are recognised by shared *derived* characters (synapomorphies), not by shared ancestral characters. Having a backbone, for example, does not show that fish form a group, because the backbone was inherited from the common ancestor of all vertebrates, including us. Hennig's ideas led to the first algorithmic methods, which searched for the tree that needed the fewest character changes (parsimony).

The second was the arrival of **molecular data**. Zuckerkandl and Pauling described molecules as "documents of evolutionary history", and noticed that proteins seemed to change at a roughly constant rate, the molecular clock (Section 3.3). In 1967 Fitch and Margoliash built one of the first trees from protein sequences, using cytochrome *c* from 20 species and a distance method (Fitch and Margoliash 1967). In the same years Cavalli-Sforza and Edwards introduced maximum likelihood and Jukes and Cantor the first probabilistic model of sequence change (Jukes and Cantor 1969). Joseph Felsenstein showed in 1978 that parsimony can be misleading (Felsenstein 1978) and in 1981 made maximum likelihood practical for DNA sequences (Felsenstein 1981). Neighbour joining followed in 1987 (Saitou and Nei 1987) and Bayesian methods in the late 1990s (Rannala and Yang 1996; Huelsenbeck et al. 2001). The history of these methods, and the debates between their proponents, are told in Felsenstein's book (Felsenstein 2004).

4.2.2 Tree terminology

A tree consists of **nodes** connected by **branches** (edges).

- The **leaves** (tips, terminal nodes) are the observed sequences or species, often called *taxa* or operational taxonomic units (OTUs).
- The **internal nodes** represent hypothetical ancestors. In a fully resolved (*bifurcating*) tree each internal node has two descendants. A node with more descendants is a **polytomy**. It can represent a genuine rapid radiation (a *hard* polytomy) or, more often, lack of resolution (a *soft* polytomy).
- The **topology** is the branching pattern alone. **Branch lengths** usually give the expected number of substitutions per site along the branch, that is, the amount of change, which is the product of time and rate. A branch length is therefore *not* a time, unless the tree has been dated with a clock model (a *chronogram*). In a time tree the branch lengths are proportional to time and the tree is *ultrametric*: all leaves are equally far from the root. In a *cladogram* only the topology is shown, and the branch lengths mean nothing.
- A **clade** (monophyletic group) is an ancestor and all its descendants. A **paraphyletic** group contains an ancestor and only some of its descendants (reptiles without birds, prokaryotes without eukaryotes). A **polyphyletic** group is defined by a character that evolved independently, without including the common ancestor (warm-blooded animals). Cladistic classification accepts only monophyletic groups. Clades are defined only on a rooted tree. An unrooted tree defines *splits* (bipartitions of the leaves), which become clades once a root is chosen.
- **Sister groups** are two clades that are each other's closest relatives: they descend from the same immediate ancestral node. The **outgroup** is a taxon known to lie outside the group of interest (the *ingroup*).

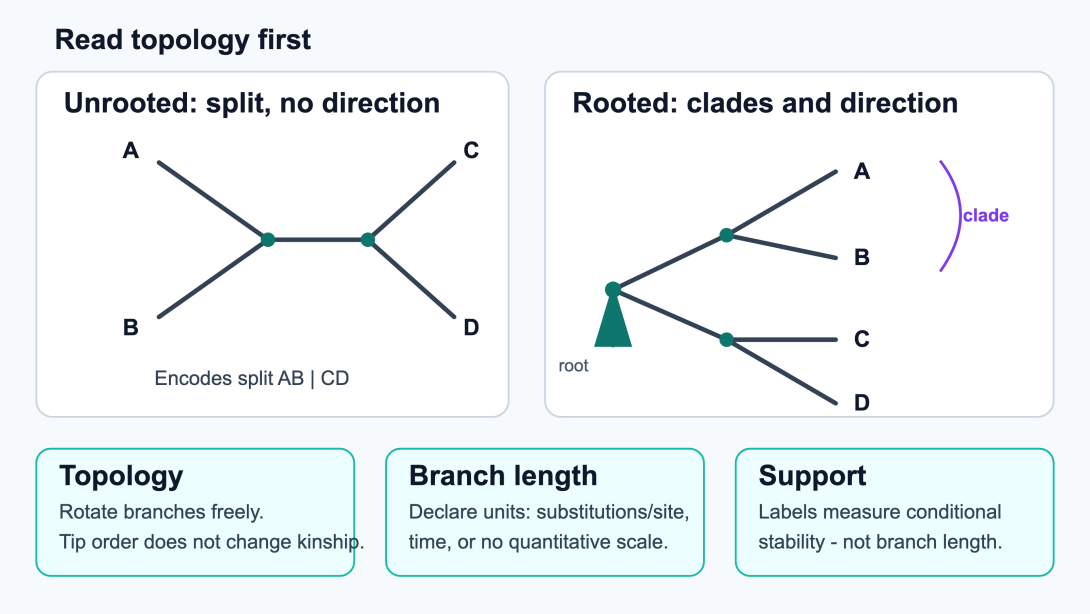

Figure 4.1: Reading a tree. An unrooted tree defines splits, such as AB|CD, but no direction in time; rooting it defines clades. Rotating the branches around a node does not change the topology, so the order of the tips on the page says nothing about relatedness. Branch lengths and support values are separate quantities, and the units of the branch lengths must be stated. Figure: Matteo Tadiello, *Modern Bioinformatics: From Foundations to Frontiers* (CC BY 4.0).

4.2.2.1 Rooted and unrooted trees

A **rooted** tree has a node, the root, that represents the most recent common ancestor of all leaves, and so gives every branch a direction in time. An **unrooted** tree shows only the relationships between the leaves. Most reconstruction methods produce unrooted trees, because the substitution models they use are *time-reversible*: the likelihood is the same wherever the root is placed. A tree is rooted afterwards, usually by

- **outgroup rooting**: including a more distant taxon and placing the root on the branch that leads to it. This is the most reliable method, but it requires prior knowledge that the outgroup really lies outside the ingroup, and a distant outgroup can itself be attracted to long branches (Section 4.3);
- **midpoint rooting**: placing the root halfway along the longest path between two leaves. It needs no outgroup but assumes a roughly constant rate, and it misplaces the root when some lineages evolve faster than others;
- a **molecular clock** model, or non-reversible models, which put the root where the clock or the model fits best. These use information in the ingroup alone, but the rooting signal is often weak, so the root position is uncertain.

The root of the whole tree of life cannot be found with an outgroup, because no outgroup exists. How it has been approached is described in Section 4.5.

4.2.2.2 The number of possible trees

The main computational problem in phylogenetics is that the number of trees grows super-exponentially with the number of taxa. An unrooted bifurcating tree with n leaves has $2n - 3$ branches. A new leaf can be attached to any of them, so the number of unrooted trees is

$$U(n) = \prod_{i=3}^{n}(2i-5) = (2n-5)!! = \frac{(2n-5)!}{2^{n-3}(n-3)!},$$

and the number of rooted trees is $R(n) = U(n+1) = (2n-3)!!$. There are 3 unrooted trees for four taxa, 15 for five, about 2×10^6 for 10 and more than 2×10^{20} for 20. For 50 taxa the number exceeds 10^{74}. Finding the best tree under the parsimony or likelihood criterion is NP-hard, so every practical method combines a criterion for scoring trees with a heuristic for searching among them (Yang and Rannala 2012; Kapli et al. 2020).

4.2.2.3 Writing trees down

Trees are stored as text in the **Newick format**, in which each clade is written within parentheses and branch lengths follow a colon. For example, `((human:0.006,chimp:0.007):0.002,gorilla:0.009,orangutan:0.` describes an unrooted tree of four apes. Newick was agreed upon informally in 1986 at a meeting in Newick's seafood restaurant in Durham, New Hampshire. Richer formats such as NEXUS (used by PAUP* and MrBayes) and the XML-based PhyloXML and NeXML can store data and annotations together with the tree.

4.2.3 Gene trees and species trees

A tree built from one gene is a **gene tree**. It describes the history of that gene, which need not be the same as the history of the species that carry it, the **species tree** (Maddison 1997). Incomplete lineage sorting, duplication and loss, horizontal gene transfer and recombination are distinct biological processes that make gene trees differ from species trees. In addition, an estimated gene tree can differ from the species tree simply because it was estimated with error. This distinction is central to phylogenomics, orthology inference and the study of human origins, and is discussed in Section 4.4.

4.3 Phylogenetic methods

Tree-building methods differ in two ways: whether they work on pairwise distances or directly on the alignment columns (characters), and whether they use an explicit statistical model of sequence evolution. The four main families are distance methods, maximum parsimony, maximum likelihood and Bayesian inference (Yang and Rannala 2012; Kapli et al. 2020). All of them start from a multiple sequence alignment (Section 1.6), and all of them assume that the alignment is correct and that sites evolve independently. The models the statistical methods depend on are described in Section 4.3.6, and measures of support in Section 4.3.9.

4.3.1 Distance methods

Distance methods first compute an $n \times n$ matrix of pairwise **evolutionary distances** and then build the tree that best fits the matrix. The observed proportion of differing sites, the p-distance, underestimates the true number of substitutions, because a site can change more than once (multiple hits, back mutations). It is therefore corrected with a substitution model. Under the Jukes–Cantor model (Jukes and Cantor 1969), for example,

$$d = -\frac{3}{4}\ln\left(1 - \frac{4}{3}p\right),$$

which equals p for small p and goes to infinity as p approaches the saturation level of $3/4$. For proteins, distances are corrected with amino acid replacement matrices (Section 4.3.6). Because of saturation, distances between very divergent sequences have large errors.

UPGMA (unweighted pair group method with arithmetic mean) is the simplest clustering method, introduced by Sokal and Michener in 1958 for numerical taxonomy. It repeatedly joins the two closest clusters and defines the distance from the new cluster to every other as the average of the distances of its members. UPGMA always produces a rooted, ultrametric tree. It is correct only if the distances are themselves ultrametric, that is, if the sequences evolved approximately under a molecular clock: when lineages evolve at different rates, a fast-evolving taxon looks far from its true sister and is joined in the wrong place. For this reason it is rarely used for phylogenies today, although the same algorithm is used for guide trees in multiple alignment and for clustering in general.

Neighbour joining (NJ), introduced by Saitou and Nei (Saitou and Nei 1987), is based on a different principle and does not assume a clock. It requires only that the distances are *additive* (the distance between two leaves is the sum of the branch lengths on the path between them), so the two lineages that descend from a node may have changed by different amounts. At each step it does not join the closest pair, but the pair that minimises the total length of the tree. This is found with a corrected matrix

$$Q(i,j) = (r-2)\,d(i,j) - \sum_{k} d(i,k) - \sum_{k} d(j,k),$$

where r is the number of clusters left. Subtracting the total distance of each taxon from all others compensates for long branches: a taxon that is far from everything is not penalised for being on a long branch. The pair with the lowest Q is joined, the branch lengths from the new node to the two taxa are estimated, the distances from the new node to all other taxa are computed, and the procedure is repeated until three nodes remain (Studier and Keppler 1988). NJ produces an unrooted tree in $O(n^3)$ time, which must be rooted by one of the methods in Section 4.2. It is *consistent*: if the distances are additive (exactly fit a tree), it recovers that tree. It was later shown to be a greedy algorithm for the balanced minimum-evolution criterion (Gascuel 2006).

Minimum evolution chooses the tree with the smallest sum of branch lengths, with branch lengths fitted to the distances by least squares. FastME searches tree space under this criterion and is both fast and accurate (Desper and Gascuel 2002). The older **Fitch–Margoliash** method instead minimises the weighted squared differences between the observed distances and the distances along the tree (Fitch and Margoliash 1967).

Distance methods are fast and are still used for very large data sets, for starting trees in likelihood searches, and for guide trees. Their weakness is that reducing an alignment to pairwise distances discards information: which sites changed, and how changes are shared among several taxa.

4.3.2 Maximum parsimony

Maximum parsimony chooses the tree that explains the data with the fewest character changes, following Hennig's principle that shared derived characters indicate common descent. For a given tree, the minimum number of changes at a site is found with **Fitch's algorithm** (Fitch 1971), a dynamic programme over the tree. Going from the leaves to the root, each internal node is given a set of states: the intersection of the sets of its two children if it is non-empty, and otherwise their union, at the cost of one change. The total number of unions over all sites is the parsimony score of the tree. **Sankoff's algorithm** generalises this to weighted changes, for example to make transitions cheaper than transversions (Sankoff 1975). Only *parsimony-informative* sites, where at least two states each occur in at least two taxa, can distinguish between trees.

Scoring a tree is fast, but finding the best tree still requires a search over tree space. Exact *branch-and-bound* searches are possible for about 20 taxa; larger data sets need the heuristics described below. Parsimony was the dominant method from the 1970s to the 1990s, and PAUP* and TNT were the main programs.

Parsimony has no explicit model of evolution and gives no branch lengths in units of substitutions per site. Its main problem is that it is not **statistically consistent** in all conditions. Felsenstein showed that when two non-sister taxa have long branches and the others short ones, parallel changes on the long branches are more frequent than the true shared changes on the short internal branch (Felsenstein 1978). Parsimony then groups the long branches together, and more data only make it more confident in the wrong tree. This region of parameter space is called the *Felsenstein zone*, and the artefact **long-branch attraction** (LBA). LBA affects all methods when the model is wrong, but model-based methods can correct for it to a large extent by accounting for multiple hits. A classic example is the early placement of fast-evolving microsporidian parasites at the base of the eukaryotic tree; they were later shown to be related to fungi.

4.3.3 Maximum likelihood

Maximum likelihood (ML) evaluates each tree by the probability of the observed alignment given the tree T, its branch lengths and an explicit substitution model θ (Section 4.3.6):

$$L(T, \theta) = P(D \mid T, \theta) = \prod_{s=1}^{m} P(D_s \mid T, \theta),$$

where the product is over the m alignment columns D_s, assumed to evolve independently. The likelihood of one column is a sum over all possible states at the internal nodes, a number that grows exponentially with the number of taxa. **Felsenstein's pruning algorithm** (Felsenstein 1981) computes it efficiently by dynamic programming, in the same way as the forward algorithm of an HMM (Section 1.6). Let $L_k(x)$ be the probability of the data below node k, given that node k has state x. For a leaf, $L_k(x)$ is 1 for the observed state and 0 otherwise. For an internal node with children i and j at branch lengths t_i and t_j,

$$L_k(x) = \Big[\sum_{y} P_{xy}(t_i)\, L_i(y) \Big] \Big[\sum_{z} P_{xz}(t_j)\, L_j(z) \Big],$$

where $P_{xy}(t)$ is the probability that state x changes into y along a branch of length t. At the root, $P(D_s) = \sum_x \pi_x L_{\text{root}}(x)$, with π_x the equilibrium frequencies. The cost is linear in the number of taxa and sites and quadratic in the number of states (4 for DNA, 20 for proteins, 61 for codons). In practice, log-likelihoods are summed over sites to avoid numerical underflow.

For a fixed topology, the branch lengths and model parameters are optimised numerically. The topology is then improved by a **heuristic tree search** that starts from an initial tree (often from neighbour joining or parsimony) and applies rearrangements:

- **NNI** (nearest-neighbour interchange) swaps subtrees across an internal branch, giving $2(n-3)$ neighbours;
- **SPR** (subtree pruning and regrafting) removes a subtree and reattaches it to any other branch;
- **TBR** (tree bisection and reconnection) cuts the tree in two and reconnects the parts in all possible ways.

Larger rearrangements explore tree space more widely but are slower. Since the search can get stuck in local optima, programs use several starting trees, random perturbations and stochastic search. The most widely used programs are **RAxML** and its successor RAxML-NG (Stamatakis 2014), **IQ-TREE** (Minh, Schmidt, et al. 2020), which combines fast hill climbing with stochastic perturbations and integrates model selection and fast bootstrap, **PhyML** (Guindon et al. 2010), and **FastTree**, which gives approximate ML trees for alignments of up to millions of sequences (Price et al. 2010).

Maximum likelihood is statistically consistent when the model is correct, uses all the information in the alignment, and allows hypotheses to be tested with likelihood-ratio tests. Its disadvantages are its computational cost and its dependence on the model: a poorly fitting model can give a confidently wrong tree.

4.3.4 Bayesian inference

Bayesian inference uses the same likelihood but combines it with **prior** distributions on trees, branch lengths and model parameters, to give the **posterior** probability of each tree:

$$P(T, \theta \mid D) = \frac{P(D \mid T, \theta)\, P(T, \theta)}{P(D)}.$$

The denominator, a sum over all trees and an integral over all parameters, cannot be computed. Instead, trees are sampled from the posterior with **Markov chain Monte Carlo** (MCMC). The chain proposes a small change, for example a new branch length or a rearrangement of the topology, and accepts it with a probability given by the Metropolis–Hastings rule, which depends only on the ratio of the posterior densities. After a *burn-in* period the chain visits trees in proportion to their posterior probability, so the posterior probability of a clade is simply the fraction of sampled trees that contain it (Rannala and Yang 1996; Huelsenbeck et al. 2001).

The main program for general phylogenetics is **MrBayes** (Ronquist et al. 2012). **BEAST** and BEAST 2 (Suchard et al. 2018; Bouckaert et al. 2019) specialise in time-calibrated trees: they combine relaxed molecular clocks, in which the rate may vary between branches (Drummond et al. 2006), fossil or sampling-date calibrations, and population models such as the coalescent. BEAST has become the standard tool for *phylodynamics*, the reconstruction of the spread of epidemics such as influenza, Ebola and SARS-CoV-2 from dated virus sequences. PhyloBayes implements site-heterogeneous models such as CAT (Lartillot and Philippe 2004) that are important for deep phylogenies (Section 4.4).

Bayesian methods have three main advantages: they give a direct probabilistic measure of uncertainty, they handle complex, parameter-rich models by integrating over parameters rather than optimising them, and they allow prior knowledge, such as fossil dates, to be included. The costs are the need to choose priors, which can influence the result, and the need to check that the MCMC chains have **converged**: several independent chains should be run, and their samples compared (for example with the average standard deviation of split frequencies, or effective sample sizes).

4.3.5 Comparing the methods

Table 4.1: Main families of tree-building methods.

Method	Criterion	Model	Strengths	Weaknesses
UPGMA	clustering of distances	clock assumed	very fast	wrong when rates vary
Neighbour joining	minimum evolution (greedy)	for distance correction	fast, consistent for additive distances	information lost in distances
Maximum parsimony	fewest changes	none	intuitive, no model needed	long-branch attraction, inconsistent
Maximum likelihood	probability of the data	explicit	uses all data, consistent, testable	slow, model-dependent
Bayesian inference	posterior probability	explicit, with priors	uncertainty, complex models, dating	slow, priors, convergence

4.3.6 Substitution models

Distance corrections, maximum likelihood and Bayesian inference all rely on a **substitution model**: a description of how one nucleotide or amino acid is replaced by another over time. Almost all models used in practice are continuous-time Markov processes. They are defined by a rate matrix Q, whose element q_{xy} is the instantaneous rate of change from state x to state y. The probability of change along a branch of length t is then

$$P(t) = e^{Qt},$$

computed by diagonalising Q. The models are normally assumed to be *stationary* (the base composition does not change over the tree), *time-reversible* ($\pi_x q_{xy} = \pi_y q_{yx}$, which is why the root position does not affect the likelihood) and the same at all sites, except for the rate. The main nucleotide models form a nested series:

Table 4.2: Nested nucleotide substitution models. JC69 = Jukes–Cantor, K80 = Kimura two-parameter, HKY = Hasegawa–Kishino–Yano, GTR = general time-reversible.

Model	Base frequencies	Exchange rates	Parameters
JC69 (Jukes and Cantor 1969)	equal	all equal	0

Model	Base frequencies	Exchange rates	Parameters
K80 (Kimura 1980)	equal	transitions ≠ transversions	1
F81 (Felsenstein 1981)	unequal	all equal	3
HKY85 (Hasegawa et al. 1985)	unequal	transitions ≠ transversions	4
GTR (Tavaré 1986)	unequal	all six different	8

Real sequences also differ in rate from site to site: some positions are invariant because of strong functional constraints, while others, such as third codon positions, change rapidly (Section 3.5). This **rate heterogeneity** is usually modelled with a **gamma distribution** of rates across sites (Yang 1994), approximated by four to eight discrete rate categories, sometimes combined with a proportion of invariable sites. The models are named by combining the parts, for example GTR+Γ or GTR+I+Γ. Ignoring rate heterogeneity makes distances too short for divergent sequences and is a common cause of long-branch attraction.

For **proteins**, the 190 exchange rates between amino acids are too many to estimate from a single alignment. Instead, *empirical* matrices are estimated from large databases of alignments, in the tradition of Dayhoff's PAM matrices (Section 1.3): JTT, WAG (Whelan and Goldman 2001) and LG (Le and Gascuel 2008) are the most common. Specialised matrices exist for mitochondrial, chloroplast and viral proteins. Codon models, which describe synonymous and non-synonymous changes separately, are used to detect selection (Section 3.6).

The assumption that all sites follow the same process is clearly false. In particular, different sites in a protein accept different sets of amino acids. **Site-heterogeneous mixture models**, such as CAT (Lartillot and Philippe 2004) and the C10–C60 profile mixtures, allow each site to belong to one of many classes with its own amino acid preferences. They fit real data much better and are less sensitive to long-branch attraction in deep phylogenies (Section 4.4). Other extensions allow the rate of a site to change over the tree (*heterotachy*), or the composition to differ between lineages (non-stationary models).

Model selection. A more complex model never fits the data worse than a simpler model nested within it, but at the cost of more parameters. Nested models can be compared with the likelihood-ratio test. More generally, models are compared with the Akaike information criterion, $\mathrm{AIC} = 2k - 2\ln L$, or the Bayesian information criterion, $\mathrm{BIC} = k\ln m - 2\ln L$, where k is the number of free parameters and m the number of sites. ModelTest (Posada and Crandall 1998) made this routine, and ModelFinder (Kalyaanamoorthy et al. 2017), in IQ-TREE, also tests rate-heterogeneity models and different models for different partitions (for example genes or codon positions) of the alignment. In Bayesian analyses, models can be compared with Bayes factors or averaged over with reversible-jump MCMC.

Model adequacy is a separate question. Model selection only finds the best of the candidate models; it does not show that this model describes the data well, and the best of several poor models is still poor. Whether a model is adequate is tested by asking if it could have produced the observed data: data sets are simulated under the fitted model (a *parametric bootstrap*, or *posterior predictive* simulation in a Bayesian analysis) and compared with the real alignment, for example in base composition across taxa or in the amount of saturation (Brown 2014). Inadequate models are a main source of the systematic errors described in Section 4.4.

4.3.7 DNA, codons or proteins?

Protein-coding genes can be analysed as nucleotides, as codons or as amino acids, and the choice matters as much as the model.

- **Nucleotides** give three characters per codon and record synonymous changes, so they hold the most information for closely related sequences: populations, species within a genus, or viral outbreaks. Their problem is **saturation**. With only four states, and with third codon positions changing rapidly, sites that have changed several times look no more different than sites that have changed once, and the similarity that remains is increasingly due to chance and to shared composition. Saturation can be seen by plotting the observed (uncorrected) distances against model-corrected distances: the curve flattens when the sequences are saturated.
- **Amino acids** have 20 states, ignore synonymous changes and evolve more slowly, so they saturate much later. They are the usual choice for deep divergences, from hundreds of millions of years onwards, and with site-heterogeneous mixture models for the deepest questions (Section 4.5). The price is that information is lost for close relationships.
- **Codon models** describe substitutions between the 61 sense codons, using the genetic code, the transition/transversion ratio and the ratio $\omega = d_N/d_S$ of non-synonymous to synonymous rates (Goldman and Yang 1994; "A Likelihood Approach for Comparing Synonymous and Nonsynonymous Nucleotide Substitution Rates, with Application to the Chloroplast Genome." 1994). They are the most realistic description of coding sequences, and are essential for detecting selection (Section 3.6), but they are much slower to compute and are less often used for tree search itself.

Compositional heterogeneity is a second problem. Standard models assume one base or amino acid composition for the whole tree (stationarity), but genomes differ widely in GC content, and the composition of proteins follows it partly. Unrelated lineages with similar composition, for example GC-rich thermophiles, are then pulled together. Remedies include removing or recoding third codon positions (RY-coding, in which only purines and pyrimidines are distinguished), LogDet distances, non-stationary models that allow the composition to change over the tree (Foster 2004), and recoding amino acids into a few groups of similar residues. Partitioning the data, with separate models for first, second and third codon positions, is a common compromise for nucleotide data of intermediate depth. A simple rule is to use nucleotides when the sequences are close, codon positions or codon models at intermediate distances, and proteins when third positions are saturated, and to check the conclusion with more than one data type.

4.3.8 Testing the molecular clock

Many analyses, such as UPGMA trees, clock rooting and divergence dating, assume a **molecular clock** (Section 3.3), and this assumption can be tested.

The **relative rate test** (Sarich and Wilson 1973) needs only three sequences: two ingroup sequences A and B, and an outgroup C. Under a clock, A and B have changed equally since they diverged, so the distances d_{AC} and d_{BC} should be equal, within their sampling error. Tajima's version counts the sites where only A or only B differs from the other two sequences, and compares the two counts with a χ^2 test (Tajima 1993). The test does not require a tree or a model of the dates.

For a whole tree, a **likelihood-ratio test** compares the maximum likelihood of the tree without a clock, which has $2n - 3$ free branch lengths for n sequences, with that of the same topology constrained to be ultrametric, which has $n - 1$ node heights. The clock model is nested in the non-clock model, so twice the difference in log-likelihood is compared with a χ^2 distribution with $n - 2$ degrees of freedom. For time-stamped samples, such as viruses collected over several years, a regression of root-to-tip distance against sampling date shows whether there is enough clock-like signal to date the tree.

With large data sets the strict clock is almost always rejected, as the first tests showed (Langley and Fitch 1974). Rejection does not mean that dating is impossible, but that rates must be modelled: by *local clocks* for different parts of the tree, or by the *relaxed clocks* used in Bayesian dating (Section 4.3), with the dates then depending more heavily on fossil calibrations and on the clock model.

4.3.9 Statistical support

A tree estimated from a finite alignment is uncertain, and different branches are uncertain to different degrees. Several measures are used to express this.

- **The nonparametric bootstrap** (Felsenstein 1985) creates many pseudo-replicate alignments by sampling columns from the original alignment with replacement, builds a tree from each, and reports for each branch the percentage of replicate trees that contain it. Values above about 70% have traditionally been taken as good support. The bootstrap measures how stable a branch is when the sites are resampled, for a given alignment, model and tree-building method. It is *not* the probability that the branch is correct: a wrong model or alignment can give a wrong branch 100% bootstrap support. In simulations it tends to be conservative for well-supported branches. With hundreds of replicates it is expensive for ML, which led to faster approximations such as the **ultrafast bootstrap** of IQ-TREE (Hoang et al. 2017). Its values are on a different scale and are usually trusted only from about 95%, compared with about 70% for the standard bootstrap. For very large trees, where a single misplaced taxon destroys a branch in all replicates, the **transfer bootstrap** counts how many taxa must be moved to recover the branch (Lemoine et al. 2018).
- **Approximate likelihood-ratio tests** (aLRT, SH-aLRT) compare, for each internal branch, the likelihood of the best tree with that of the best alternative arrangement around that branch (Anisimova and Gascuel 2006; Guindon et al. 2010). They are fast and widely reported together with the ultrafast bootstrap.
- **Posterior probabilities** from Bayesian analyses are the probability that a clade is correct *given the model and priors*. They are easier to interpret than bootstrap values, but they tend to be high (often 1.0) for short branches with little support, especially when the model is misspecified. Bootstrap values and posterior probabilities are therefore not directly comparable.
- **Topology tests** compare whole trees, for example the ML tree with a tree that groups taxa as an alternative hypothesis predicts. The Kishino–Hasegawa (KH), Shimodaira–Hasegawa (SH) and approximately unbiased (AU) tests (Shimodaira 2002) use the per-site likelihoods of the trees, and ask whether the difference is larger than expected by chance.

Support values and branch lengths are different quantities that are easy to confuse on a printed tree. The branch length is drawn as the length of the branch, with a scale bar in substitutions per site. The support value is a number written next to a node or branch, and in Newick files it is stored as the label of the internal node, as in `(A:0.1,B:0.2)95:0.05`. A long branch can have low support and a very short branch high support.

All of these measures assess *random error*, which decreases as more data are added. None of them protects against *systematic error* from a wrong model or a wrong alignment, which in phylogenomics can give 100% support for an incorrect tree (Section 4.4).

The subsections on data types and on testing the molecular clock were written for this book from the primary literature cited in the text.

4.4 Alignments, genomes and conflicting trees

The classical methods were developed for one gene and tens of taxa. Today, trees are routinely built from hundreds or thousands of genes. With so much data, random error is no longer the main problem.

Errors in the input alignments, model misspecification and genuine conflict between the histories of different genes become more important (Delsuc et al. 2005; Jeffroy et al. 2006; Philippe et al. 2011; Kapli et al. 2020).

4.4.1 Alignment uncertainty

Phylogenetic methods treat the multiple alignment as known, but the alignment is itself an estimate (Section 1.6). In variable regions, different programs, or even different guide trees in the same program, give different alignments, and the trees built from them can differ (Wong et al. 2008). Aligners also interact with the tree in non-obvious ways. Progressive aligners that do not distinguish insertions from deletions tend to "over-align" gaps, and PRANK was designed with a phylogeny-aware gap treatment to avoid this (Löytynoja and Goldman 2008).

There are three ways of dealing with alignment uncertainty:

- **Filtering**: removing poorly aligned and highly variable columns before building the tree, with programs such as Gblocks (Talavera and Castresana 2007) or trimAl (Capella-Gutiérrez et al. 2009). Moderate trimming usually helps, but aggressive trimming removes real phylogenetic signal and can make trees worse.
- **Comparing alternatives**: building trees from several alignments and reporting only the conclusions that are robust to the choice.
- **Joint estimation**: treating the alignment as a parameter and co-estimating alignment and tree in a statistical framework, starting with the TKF91 model of insertions and deletions (Thorne et al. 1991). BAli-Phy samples alignments and trees jointly with MCMC (Redelings and Suchard 2005). This is the most principled solution, but it is computationally feasible only for small data sets.

4.4.2 Phylogenomics

Phylogenomics uses genome-scale data to infer phylogenies. The first step is to identify sets of orthologous genes, usually single-copy genes present in most of the species (Section 3.4), because paralogues that are mistaken for orthologues (*hidden paralogy*) give wrong trees. There are two main ways to combine the genes:

- **Concatenation** (the *supermatrix* approach): the alignments of all genes are joined end to end and analysed as one, often with a separate model for each gene (a *partitioned* analysis). It assumes that all genes share one tree.
- **Separate analysis**: a tree is built for each gene, and the gene trees are combined into a species tree, either as a *supertree* or with methods based on the multispecies coalescent (below).

Early phylogenomic studies showed that single genes are often in conflict, but that concatenating a few dozen genes gave a single, well-supported tree (Rokas et al. 2003). It was soon found that concatenation can give 100% support to conflicting trees in different studies (Jeffroy et al. 2006). With many genes, **systematic errors** dominate, because they do not decrease with more data (Philippe et al. 2011):

- **long-branch attraction** (Section 4.3), when some lineages evolve much faster than others;
- **compositional heterogeneity**, when unrelated lineages share a similar GC or amino acid composition and are grouped together;
- **heterotachy**, when the rate of a site changes over time;
- **saturation**, when sites have changed so often that the signal of old divergences is lost.

The remedies are better models (site-heterogeneous mixtures, non-stationary models; Section 4.3.6), denser taxon sampling to break up long branches, removal of the fastest-evolving sites or genes, and recoding amino acids into groups to reduce compositional bias. The position of animals and fungi, the root of the animal tree (sponges or comb jellies first?) and the relationships between eukaryotic supergroups are well-known examples where the answer depends on how these errors are handled (Steenwyk et al. 2023).

4.4.3 Gene trees and species trees

Even with perfect data and a perfect model, a gene tree need not have the same shape as the species tree (Maddison 1997; Degnan and Rosenberg 2009). Several distinct biological processes cause conflict, and they leave different signatures:

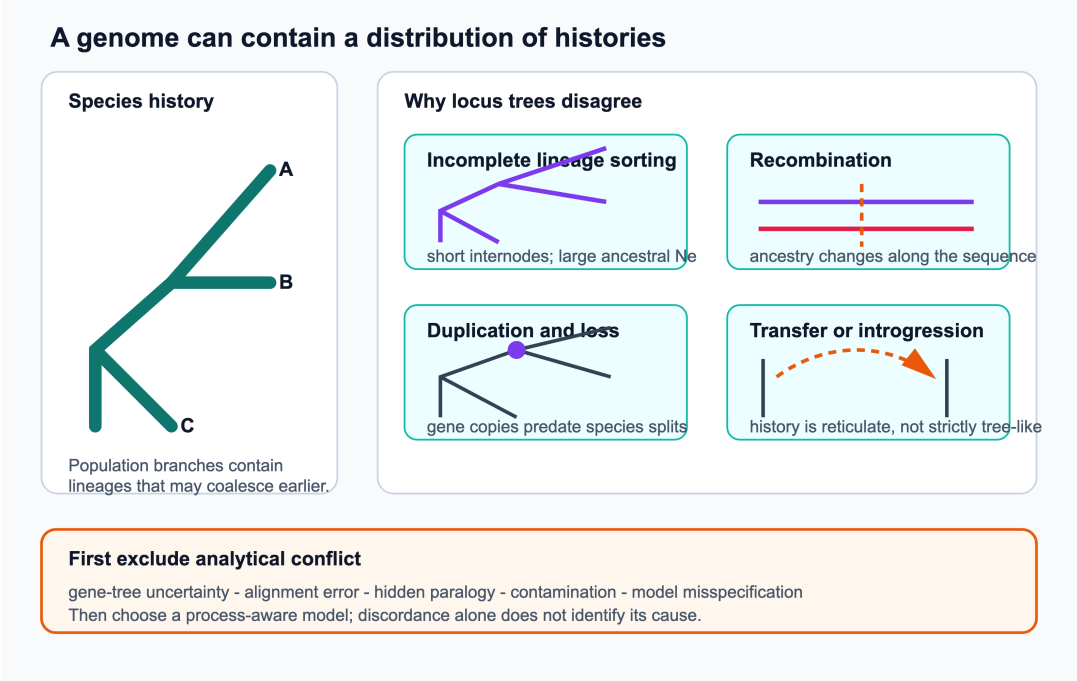

Figure 4.2: Why gene trees disagree with the species tree. The branches of a species tree are populations, in which the lineages of a gene can coalesce earlier than the speciations; incomplete lineage sorting, recombination, duplication and loss, and transfer or introgression all produce gene trees that differ from the species tree. Gene-tree error, alignment error, hidden paralogy, contamination and model misspecification must be excluded first. Figure: Matteo Tadiello, *Modern Bioinformatics: From Foundations to Frontiers* (CC BY 4.0).

- **Incomplete lineage sorting** (ILS). A gene tree traces the ancestry of gene copies back in time, and copies coalesce into their common ancestor at some time *before* the speciation that separated their carriers. If two speciation events follow each other quickly, compared with the effective population size, ancestral polymorphisms can survive through both speciations and be sorted randomly into the descendant species. A gene can then group humans with gorillas rather than with chimpanzees, as about a third of the human genome does (Section 4.5). The **multispecies coalescent** model of population genetics predicts how often each gene tree occurs. For three species, if the internal branch of the species tree has length t in coalescent units (generations divided by $2N_e$), the gene tree that matches the species tree has probability $1 - \frac{2}{3}e^{-t}$ and each of the two discordant trees $\frac{1}{3}e^{-t}$, so short internal branches and large ancestral populations give much discordance. In extreme cases the most common gene tree differs from the species tree

(the *anomaly zone*) (Degnan and Rosenberg 2006), and concatenation can then be statistically inconsistent.

- **Gene duplication and loss.** If a gene duplicated before a speciation and different copies were lost in different lineages, the surviving genes are paralogues whose tree reflects the duplication, not the speciation (hidden paralogy; Section 3.4).
- **Horizontal gene transfer** (HGT), common in prokaryotes, places a gene in a lineage it did not descend in (Section 3.7). Hybridisation and introgression have the same effect in eukaryotes.
- **Recombination** within a locus means that different parts of one gene have different histories, so that no single tree describes the whole gene. Methods that assume one tree per gene, including ASTRAL below, therefore assume that each locus is free of internal recombination.

In practice, much of the observed conflict is not biological at all but **gene-tree estimation error**: single genes are short, carry little signal, and are affected by the same alignment and model errors as any other tree. The causes can often be told apart. ILS is concentrated around short internal branches, and for three species it makes the two minority gene trees about equally frequent; introgression makes one of them more frequent than the other (the basis of the ABBA–BABA test (Green et al. 2010; Durand et al. 2011)). Duplication and loss and HGT are tied to specific events and lineages. Estimation error gives conflict that is poorly supported and changes with the data or model. These causes should be distinguished before HGT, or any other single process, is invoked to explain discordance.

Species-tree methods estimate the species tree from many gene trees while accounting for these processes (Edwards 2009). The most widely used are *summary methods* based on the multispecies coalescent, such as ASTRAL (Mirarab et al. 2014; Zhang et al. 2018), which finds the species tree that agrees with the largest number of four-taxon subtrees (quartets) of the gene trees. Because the most frequent unrooted gene tree for any four taxa always matches the species tree under the coalescent, this is consistent under ILS. Full Bayesian methods that co-estimate gene trees and species tree (such as *BEAST) are more accurate but much slower. Concatenation and coalescent methods give the same answer for most well-resolved relationships, but they can differ for rapid radiations.

4.4.4 Consensus trees, supertrees and concordance

When many trees are available, from bootstrap replicates, an MCMC sample or many genes, they have to be summarised. A **consensus tree** contains the splits that occur in a given fraction of the input trees: all of them in the *strict* consensus, more than half in the *majority-rule* consensus (Margush and McMorris 1981). **Supertree** methods combine trees with different but overlapping sets of taxa into one tree (Bininda-Emonds 2004). Like the coalescent methods above, they treat the estimated gene trees as the data, and are sensitive to poorly estimated gene trees.

The numbers on such trees must be read with care. On a consensus of gene trees, the percentage at a node is the fraction of *genes* that support a split, not a bootstrap value, which measures how stable the split is when the *sites* of one alignment are resampled. Resampling whole genes and resampling sites ask different questions. In a large concatenated data set, almost every branch gets 100% bootstrap support, even when many genes disagree. **Concordance factors** describe the conflict instead: the *gene concordance factor* of a branch is the percentage of gene trees that contain it, and the *site concordance factor* the percentage of informative sites that support it rather than the two alternative arrangements (Minh, Hahn, et al. 2020). A branch with 100% bootstrap support but a gene concordance factor of 35% is well supported by the data as a whole but contested by most individual genes, a typical sign of a rapid radiation or of systematic error.

4.4.5 Reconciliation

Reconciliation compares a gene tree with a species tree and infers the events that explain the differences. Goodman and colleagues introduced the idea in 1979, using globins (Goodman et al. 1979). Each node of the gene tree is mapped to the species tree: if a gene tree node's two descendant subtrees contain genes from overlapping sets of species, the node is interpreted as a duplication, otherwise as a speciation. Modern methods infer duplications and losses (DL models), or duplications, transfers and losses (DTL models), by finding the most parsimonious or most likely set of events. Reconciliation is the basis of tree-based orthology inference (Section 3.4). It also works in the other direction: errors in gene trees can be corrected by using the species tree as a prior, as in methods that infer gene trees together with the species tree (Szöllősi et al. 2014).

4.4.6 Phylogenomics for function prediction

The word phylogenomics was first used for a different idea: the use of gene trees to predict function (Eisen 1998). Annotation by the best database hit (Chapter 10) ignores the history of the family. If a family contains two subfamilies created by an old duplication, with different functions, an uncharacterised protein that falls in subfamily B should not get the function of a protein from subfamily A, even if that protein happens to be its best hit. The phylogenomic approach builds a tree of the family, marks the members with experimentally known functions, infers duplication and speciation nodes by reconciliation, and transfers a function only within the clade, usually a group of orthologues, in which it is supported. Probabilistic versions such as SIFTER model how function changes along the tree (Engelhardt et al. 2005), and the Gene Ontology consortium propagates annotations manually along PANTHER family trees (Gaudet et al. 2011). The method depends on the quality of the tree, the taxon sampling and the rooting, and a function can also change within a group of orthologues.

4.4.7 Phylogenetic networks

When the history of a set of sequences includes recombination, hybridisation or HGT, a single tree cannot represent it. **Phylogenetic networks** generalise trees in two ways (Huson and Bryant 2005):

- **Split networks**, built for example with Neighbor-Net (Bryant 2003) and SplitsTree, display conflicting signals in the data as boxes, without claiming that each box corresponds to a specific evolutionary event. They are useful as exploratory tools: a tree-like network shows that the data are consistent with a tree, while a tangled one shows strong conflict.
- **Explicit networks**, such as hybridisation, recombination and ancestral recombination graphs, represent specific reticulation events with nodes that have two parents.

Recombination is a particular problem for viruses and for bacteria that exchange DNA frequently. A tree built from a recombinant alignment is a mixture of several histories and can be wrong even with strong support. The usual practice is to detect recombination breakpoints first (Kosakovsky Pond et al. 2006), and then to build separate trees for non-recombining segments, to remove the recombined regions, or to use a network.

For prokaryotes, the question of whether evolution is best described by a tree or a network is central to the debate about the tree of life (W. F. Doolittle 1999); see Section 3.7 and Section 4.5.

4.5 The tree of life

Molecular phylogenetics has changed our view of the relationships between all living organisms. This section follows the main steps, from the discovery of the archaea to the current debates about the root of the tree and the origin of eukaryotes, and ends with the best-studied small tree of all, that of humans and the other great apes.

4.5.1 Three domains

Until the 1970s, life was divided into prokaryotes and eukaryotes, and the prokaryotes could not be classified phylogenetically at all, since they have few informative morphological characters. In 1977 Carl Woese and George Fox compared fragments of the 16S ribosomal RNA from many prokaryotes and found that the methanogens were as different from other bacteria as from eukaryotes (Woese and Fox 1977). Ribosomal RNA was an ideal marker: it is present in all cellular life, it is essential and rarely transferred, and it has both conserved and variable regions. Woese proposed the **three-domain system** of Bacteria, Archaea and Eukarya (Woese et al. 1990), which replaced the prokaryote–eukaryote dichotomy and the five-kingdom system.

Since 16S rRNA genes can be amplified directly from the environment, the rRNA tree also opened up the study of uncultivated microbes. Most microbial diversity turned out to be invisible to cultivation. Metagenomics later added whole genomes from uncultivated organisms: a tree built from ribosomal proteins of over 3,000 genomes showed that most diversity is bacterial, and that a large fraction belongs to the **candidate phyla radiation** of small, mostly symbiotic bacteria (Brown et al. 2015; Hug et al. 2016). Genome-based trees are now used to define prokaryotic taxonomy itself, as in the Genome Taxonomy Database (GTDB) (Parks et al. 2018).

4.5.2 Rooting the tree of life

A tree of all life has no outgroup, so it cannot be rooted in the usual way. In 1989 two groups addressed the problem with **paralogous genes** that duplicated before the last universal common ancestor (Gogarten et al. 1989; Iwabe et al. 1989). Each copy of such a pair, for example the two elongation factors EF-Tu and EF-G, or the catalytic and regulatory subunits of ATP synthase, can serve as an outgroup for the tree of the other. Both studies placed the root between the Bacteria and the Archaea + Eukarya, which has been the standard view since, although the signal in such ancient duplications is weak and the analyses are sensitive to long-branch attraction.

The organism at the root, the **last universal common ancestor (LUCA)**, can be characterised by the genes that are reconstructed as present at the root. Weiss and colleagues identified 355 protein families that suggest an anaerobic, thermophilic organism that fixed carbon and nitrogen and depended on hydrogen, possibly in a hydrothermal environment (Weiss et al. 2016). A more recent analysis using gene-tree–species-tree reconciliation estimated that LUCA lived about 4.2 billion years ago and already

had a relatively complex genome, including an early immune system (Moody et al. 2024). Both the age and the gene content are uncertain, because HGT and gene loss make it hard to decide which genes really go back to LUCA. The root of the Bacteria themselves has been placed with similar methods between two large groups, the Terrabacteria and the Gracilicutes (Coleman et al. 2021). The origin of life before LUCA is discussed in Section 3.2.

4.5.3 Two domains and the origin of eukaryotes

Where do eukaryotes come from? The three-domain tree makes Archaea and Eukarya sister groups. The alternative **eocyte hypothesis**, proposed by James Lake in the 1980s, places eukaryotes *within* the Archaea. With better models and more genomes, phylogenomic analyses have come to support the second view, the **two-domain tree** (Williams et al. 2019).

The decisive data came from metagenomics. In 2015, genomes assembled from deep-sea sediments near the hydrothermal vent field Loki's Castle revealed the **Lokiarchaeota**, archaea that encode many proteins previously thought to be specific to eukaryotes, such as actins and small GTPases (Spang et al. 2015). The related **Asgard archaea** were then found worldwide (Zaremba-Niedzwiedzka et al. 2017), the first one was cultivated after a twelve-year effort (Imachi et al. 2020), and the most recent analyses place eukaryotes within the Asgard archaea, from within the Heimdallarchaeia (Eme et al. 2023). In this view, eukaryotes arose when an Asgard archaeon took up an alphaproteobacterium that became the mitochondrion. Eukaryotic genomes are therefore chimeras: genes for information processing (replication, transcription, translation) are mostly archaeal, while many metabolic genes are bacterial, partly through *endosymbiotic gene transfer* (Section 3.7).

Within the eukaryotes, the classical kingdoms (animals, plants, fungi, protists) have been replaced by a handful of **supergroups**. Animals and fungi belong to the Opisthokonta, plants to the Archaeplastida, and most of the diversity is in protist lineages such as the SAR group (stramenopiles, alveolates and rhizarians) and several lineages once grouped together as the Excavata. The relationships between the supergroups, and the position of the eukaryotic root, are still debated (Burki et al. 2020). Combining molecular clocks with fossils, the last common ancestor of eukaryotes is estimated to have lived roughly 1–2 billion years ago, although the estimates vary widely (Betts et al. 2018).

4.5.4 Tree or network?

The tree of life is a tree only for some genes. In prokaryotes, frequent horizontal gene transfer means that different genes have different histories, and some authors have argued that the tree of life should be replaced by a network (W. F. Doolittle 1999). Most phylogenomic analyses take a middle position: a core of genes that are rarely transferred, such as those for ribosomal proteins, gives a consistent "tree of cells", on top of which there is a web of transfers (Section 3.7; Section 4.4). The origin of eukaryotes, by fusion of an archaeon and a bacterium, is itself a reticulation at the base of the eukaryotic branch.

4.5.5 Taxonomy and the tree

Taxonomy is the science of naming, describing and classifying organisms. Phylogeny and taxonomy are related but not the same: a phylogeny is a hypothesis about history, while a taxonomy is a system of names, governed by conventions, that is used to communicate about organisms. Since Hennig, most taxonomists aim for a classification in which every named group is a clade (Section 4.2), so taxonomies are revised as trees change. Paraphyletic groups such as "reptiles" without birds, or the "Pongidae" discussed below, are then abandoned or kept only as informal names.

The **Linnaean ranks** (domain, kingdom, phylum, class, order, family, genus, species) are a legacy of pre-evolutionary classification. A tree has no ranks, only nested clades, and most clades are left unranked. Ranks are assigned by convention within each group, so they are **not comparable across groups**: a mammalian genus and a bacterial genus need not be of similar age or divergence, and a "family" of insects may be much older than a "family" of birds. Counting families or genera to compare diversity between groups is therefore misleading.

Names are governed by separate **codes of nomenclature**: for animals (ICZN), for algae, fungi and plants (ICN), for prokaryotes (ICNP) and for viruses (ICTV). The codes regulate names, priority and type specimens, but not the classification itself. The prokaryotic code requires a described type strain deposited in culture collections, which excluded most of the diversity known only from sequences; such organisms received provisional *Candidatus* names. The **SeqCode** now allows a genome sequence to serve as the type, so that uncultivated prokaryotes can be validly named (Hedlund et al. 2022).

Species are the most debated rank. The biological species concept, based on reproductive isolation, cannot be applied to asexual organisms or to most prokaryotes, which exchange genes horizontally across species boundaries (Section 3.7). Prokaryotic species were traditionally defined operationally, by 70% DNA–DNA hybridisation and later also by 16S rRNA identity (about 97–99%; Section 5.7). Genome sequences replaced these with the **average nucleotide identity** (ANI, Section 1.5) of shared regions: an ANI of about 95% corresponds to the old hybridisation threshold (Konstantinidis and Tiedje 2005), and comparisons of tens of thousands of genomes show a gap in the distribution of ANI values around 95%, suggesting a natural, if fuzzy, species boundary (C. Jain et al. 2018). Whether this gap reflects biology or the uneven sampling of genomes is still discussed.

The **Genome Taxonomy Database** (GTDB) applies these ideas systematically to bacteria and archaea (Parks et al. 2018; Parks et al. 2020). It builds trees from conserved single-copy proteins (120 for bacteria, 53 for archaea) of all available genomes, including metagenome-assembled ones, and requires every taxon to be monophyletic. Ranks are normalised with the **relative evolutionary divergence** (RED): each node in the tree is given a value between 0 at the root and 1 at the tips, interpolated along the branches so that lineages evolving at different rates are treated fairly, and taxa of the same rank are required to have similar RED values. Species are defined as clusters of genomes with ANI of at least about 95%. The result changed the classification of a large fraction of genomes, split polyphyletic groups (often marked with suffixes, such as Firmicutes_A) and merged others. It is the closest thing to a phylogenetically consistent taxonomy for any large group of organisms, but it differs from NCBI Taxonomy, which is a curated working classification and states that it is not an authority on names (Section 2.4).

Sequence-based taxonomy has changed what is classified. After Woese, 16S rRNA surveys showed that most microbial lineages had never been cultivated, and metagenomics now provides genomes for them (Section 5.7). A large part of the named phyla of bacteria and archaea is known only from sequences, and the same is true for viruses, many of which are now classified from metagenomic genomes alone. In practice, a taxonomic label in a metagenomic study is an inference that depends on the reference taxonomy (NCBI or GTDB) and its version, and it should be reported as such.

4.5.6 Hominoid and human evolution

The great apes (family Hominidae) are humans, chimpanzees and bonobos, gorillas and orangutans. Together with the gibbons they form the hominoids. Until the 1960s, humans were usually placed in their own family, and the other great apes in the Pongidae. This turned out to be a paraphyletic group: immunological and protein data from Morris Goodman and others, and later DNA sequences, showed that chimpanzees are more closely related to humans than to gorillas. The current consensus tree is ((((human, (chimpanzee, bonobo)), gorilla), orangutan), gibbons). Classical estimates put the divergence of humans and chimpanzees at about 5–7 million years ago, gorillas at 8–10 million years

ago and orangutans at 15–20 million years ago, but these dates depend strongly on the mutation rate and generation time used (Scally and Durbin 2012).

The genomes of the chimpanzee (The Chimpanzee Sequencing and Analysis Consortium 2005), gorilla (Scally et al. 2012) and other great apes (Prado-Martinez et al. 2013) made the great-ape tree a textbook case of **incomplete lineage sorting** (Section 4.4). Because the human–chimpanzee and human–gorilla speciations were close in time and ancestral populations were large, about 30% of the gorilla genome is closer to human or chimpanzee than these are to each other (Scally et al. 2012). Models that combine the coalescent with a hidden Markov model along the genome (CoalHMM) estimate speciation times and ancestral population sizes from these patterns (Hobolth et al. 2007). Patterns on the X chromosome even suggested that gene flow continued between early human and chimpanzee populations after their initial split (Patterson et al. 2006), a claim that is still debated. The first complete, telomere-to-telomere genomes of all great apes now give access also to the repetitive and structurally variable parts of the genomes (Yoo et al. 2025).

The fossil record of the *hominins*, the lineage leading to humans after the split from chimpanzees, includes early forms such as *Sahelanthropus* and *Ardipithecus*, several species of *Australopithecus* (including "Lucy", *A. afarensis*, 3.2 million years old) and the genus *Homo*, which appeared about 2.5 million years ago. Several *Homo* species coexisted until recently. Anatomically modern humans arose in Africa about 300,000 years ago and spread across the world from about 60,000 years ago. Ancient DNA has shown that they met and mixed with Neanderthals and Denisovans. The genomics of these events, and what they reveal about human genome evolution, is discussed in Chapter 6.

Parts of this section are adapted from the Wikipedia articles Three-domain system, Two-domain system, Tree of life (biology), Last universal common ancestor, Asgard (archaea), Eukaryote, Hominidae and Human evolution (CC BY-SA 4.0, retrieved 3 October 2026). The subsection on taxonomy was written for this book from the primary literature cited in the text.

4.6 Key concepts

A checklist for revision.

- **History:** Haeckel's trees; Hennig and cladistics; Fitch and Margoliash (1967); Felsenstein's contributions (long-branch attraction, pruning algorithm, bootstrap); neighbour joining; Bayesian phylogenetics
- **Tree terminology:** rooted/unrooted, topology, branch lengths (change, not time) and ultrametric time trees; clades, mono-, para- and polyphyly; splits vs. clades; sister groups; polytomies; outgroup, midpoint and clock rooting and their assumptions; the number of possible trees, $(2n-5)!!$; Newick format
- **Distance methods:** corrected distances and saturation (Jukes–Cantor correction); UPGMA and the molecular-clock (ultrametric) assumption; neighbour joining, additive distances and its Q criterion; minimum evolution and FastME
- **Maximum parsimony:** Fitch's and Sankoff's algorithms; informative sites; long-branch attraction and the Felsenstein zone; statistical inconsistency
- **Maximum likelihood:** the likelihood of a tree; Felsenstein's pruning algorithm; tree search (NNI, SPR, TBR); RAxML, IQ-TREE, PhyML, FastTree
- **Bayesian inference:** priors and posteriors; MCMC, burn-in and convergence; MrBayes; dating with relaxed clocks in BEAST; phylodynamics

- **Substitution models:** Markov models, $P(t) = e^{Qt}$, stationarity and reversibility; JC69, K80, F81, HKY, GTR; rate heterogeneity (+Γ, +I); empirical protein matrices (JTT, WAG, LG); site-heterogeneous mixture models (CAT); model selection with LRT, AIC and BIC; model adequacy (parametric bootstrap, posterior predictive checks)
- **Data types and clocks:** nucleotides vs. codons vs. amino acids and when each is appropriate; saturation and how to detect it; compositional heterogeneity and its remedies (removing third positions, RY-coding, LogDet, non-stationary models, recoding); partitioning by codon position; codon models and ω; relative rate tests (Sarich–Wilson, Tajima); likelihood-ratio test of clock vs. no clock ($n - 2$ degrees of freedom); root-to-tip regression; local and relaxed clocks
- **Support:** nonparametric and ultrafast bootstrap (not the probability that a clade is true); support values vs. branch lengths; transfer bootstrap; aLRT; posterior probabilities and why they differ from bootstrap values; topology tests (KH, SH, AU); random vs. systematic error
- **Alignment uncertainty:** alignment errors and trees; trimming (Gblocks, trimAl); joint estimation of alignment and tree (BAli-Phy)
- **Phylogenomics:** orthologue selection and hidden paralogy; concatenation vs. separate analysis; systematic errors (long-branch attraction, compositional bias, heterotachy, saturation) and their remedies
- **Gene trees vs. species trees:** incomplete lineage sorting and the multispecies coalescent; duplication and loss; HGT and introgression; recombination; three-taxon gene-tree probabilities under the coalescent; gene-tree estimation error; ASTRAL; strict and majority-rule consensus trees and supertrees; gene versus site resampling; gene and site concordance factors; reconciliation (DL and DTL models); split and explicit phylogenetic networks
- **Phylogenomic function prediction:** Eisen's phylogenomics; transferring function within a clade of orthologues rather than from the best hit; SIFTER; GO annotation along PANTHER trees
- **Taxonomy:** taxonomy vs. phylogeny; Linnaean ranks vs. clades and why ranks are not comparable across groups; codes of nomenclature, *Candidatus* names and the SeqCode; species concepts, DNA–DNA hybridisation, 16S thresholds and ANI ≈ 95%; GTDB, monophyly and relative evolutionary divergence; NCBI Taxonomy as a working classification; sequence-based taxonomy of uncultivated organisms
- **Tree of life:** Woese and the three domains; candidate phyla radiation; GTDB; rooting with ancient paralogues; LUCA; Asgard archaea and the two-domain tree; eukaryotic supergroups; tree vs. network of life
- **Hominoid evolution:** the great-ape tree; divergence times and their dependence on mutation rate; incomplete lineage sorting in the human–chimpanzee–gorilla trio; CoalHMM; the hominin fossil record

4.7 Recommended reading

These papers are recommended for reading in full:

- Saitou and Nei (1987) — neighbour joining; the distance method still used everywhere, and a model of a clear algorithm paper.
- Felsenstein (1981) — maximum likelihood trees from DNA sequences and the pruning algorithm.
- Kapli et al. (2020) — tree building in the genomic age; an up-to-date review of methods, models and pitfalls.
- Minh, Schmidt, et al. (2020) — IQ-TREE 2; what a modern maximum-likelihood program does (models, search, support).
- Philippe et al. (2011) — why more sequences are not enough; systematic error in phylogenomics.
- Hug et al. (2016) — a new view of the tree of life from thousands of genomes.

Titles, abstracts, links and the full texts are in Section A.4; a longer list of further papers is in Section B.4.

4.8 Background reading (open access)

- **Understanding Evolution: Phylogenetic systematics** — An illustrated introduction from Berkeley's Understanding Evolution site to phylogenetic trees: how to read them, how they are built with cladistics, and common misconceptions.
  https://evolution.berkeley.edu/phylogenetic-systematics/
- **Phylogenetics (Wikipedia)** — In biology, phylogenetics is the study of the evolutionary history of life using observable characteristics of organisms, which is known as phylogenetic inference.
  https://en.wikipedia.org/wiki/Phylogenetics
- **Phylogenetic tree (Wikipedia)** — A phylogenetic tree or phylogeny is a graphical representation which shows the evolutionary history between a set of species or taxa during a specific time.
  https://en.wikipedia.org/wiki/Phylogenetic_tree
- **Cladistics (Wikipedia)** — Cladistics is an approach to biological classification in which organisms are categorized in groups ("clades") based on hypotheses of most recent common ancestry.
  https://en.wikipedia.org/wiki/Cladistics
- **Computational phylogenetics (Wikipedia)** — Computational phylogenetics, phylogeny inference, or phylogenetic inference focuses on computational and optimization algorithms, heuristics, and approaches involved in phylogenetic analyses. The goal is to find a phylogenetic tree representing optimal evolutionary ancestry between a set of genes, species, or taxa.
  https://en.wikipedia.org/wiki/Computational_phylogenetics
- **Models of DNA evolution (Wikipedia)** — A number of different Markov models of DNA sequence evolution have been proposed. These substitution models differ in terms of the parameters used to describe the rates at which one nucleotide replaces another during evolution. These models are frequently used in molecular phylogenetic analyses.
  https://en.wikipedia.org/wiki/Models_of_DNA_evolution
- **Substitution model (Wikipedia)** — In biology, a substitution model, also called models of sequence evolution, are Markov models that describe changes over evolutionary time. These models describe evolutionary changes in macromolecules, such as DNA sequences or protein sequences, that can be represented as a sequence of symbols.
  https://en.wikipedia.org/wiki/Substitution_model
- **UPGMA (Wikipedia)** — UPGMA is a simple agglomerative (bottom-up) hierarchical clustering method. It also has a weighted variant, WPGMA, and they are generally attributed to Sokal and Michener.
  https://en.wikipedia.org/wiki/UPGMA
- **Neighbor joining (Wikipedia)** — In bioinformatics, neighbor joining is a bottom-up (agglomerative) clustering method for the creation of phylogenetic trees, created by Naruya Saitou and Masatoshi Nei in 1987.
  https://en.wikipedia.org/wiki/Neighbor_joining
- **Maximum parsimony (Wikipedia)** — In evolutionary biology, maximum parsimony is a method used to build phylogenetic trees based on the principle of simplicity. Under the maximum-parsimony criterion, the best tree will minimize the amount of homoplasy.
  https://en.wikipedia.org/wiki/Maximum_parsimony
- **Bayesian inference in phylogeny (Wikipedia)** — Bayesian inference of phylogeny combines the information in the prior and in the data likelihood to create the so-called posterior probability of trees, which is the probability that the tree is correct given the data, the prior and the likelihood model.
  https://en.wikipedia.org/wiki/Bayesian_inference_in_phylogeny
- **Bootstrapping (statistics) (Wikipedia)** — Bootstrapping is a procedure for estimating the distribution of an estimator by resampling one's data or a model which is estimated from the data. Bootstrapping assigns measures of accuracy to sample estimates.
  https://en.wikipedia.org/wiki/Bootstrapping_(statistics)

- **Phylogenomics (Wikipedia)** — Phylogenomics is the intersection of the fields of evolution and genomics. The term has been used in multiple ways to refer to analysis that involves genome data and evolutionary reconstructions. It is a group of techniques within the larger fields of phylogenetics and genomics.
  https://en.wikipedia.org/wiki/Phylogenomics
- **Incomplete lineage sorting (Wikipedia)** — Incomplete lineage sorting (ILS) (also referred to as hemiplasy, deep coalescence, retention of ancestral polymorphism, or trans-species polymorphism) is a phenomenon in evolutionary biology and population genetics that results in discordance between species and gene trees.
  https://en.wikipedia.org/wiki/Incomplete_lineage_sorting
- **Phylogenetic network (Wikipedia)** — A phylogenetic network is any graph used to visualize evolutionary relationships between nucleotide sequences, genes, chromosomes, genomes, or species. They are employed when reticulation events such as hybridization, horizontal gene transfer, recombination, or gene duplication and loss are believed to be involved.
  https://en.wikipedia.org/wiki/Phylogenetic_network
- **Tree of life (biology) (Wikipedia)** — The tree of life or universal tree of life is a metaphor, conceptual model, and research tool used to explore the evolution of life and describe the relationships between organisms, both living and extinct, as described in a famous passage in Charles Darwin's On the Origin of Species (1859).The affinities of all the beings of the same class have sometimes been represented by a great tree.
  https://en.wikipedia.org/wiki/Tree_of_life_(biology)
- **Two-domain system (Wikipedia)** — The two-domain system is a biological classification system that groups all cellular organisms in the tree of life into two domains: Archaea and Bacteria, while eukaryotes are considered a specialized clade under Archaea.
  https://en.wikipedia.org/wiki/Two-domain_system
- **Human evolution (Wikipedia)** — Homo sapiens is a distinct species of the hominid family of primates, which includes all the great apes. Over their evolutionary history, humans gradually developed traits such as bipedalism, dexterity, and complex language.
  https://en.wikipedia.org/wiki/Human_evolution

4.9 Student recommendations

Recommended by students preparing for the exam: papers, reviews, online lectures, tutorials and short explanations. To suggest something, use the suggestion form (SU login).

No recommendations yet.

4.10 Review problems

These problems are adapted from Matteo Tadiello, *Modern Bioinformatics: From Foundations to Frontiers* (CC BY 4.0), used with permission. For a longer treatment of this topic, see the chapters "Phylogenetics" and "Phylogenomics and Discordant Histories" of that book. In the HTML version, click a box to show the extensions, solution outline and common errors.

4.10.1 Interpreting tree topology

In a published tree, human is drawn next to mouse, and chimpanzee further away. Does the drawing show that humans are more closely related to mice than to chimpanzees? Justify your interpretation.

Extensions, solution outline and common errors

Extensions:

1. What information on a tree defines relatedness?
2. What changes when branches are rotated?
3. What is the difference between a rooted and an unrooted tree?
4. Can a living species at a tip be the ancestor of another tip?

Solution outline:

- Ignore the distance on the page and the order of the tips; find the most recent common ancestors implied by the topology.
- Rotating the descendants around an internal node does not change the topology.
- On a rooted tree, compare how recent the shared ancestors are; on an unrooted tree, only splits can be discussed, without direction.
- State how the tree was rooted and whether that assumption is justified.
- Distinguish branch lengths, support values and time.
- Sampled living species are treated as tips, not as the ancestors of other tips.

Common errors:

- Reading the left-to-right order of the tips, or their closeness on the page, as relatedness.
- Calling the first-diverging living lineage “primitive”.
- Treating the arbitrary root of a plotting program as biological evidence.

Connections: Section 4.2; homology in 1; orthology in Section 3.4.

4.10.2 Comparing parsimony, distance, likelihood and Bayesian inference

An aligned single-copy gene has been sequenced from 40 species. Choose and justify a strategy for building the tree, including preprocessing, the estimation of uncertainty and checks of the model.

Extensions, solution outline and common errors

Extensions:

1. How does neighbour joining differ from maximum likelihood?
2. Why is parsimony not free of assumptions?
3. What extra quantity does Bayesian inference compute?
4. Is the likelihood of the best tree the probability that the tree is true?

Solution outline:

- The target is a gene tree. Check the alignment, recombination and orthology first.
- A neighbour-joining tree from corrected distances is a fast first look, but reducing the alignment to pairwise distances discards information in the site patterns.

- Parsimony minimises the number of character changes and can be statistically inconsistent when branch lengths are very unequal (long-branch attraction).
- Maximum likelihood maximises $P(D \mid T, b, \theta)$ under an explicit substitution model, computed with the pruning algorithm, and searches tree space heuristically.
- Bayesian inference combines the likelihood with priors to sample from $P(T, b, \theta \mid D)$, using MCMC, and requires checks of convergence.
- For a single locus, model-based maximum likelihood with several searches, support values and model checks is a reasonable default; another approach is needed if the history violates the assumption of a single tree.

Common errors:

- Saying that maximum likelihood "calculates all possible trees".
- Confusing $P(D \mid T)$ with $P(T \mid D)$.
- Choosing the software before checking what history the sequences represent.

Connections: Section 4.3; Section 4.3.9; multiple alignment in Section 1.6.

4.10.3 Substitution models and likelihood

Explain why the proportion of differing sites is generally not a good measure of evolutionary distance, and describe the role of the substitution model in the likelihood of a tree.

Extensions, solution outline and common errors

Extensions:

1. What is a rate matrix?
2. Compare JC69, HKY85 and GTR.
3. What does gamma-distributed rate variation do?
4. How can a likelihood be computed without assigning every ancestral sequence?

Solution outline:

- Observed differences hide multiple substitutions and reversions at the same site; evolutionary distance is the expected number of substitutions per site.
- Define the rate matrix Q and $P(t) = e^{Qt}$; the branch length connects the process to the transition probabilities.
- The models differ in their assumptions about equilibrium frequencies and exchange rates; a more complex model is not automatically closer to the truth.
- Discrete gamma categories approximate variation in rate between sites; they do not model changes in the rate of a site over time.
- Felsenstein's pruning algorithm propagates conditional likelihood vectors from the leaves towards the root, multiplying over the child branches at each internal node and summing over the possible states at the root.
- Pruning makes the likelihood of one tree fast to compute; the search over topologies remains a hard combinatorial problem.

Common errors:

- Calling substitutions directly observed events.
- Saying that GTR is always best because it has more parameters.
- Treating the arbitrary root used in the pruning calculation as a biological root.

Connections: Section 4.3.6; Section 4.3; mutation versus substitution in Section 3.3; alignment scores in Section 1.3.

4.10.4 A strongly supported but implausible tree

Two rapidly evolving parasites form a clade with 100% bootstrap support, contrary to well-supported independent evidence. Design an analysis that distinguishes random from systematic error.

Extensions, solution outline and common errors

Extensions:

1. What is long-branch attraction?
2. Can maximum likelihood also be wrong?
3. Would removing the fast-evolving taxa solve the problem?
4. What does 100% bootstrap support actually mean?

Solution outline:

- Recheck the identity of the sequences, contamination, orthology, domain architecture, taxon coverage and alignment.
- In long-branch attraction, convergent changes on two separate long branches outweigh the signal of a short internal branch; parsimony can then be statistically inconsistent.
- Maximum likelihood can also fail when the model is badly misspecified, for example with heterogeneous composition or rates, or when the taxon sampling is poor.
- Test for compositional bias and saturation, add taxa that break up the long branches, vary the outgroups, and use site- or composition-heterogeneous models.
- Compare support across alignments and models rather than deleting inconvenient taxa.
- A bootstrap value of 100% means that the split is recovered from every resampled alignment with the same method; it is not the probability that the split is true, and it does not protect against errors shared by all replicates.

Common errors:

- Diagnosing long-branch attraction merely because two branches look long.
- Assuming that more sites remove systematic error.
- Removing discordant taxa until the expected tree is recovered.

Connections: Section 4.3; Section 4.3.9; systematic error in Section 4.4.

4.10.5 Rooting and dating a tree

Given an unrooted gene tree of mammals, explain how to place the root and estimate divergence times with their uncertainty.

Extensions, solution outline and common errors

Extensions:

1. What makes a good outgroup?
2. Why can midpoint rooting fail?

3. What information separates rate from time?
4. Compare strict and relaxed clocks.

Solution outline:

- Check that the gene history is appropriate for the question about species, and that the outgroup sequences are homologous.
- Use independently justified outgroups that are not too distant, and test whether the root is stable across outgroups and models.
- Midpoint rooting assumes roughly equal distances from the root to all tips; variation in rate between lineages violates this.
- A branch length is $b = r\Delta t$: sequences estimate the amount of change, while dated tips, fossils, geological events or an external rate give the time scale.
- A strict clock assumes one rate for all branches; relaxed clocks allow the rate to vary between branches.
- Specify where the calibrations are placed and their uncertainty, the tree prior, and sensitivity analyses; report credible intervals that are conditional on these choices.

Common errors:

- Treating the most "primitive-looking" or longest-branched taxon as the root.
- Equating the age of a fossil with the exact age of a node.
- Reporting precise dates without calibrations or sensitivity to the priors.

Connections: Section 4.2; Bayesian dating in Section 4.3; the molecular clock in Section 3.3.

4.10.6 A species tree under incomplete lineage sorting

Hundreds of gene trees disagree about the relationships of three species from a rapid radiation. Does this refute a bifurcating species history? Design an appropriate analysis.

Extensions, solution outline and common errors

Extensions:

1. What is incomplete lineage sorting?
2. Give the probabilities of the three gene trees for three species.
3. Why can a majority vote over gene trees fail with more species?
4. Compare concatenation, ASTRAL and full multispecies-coalescent methods.

Solution outline:

- In incomplete lineage sorting, ancestral gene lineages persist through two successive speciations before they coalesce.
- With the internal branch of the species tree of length t in coalescent units, the gene tree that matches the species tree has probability $1 - \frac{2}{3}e^{-t}$, and each of the two discordant trees $\frac{1}{3}e^{-t}$.
- Short internal branches and large ancestral effective population sizes increase discordance.
- With more species, a discordant gene tree can be more frequent than the matching one (the anomaly zone), so a simple majority vote can give the wrong species tree (Degnan and Rosenberg 2006).
- Concatenation assumes one tree for all genes. Summary methods such as ASTRAL use the

estimated gene trees, and full methods also integrate over the uncertainty in sequences and gene trees.
- Check for gene-tree estimation error, recombination within loci, hidden paralogy and introgression before attributing all conflict to incomplete lineage sorting.

Common errors:

- Saying that every locus should match the species tree.
- Treating loci as independent without checking linkage and recombination.
- Interpreting an ASTRAL tree as robust to every kind of discordance.

Connections: Section 4.4; drift and effective population size in Section 3.3; great-ape evolution in Section 4.5.

4.10.7 Recombination, horizontal transfer and other causes of conflict

A bacterial gene supports a topology different from the tree of the core genome. Evaluate horizontal transfer as one hypothesis among the biological and analytical explanations of the conflict.

Extensions, solution outline and common errors

Extensions:

1. How does recombination violate standard tree inference?
2. How could recombination breakpoints be detected?
3. What else causes conflict between gene trees and species trees?
4. When is a network preferable to a tree?

Solution outline:

- Horizontal transfer is a hypothesis, not the definition of conflict.
- Check orthology, contamination, assembly context, alignment, the amount of signal, composition and support values.
- Recombination changes the tree along the sequence; detect breakpoints and analyse the segments separately, or use a method that allows recombination, rather than forcing one tree.
- Look for independent evidence of transfer: a well-supported conflicting gene tree, an insertion at an unusual genomic position, a patchy presence–absence pattern, and composition compared with suitable controls.
- Consider incomplete lineage sorting, duplication and loss, introgression, recombination and estimation error as alternatives.
- Use reconciliation or explicit network models when reticulation is the target; a split network that only displays incompatible signals is descriptive.

Common errors:

- Calling every discordant bacterial gene horizontally transferred.
- Treating unusual GC content as proof.
- Building one tree from a mosaic alignment and taking its support values literally.

Connections: Section 4.4; horizontal gene transfer in Section 3.7; gene order in Section 6.5; pan-genomes in Section 6.6.

4.10.8 Designing a phylogenomic analysis

Design a study of the history of a difficult radiation of 80 species with 2,000 candidate loci, including alternative representations if a single bifurcating species tree is inadequate.

Extensions, solution outline and common errors

Extensions:

1. How would you choose taxa and loci?
2. Would you trim the alignments and partition the data by gene?
3. Which results would show that the conclusions are robust?
4. What must be archived so that the analysis can be repeated?

Solution outline:

- Define whether the target is a bifurcating species tree, a reticulate history or the distribution of gene histories.
- Sample taxa that break up long branches; establish orthology with gene trees, copy number, conserved gene order and domains; record missing data.
- Align each locus, inspect the uncertainty in the alignments, define loci so that they do not span recombination breakpoints, and trim moderately rather than automatically.
- Compare partitioning and model schemes; infer the gene trees with their uncertainty, and a partitioned concatenated maximum-likelihood tree.
- Estimate a coalescent species tree, report gene and site concordance factors, and test for introgression or duplication and transfer where the conflict is structured.
- Test the robustness of the topology to alignments, models, taxon subsets, loci, outgroups and support measures.
- Archive the accession numbers and versions, alignments, exclusions, partitions, commands, software versions, random seeds, trees and bootstrap or posterior samples.

Common errors:

- Assuming that 2,000 loci guarantee the correct answer.
- Reporting only a consensus tree with support values and hiding the discordance.
- Letting the preferred topology decide which data are filtered out.

Connections: Section 4.4; orthology inference in Section 3.4; alignment uncertainty and support in Section 4.3.9.

4.10.9 Data type, saturation and the clock

You want to date the divergence of several vertebrate classes from a set of nuclear protein-coding genes. Decide whether to analyse nucleotides, codons or amino acids, and how you would test whether a molecular clock can be assumed.

Extensions, solution outline and common errors

Extensions:

- How would you detect saturation of third codon positions?
- How can differences in GC content between lineages mislead a tree?
- Give the degrees of freedom of the likelihood-ratio test of a clock for n sequences, and explain them.

Solution outline:

1. At divergences of hundreds of millions of years, third codon positions are usually saturated: plot uncorrected against corrected distances, or compare trees from different codon positions.
2. Use amino acids, or nucleotides without third positions (or RY-coded), possibly partitioned by codon position; check for compositional heterogeneity and consider non-stationary or recoded analyses; codon models are realistic but costly.
3. Test the clock with relative rate tests for pairs of lineages against an outgroup, and with a likelihood-ratio test of the clock-constrained tree ($n - 1$ node heights) against the unconstrained tree ($2n - 3$ branch lengths), $n - 2$ degrees of freedom.
4. If the strict clock is rejected, as is likely, use a relaxed-clock Bayesian analysis with several fossil calibrations, and report how sensitive the dates are to the clock model and the calibrations.

Common errors:

- Using all nucleotide positions for deep divergences and trusting high support.
- Treating branch lengths as times without a clock model.
- Assuming that failure to reject the clock proves it (low power with few sites).

Connections: Section 4.3.6, Section 4.3; the molecular clock (Section 3.3); detecting selection with codon models (Section 3.6).

5 Genomics

> **From the exam description**
>
> Methods for sequencing, algorithms for assembly, gene predictions, etc.

5.1 Overview

Genomics turns DNA molecules into genome sequences and genome sequences into biological knowledge. In less than fifty years, sequencing has gone from a few hundred bases per experiment to complete human genomes in a day, and each new technology has required new algorithms. This chapter follows that history, with the focus on the computational methods. Students should know how the technologies work, but above all why they lead to the algorithmic problems they do.

- sequencing technologies, from Sanger to single-molecule long reads, and the theory of shotgun sequencing and coverage (Section 5.2);
- genome assembly: overlap graphs, string graphs and de Bruijn graphs, repeats, scaffolding and assembly quality (Section 5.3);
- read mapping and variant calling: indexes, SAM and VCF records, mapping quality, genotype likelihoods, structural variants, phasing, targeted sequencing, copy number and somatic variants in cancer (Section 5.4);
- regulatory and epigenomic sequencing: ChIP-seq, ATAC-seq, bisulfite and long-read methylation calling, and CLIP-seq (Section 5.5);
- gene prediction in prokaryotes and eukaryotes (Section 5.6);
- metagenomics: amplicon and shotgun sequencing, profiling, assembly and binning (Section 5.7);
- human genetics: linkage disequilibrium, genome-wide association studies, fine-mapping, polygenic scores, and the search for Mendelian disease variants by exome and genome sequencing (Section 5.8).

The algorithms for exact matching that underlie read mapping are described in Section 1.4. What genome sequences have revealed about genome organisation and evolution is the subject of Chapter 6, and the sequencing of RNA of Chapter 7.

5.2 Sequencing methods

Every genome analysis starts with reading DNA, and the properties of the reads, their length, their error profile and their cost, determine which algorithms are needed. This section describes the main sequencing technologies, roughly in historical order, and the basic theory of shotgun sequencing (Shendure et al. 2017; Goodwin et al. 2016).

5.2.1 First generation: Sanger sequencing

Two methods for sequencing DNA were published in 1977. Allan Maxam and Walter Gilbert used chemicals that cleave DNA after specific bases (Maxam and Gilbert 1977). Frederick Sanger's **chain-termination method** (Sanger, Nicklen, et al. 1977) became the standard. A DNA polymerase copies a single-stranded template in the presence of normal nucleotides and a small amount of *dideoxynucleotides* (ddNTPs), which lack the 3' hydroxyl group needed to extend the chain. Each time a ddNTP is incorporated, synthesis stops, so the reaction produces fragments ending at every position. Originally four reactions, one per base, were run in separate lanes of a gel. The same year Sanger's group published the first complete DNA genome, the 5,386 bases of the bacteriophage φX174, and in 1980 Sanger and Gilbert shared the Nobel Prize in Chemistry.

Sanger sequencing was automated in the 1980s by labelling each of the four ddNTPs with a different fluorescent dye, so that all four reactions could run in one lane and be read by a laser (Smith et al. 1986), and later by replacing gels with capillaries. Capillary sequencers produced the first bacterial genomes and the human genome. Reads are 500–1,000 bases long and very accurate. To use them, each base needed a reliable error estimate. The program **Phred** (Ewing et al. 1998) introduced the quality score; most modern sequencing technologies still report Phred-scaled or Phred-like base qualities,

$$Q = -10 \log_{10} P_{\text{error}},$$

so that $Q = 20$ means a 1% error probability and $Q = 30$ 0.1%. Sanger sequencing is still used to check individual clones and mutations, but it is too slow and expensive for genomes: it produces about one read per capillary per run.

5.2.2 Second generation: massively parallel short reads

"Next-generation" sequencing (NGS) replaced the separation of fragments by size with *sequencing by synthesis* of millions of immobilised, clonally amplified DNA molecules, imaged in parallel.

- **Pyrosequencing** detects the pyrophosphate released when a nucleotide is incorporated, through an enzymatic cascade that ends with light from luciferase (Ronaghi et al. 1998). One nucleotide type is added at a time. **454 sequencing** (2005) ran pyrosequencing in about a million picolitre wells, each containing a bead with DNA amplified by emulsion PCR (Margulies et al. 2005). Reads were 100–700 bases. Since the signal is proportional to the number of identical bases incorporated, the characteristic errors are **indels in homopolymer runs**.
- **Illumina** sequencing (originally Solexa) amplifies each molecule into a cluster on a glass flow cell by *bridge amplification*, and then adds all four nucleotides at once, each with a different fluorescent label and a reversible terminator, so that exactly one base is added per cycle (Bentley et al. 2008). After imaging, the label and terminator are removed and the next cycle begins. Reads are typically 2×150 bases. Errors are mainly **substitutions**, at a rate typically well below 1% (depending on instrument and chemistry), increasing towards the end of the read as molecules in a cluster get out of phase. Illumina came to dominate the market. It reduced the cost of a human genome from millions of dollars in 2007 to around a thousand dollars in 2014 and a few hundred in 2026.
- **Ion Torrent** sequencing detects the protons released during incorporation with a semiconductor chip, a pH meter rather than a camera. Like 454, it has homopolymer errors.

Short reads are cheap and accurate, but they cannot span repeats longer than a few hundred bases, which limits both assembly (Section 5.3) and the detection of structural variants (Section 5.4).

5.2.3 Third generation: single-molecule long reads

Single-molecule technologies read native DNA molecules without amplification, and produce reads that are tens of kilobases or longer.

- **Pacific Biosciences** (PacBio) watches a single DNA polymerase at the bottom of a *zero-mode waveguide*, a well so small that only the fluorescent nucleotide being incorporated is illuminated (Eid et al. 2009). The original "continuous long reads" (CLR) had error rates of 10–15%, mostly random insertions and deletions. In **HiFi** sequencing, a circular template is read many times, and a consensus of the passes (*circular consensus sequencing*) gives reads of 15–25 kb with an accuracy above 99.9% (Wenger et al. 2019).
- **Oxford Nanopore** (ONT) passes a single DNA strand through a protein pore in a membrane, and measures the changes in the ionic current, which depend on the bases currently in the pore (Deamer et al. 2016). The signal is translated into bases by a neural-network *basecaller*. Read length is limited only by the length of the DNA molecule. "Ultra-long" reads can exceed a megabase (M. Jain et al. 2018). Error rates were initially 10–15%, with systematic errors in homopolymers. With newer pores, chemistry and basecallers they have fallen to around 1% for single-strand (*simplex*) reads in 2026, and lower for *duplex* reads, in which both strands of a molecule are read. Nanopore devices are small, sometimes handheld, and give results in real time, which has made them useful in the field and in outbreak surveillance. ONT can also sequence RNA directly.

Quoted accuracies change quickly and depend on the chemistry, the basecaller, the read type (CLR or HiFi, simplex or duplex) and whether a consensus of several reads is taken. Compare technologies qualitatively, by their error *types*, and treat any number as a snapshot with a date.

Both long-read technologies also detect **base modifications**, such as cytosine methylation, from the polymerase kinetics (PacBio) or the current signal (ONT), without chemical conversion.

Long-read transcriptomics. Short RNA-seq reads cover only fragments of a transcript, so which exons belong together in one isoform must be inferred, which is ambiguous for genes with many isoforms. Long reads can cover a complete transcript in a single read. PacBio **Iso-Seq** sequences full-length cDNA as HiFi reads. ONT sequences either cDNA or, in **direct RNA sequencing**, the native RNA molecule itself, without reverse transcription or PCR (Garalde et al. 2018), so that RNA modifications such as N^6-methyladenosine, and the length of the poly(A) tail, can in principle be inferred directly from the electrical signal. Modification calling remains dependent on the model, the sequence context and the training data. Direct RNA sequencing needs more input RNA and has higher error rates than DNA sequencing. Since long-read runs give fewer reads than short-read runs, they are mainly used to discover and annotate isoforms (Section 5.6), while expression levels are still often quantified with short reads. The analysis of RNA-seq data is described in Section 7.3.

Table 5.1: Main sequencing technologies. Numbers are approximate, as of 2026, and change quickly.

Technology	Read length	Main error type	Typical accuracy	Strengths
Sanger (capillary)	500–1,000 bp	few	> 99.9%	accurate, simple; low throughput
454 pyrosequencing	100–700 bp	homopolymer indels	~99%	first NGS; discontinued
Illumina	2 × 50–300 bp	substitutions	> 99.9%	cheap, very high throughput
PacBio HiFi	15–25 kb	few, some indels	> 99.9%	long and accurate
Oxford Nanopore	10 kb – > 1 Mb	indels, homopolymers	~99% (simplex), higher for duplex	longest reads, portable, real time

5.2.4 Base qualities are model estimates

A base call and its quality are the output of a statistical model, the basecaller, applied to an optical or electrical signal. A Phred score is therefore a *predicted* error probability. It is useful only if it is *calibrated*: among all bases given $Q = 30$, about one in a thousand should be wrong when compared with a trusted sequence. Calibration is checked empirically, and base-quality recalibration (Section 5.4) corrects it using known variant sites. Qualities from different technologies, chemistries and basecaller versions are not directly comparable, and re-basecalling the same raw signal with a newer model can change the reads. The basecaller and its model version are therefore part of the record of an experiment.

Errors are also not independent. Consensus methods, such as PacBio HiFi reads built from several passes over the same molecule, or the consensus of many reads in an assembly, remove random errors efficiently, but *systematic* errors that depend on the sequence context, such as indels in homopolymers, recur in every read and are not averaged away. Residual errors in high-accuracy data are therefore concentrated in particular sequence contexts.

5.2.5 Shotgun sequencing and coverage

Because each read covers only a small part of a genome, genomes are sequenced by the **shotgun** method: the DNA is broken into random fragments, many of them are sequenced, and the genome is reconstructed computationally from the overlaps. Rodger Staden described the computational strategy in 1979 (Staden 1979). Early genome projects first mapped large clones and then sequenced each clone by shotgun (*clone-by-clone*), while *whole-genome shotgun* sequencing was first used for the bacterium *Haemophilus influenzae* in 1995 (Fleischmann et al. 1995). The debate about whether whole-genome shotgun could work for the human genome (Weber and Myers 1997) is described in Chapter 6.

How much sequencing is needed? If N reads of length L are sampled uniformly from a genome of length G, the **coverage** (depth) is

$$c = \frac{NL}{G}.$$

Lander and Waterman showed in 1988 that the number of reads covering a given base is then approximately Poisson-distributed with mean c, so the fraction of the genome not covered by any read is e^{-c} (Lander and Waterman 1988). With 8× coverage this is about 0.03%, or about 1 kb in a 3 Mb bacterial genome. The expected number of contigs, islands of overlapping reads, is about $Ne^{-c(1-\theta)}$, where θ is the fraction of a read that must overlap with another to be detected. In practice, coverage is far from uniform because of biases in library preparation and amplification, especially in GC-rich or GC-poor regions, so much higher depths are used: 30× is standard for human resequencing with short reads, and 50–100× for assembly.

5.2.6 Paired-end and mate-pair reads

Read pairs add long-range information to short reads. In **paired-end** sequencing, both ends of each fragment of a few hundred bases are read, so the two reads are known to lie at an approximately known distance, in opposite orientation. Two lengths must be kept apart. The **read length** is the number of bases sequenced from each end (for example 150). The **insert size** (or fragment length) is the length of the DNA fragment between the adapters, from the outer end of one read to the outer end of the other (for example 300–500 bases); it is not chosen by the sequencer but by library preparation, and it varies around a mean. If the insert is shorter than twice the read length the two reads overlap, and if it is shorter than one read the read continues into the adapter, which must then be trimmed. **Mate-pair** libraries

are made by circularising longer fragments (2–20 kb) and sequencing across the junction, giving pairs that span much larger distances. Pairs are used in assembly to order and orient contigs (*scaffolding*), in mapping to place reads in repeats, and in variant calling to detect structural variants, whose signature is pairs that map at unexpected distances or orientations. Other sources of long-range information are *Hi-C* chromatin contact data, optical maps of long DNA molecules, and, increasingly, long reads themselves.

5.3 Genome assembly

De novo assembly reconstructs a genome from reads without a reference. It is one of the classical algorithmic problems of bioinformatics, and the algorithms have changed with each generation of sequencing technology (Nagarajan and Pop 2013). This section describes the main paradigms, the central role of repeats, scaffolding and the evaluation of assemblies.

5.3.1 The problem and why repeats matter

If reads were error-free and the genome had no repeats, assembly would be the **shortest common superstring** problem: find the shortest string that contains every read. This problem is NP-hard, but a greedy algorithm that repeatedly merges the two reads with the longest overlap works well in practice, and the first assemblers, such as phrap and the TIGR Assembler used for *H. influenzae* (Fleischmann et al. 1995), were essentially greedy.

The real difficulty is **repeats**. If a repeat is longer than the reads (or than the span of read pairs), the reads from its copies cannot be told apart. The assembler cannot know how the unique sequences on either side of the copies are connected, and the shortest superstring would collapse the copies into one. Repeats are everywhere: transposable elements make up about half of the human genome, and segmental duplications, tandem repeats, ribosomal RNA operons and centromeric satellites span tens of kilobases to megabases. An assembler therefore stops at repeats it cannot resolve and outputs **contigs**, contiguous sequences between unresolved repeats or gaps in coverage. Modern assemblers represent the ambiguity explicitly as a graph, and the history of assembly is largely a history of how to build and simplify such graphs (Compeau et al. 2011).

5.3.2 Overlap–layout–consensus and string graphs

The **overlap–layout–consensus** (OLC) paradigm, formalised for shotgun sequencing in the 1980s and 1990s, has three steps (Anson and Myers 1999):

1. **Overlap**: find all pairs of reads that overlap, usually by first finding shared k-mers (seeds) and then aligning the candidate pairs. With N reads this is the most expensive step.

2. **Layout**: build an *overlap graph* with reads as nodes and overlaps as edges, and find paths through it that correspond to contigs. Ideally one wants a path that visits every read exactly once, a *Hamiltonian path*, which is NP-hard in general.
3. **Consensus**: align the reads in each contig and compute the consensus sequence, which corrects sequencing errors.

OLC assemblers built the first large genomes from Sanger reads: the Celera Assembler for *Drosophila* (Myers et al. 2000) and the human genome, Arachne and others. Myers simplified the overlap graph to the **string graph** (Myers 2005) by removing contained reads and *transitive* edges (if A overlaps B, B overlaps C, and A overlaps C, the edge A–C is redundant). In the string graph, unambiguous stretches collapse into chains (*unitigs*), and branching points correspond to repeat boundaries.

5.3.3 De Bruijn graphs

With second-generation sequencing, assembly had to handle hundreds of millions of short reads, and computing all pairwise overlaps became too expensive. The solution was a graph formulation originally proposed for sequencing by hybridisation (Idury and Waterman 1995; Pevzner et al. 2001). Each read is broken into all its overlapping ***k*-mers**, and a **de Bruijn graph** is built with the $(k-1)$-mers as nodes and each k-mer as an edge from its prefix to its suffix. For the sequence `ATGGCGTGCA` and $k = 3$, for example, the edges are `ATG`, `TGG`, `GGC`, `GCG`, `CGT`, `GTG`, `TGC`, `GCA`, connecting the 2-mers `AT` $\to$ `TG` $\to$ `GG` $\to$ `GC` $\to$ `CG` $\to$ `GT` $\to$ `TG` $\to$ `GC` $\to$ `CA`. The repeated 2-mers `TG` and `GC` become single nodes visited twice, so the graph contains a cycle.

The genome is a path that uses every *edge* once, an **Eulerian path**, which can be found in linear time. This is the key algorithmic advantage over the Hamiltonian path of the overlap graph (Compeau et al. 2011). In practice, an exact Eulerian path is not what assemblers compute. Repeats longer than k create branches in the graph, and the assembler outputs the unambiguous paths between branches as contigs. Sequencing errors create characteristic structures that must be removed: *tips* (dead ends caused by an error near the end of a read) and *bubbles* (two parallel paths caused by an error in the middle of a read, or by a heterozygous site). Low-coverage k-mers are discarded or corrected before the graph is built.

The choice of k is a trade-off: a small k makes the graph more tangled by repeats, a large k makes it fragmented where coverage is low. Velvet (Zerbino and Birney 2008), ABySS (Simpson et al. 2009) and SOAPdenovo were among the first short-read de Bruijn assemblers. SPAdes (Bankevich et al. 2012) combines graphs for several values of k and handles the uneven coverage of single-cell and metagenomic data, and MEGAHIT (Li et al. 2015) uses succinct data structures to reduce memory.

Short-read assemblies of large eukaryotic genomes are fragmented into tens of thousands of contigs, because most repeats are longer than the reads. Such draft genomes contain most genes, but repeats, segmental duplications and centromeres are collapsed or missing.

5.3.4 Long-read assembly

Long reads span most repeats and have brought assembly back to overlap-based methods. The first long-read assemblies corrected the noisy PacBio reads with each other before assembly (Chin et al. 2013). Canu adapted OLC to noisy reads (Koren et al. 2017), and Flye builds a *repeat graph* from approximate overlaps (Kolmogorov et al. 2019). With accurate HiFi reads, string-graph assemblers such as **hifiasm** (Cheng et al. 2021) produce contigs that are often tens of megabases long. Today, the best assemblies combine HiFi reads for accuracy, ultra-long nanopore reads to span the longest repeats, and Hi-C or parental data to separate haplotypes and chromosomes.

The contrast "de Bruijn graphs for short reads, overlap graphs for long reads" is a useful way to understand the two ideas, and describes the history well, but it is not a classification of current assemblers. Many modern tools mix the ideas. Flye's repeat graph is a de Bruijn-like graph built from approximate overlaps, several HiFi assemblers build de Bruijn or related graphs from long k-mers or minimizers, and hybrid assemblers build a graph from accurate HiFi reads and resolve its tangles with ultra-long nanopore reads (Rautiainen et al. 2023). Most long-read tools find overlaps with minimizers (Section 5.4) rather than with all-against-all alignment.

Haplotype-resolved assembly. A diploid genome contains two copies of each chromosome, which differ at millions of sites. Traditional assemblers produced a *collapsed* consensus, a mosaic of the two haplotypes. With accurate long reads, the two haplotypes can be assembled separately (*phased*), either using reads from the parents to assign each read to a haplotype (*trio binning*) or using Hi-C data, which link variants on the same chromosome (Cheng et al. 2021).

This adds to the classical vocabulary of contigs and scaffolds. A *haplotig* is a contig that represents a single haplotype. A *collapsed* or *pseudo-haplotype* assembly may switch between haplotypes along a contig. Many assemblies are reported as a *primary* assembly, which contains one copy of each region, plus *alternate* haplotigs for the regions where the second haplotype differs. A *haplotype-resolved* (fully phased) assembly instead gives two complete sets of contigs, one per haplotype. A *chromosome-scale* assembly has scaffolds that each correspond to a chromosome but may still contain gaps, whereas a *telomere-to-telomere* assembly is gapless from one end of each chromosome to the other.

Telomere-to-telomere assemblies. In 2022 the Telomere-to-Telomere (T2T) consortium published the first complete sequence of a human genome, CHM13, from a cell line that is effectively haploid (Nurk et al. 2022). It added about 200 Mb (8%) to the previous reference, including all centromeres, the short arms of the acrocentric chromosomes and large segmental duplications. Complete genomes of other great apes followed (Yoo et al. 2025). The Vertebrate Genomes Project aims at reference-quality, near-complete assemblies of all vertebrate species (Rhie et al. 2021), and the Human Pangenome Reference Consortium has assembled phased genomes of many individuals to represent human diversity, rather than a single reference (Liao et al. 2023).

5.3.5 Polishing

The layout of an assembly fixes the order of the reads, but its consensus may still contain errors, particularly when it is built from noisy long reads. **Polishing** realigns reads to the draft contigs and recomputes the consensus. Racon, for example, builds a partial-order alignment of the reads mapped to each contig window (Vaser et al. 2017). Other polishers use the raw signal or models trained for one technology, and accurate short reads can correct remaining small errors in a long-read assembly. Polishing is usually repeated a few times, and should stop when independent measures of accuracy no longer improve.

Polishing can also make an assembly worse. Reads from one copy of a repeat may be mapped to another copy and make the copies identical; in a collapsed diploid assembly, true heterozygous sites are pushed towards the majority allele; and short-read polishing can reintroduce errors in regions that short reads map poorly. Polishing improves the local consensus but does not repair misjoins. For phased assemblies, reads should be assigned to a haplotype before polishing. Accuracy should be evaluated with data that were not used for polishing, for example with k-mers from an independent accurate read set, since evaluating with the same reads is circular.

5.3.6 Scaffolding

Scaffolding orders and orients contigs and estimates the size of the gaps between them, using information that spans gaps: read pairs, mate pairs, long reads, optical maps or Hi-C contacts, whose frequency decreases with distance along the chromosome, so that Hi-C can assign contigs to chromosomes and order them (Burton et al. 2013). The result is a set of **scaffolds** in which gaps are filled with stretches of `N`. Scaffolding is a graph problem: contigs are nodes, linking evidence gives edges, and conflicting links caused by repeats and chimeric reads must be resolved. Errors in scaffolding, such as inversions and misjoins, are a common source of assembly errors.

5.3.7 Assembly quality

Assemblies are evaluated by three properties:

- **Contiguity.** The **N50** is the length such that contigs of that length or longer contain half of the assembly. It is the most quoted statistic, but it is easy to inflate by joining contigs incorrectly. NG50 uses half of the estimated genome size instead of the assembly size, which makes assemblies of different sizes comparable. Contig and scaffold N50 should be reported separately.
- **Completeness. BUSCO** searches the assembly for a set of genes that are expected to be present in a single copy in a given lineage, and reports the percentage found complete, fragmented, duplicated or missing (Simão et al. 2015). *k*-mer based methods such as Merqury compare the *k*-mers in the assembly with those in accurate reads from the same individual (Rhie et al. 2020).
- **Correctness.** Base-level accuracy is measured as a consensus quality value (QV; Q40 means one error per 10 kb). Structural correctness (misjoins, inversions, collapsed repeats) is assessed by comparison with a reference, optical maps or Hi-C data.

Reference-based tools such as QUAST align an assembly to a related reference genome and report misassemblies, but differences from the reference can be real biological differences rather than errors (Gurevich et al. 2013). With *k*-mers from the parents, Merqury also measures how well the haplotypes of a phased assembly are separated (Rhie et al. 2020). Further aspects of quality, such as contamination and the representation of haplotypes, are summarised in Figure 5.1.

These are different axes. N50 measures only contiguity, not correctness: an assembler that joins contigs aggressively across repeats can produce a high N50 together with many misassemblies, and a complete set of BUSCO genes says nothing about the repeats between them. An assembly should therefore be judged on all three.

Community competitions compared assemblers on the same data. The Assemblathons showed that different assemblers excel by different metrics, and that the results vary strongly between genomes (Bradnam et al. 2013).

5.4 Mapping and variant calling

Once a reference genome exists, most sequencing is **resequencing**: reads from a new individual, tumour or strain are mapped to the reference, and the differences are identified. This is the basis of human genetics, cancer genomics, population genomics and clinical diagnostics.

5.4.1 Read mapping

A read mapper must place hundreds of millions of reads on a genome of billions of bases, allowing for sequencing errors and true differences, and decide how confident each placement is. Aligning each read with the Smith–Waterman algorithm against the whole genome is far too slow, so all mappers first **index** the reference, find candidate locations with exact matches (*seeds*), and then align the read only at those locations (*seed and extend*). The index structures are described in Section 1.4.

- **Hash-based mappers.** The first generation, such as MAQ (Li et al. 2008), built a hash table of short words in the reads or in the genome, often with *spaced seeds* to tolerate mismatches. They were fast but used much memory.
- **Burrows–Wheeler mappers. Bowtie** (Langmead et al. 2009) and **BWA** (Li and Durbin 2009) index the genome with the Burrows–Wheeler transform and the FM-index, which allows exact matches to be found in time proportional to the length of the read, independent of the genome size, with an index of a few gigabytes for the human genome. Mismatches are handled by backtracking. BWA-MEM, the standard for short reads, finds maximal exact matches as seeds and extends them with banded Smith–Waterman alignment.
- **Long-read mappers.** For long, noisy reads, **minimap2** (Li 2018) samples *minimizers* (the smallest k-mer in each window) as seeds, *chains* collinear seed hits by dynamic programming, and aligns only between the anchors. It has become the standard tool for long reads and genome-to-genome alignment.

RNA-seq reads must be aligned across introns with *spliced* aligners such as STAR, or quantified without alignment; these are discussed in Chapter 7.

The output is stored in the **SAM** format, or its compressed binary equivalent **BAM** or reference-based **CRAM**, and processed with tools such as SAMtools (Li et al. 2009; Danecek et al. 2021). Before variant calling, reads are sorted, PCR duplicates are marked, and sometimes base qualities are recalibrated.

5.4.1.1 The SAM record

Each line of a SAM file describes one alignment of one read, in eleven tab-separated mandatory fields followed by optional tags (Li et al. 2009): the read name (QNAME), a bitwise **FLAG**, the reference sequence (RNAME), the 1-based leftmost position (POS), the mapping quality (**MAPQ**, see below), the **CIGAR** string, the position of the mate (RNEXT, PNEXT), the inferred insert size (TLEN), and the read sequence and base qualities (SEQ, QUAL). The FLAG packs yes/no properties into one integer, each bit meaning one thing: paired (1), properly paired (2), unmapped (4), mapped to the reverse strand (16), secondary alignment (256), PCR or optical duplicate (1024) and supplementary alignment (2048), the last used for the second part of a split read. A FLAG of 99 (1 + 2 + 32 + 64) is thus the first read of a properly mapped pair whose mate is on the reverse strand. The CIGAR string describes the alignment as runs of operations, for example `5S90M2I3M` for 5 soft-clipped bases, 90 aligned bases (match or mismatch), a 2-base insertion and 3 more aligned bases. Other operations are D (deletion), N (skipped reference, an intron in spliced RNA-seq alignments) and H (hard clipping). Optional tags give, for example, the edit distance (NM) and the read group (RG), which records the sample and sequencing run. Coordinate conventions differ between formats, 1-based in SAM and VCF but 0-based in BAM and BED (Section 2.4), which is a common source of off-by-one errors.

> **Practical quality control of sequencing data**
>
> Most errors in genome analyses come from the data, not from the algorithms. Before and after mapping, check:
>
> - **Base quality**: the distribution of Phred scores along the read (for example with FastQC); low-quality ends are trimmed.
> - **Adapter content**: adapter sequence appears when the insert is shorter than the read (Section 5.2) and must be trimmed (for example with cutadapt or fastp).
> - **Duplication**: PCR and optical duplicates inflate the apparent coverage and the support for errors; a high duplication rate indicates a library with few distinct molecules.
> - **Contamination**: reads from other organisms (bacteria, human DNA in non-human samples, adapter dimers) and cross-contamination between samples, detected by classifying reads against databases or from unexpected allele fractions.
> - **Coverage**: mean depth, and its uniformity, including GC bias and the fraction of the target covered at the depth needed for calling.
> - **Mapping**: the fraction of reads mapped, the distribution of mapping qualities, the fraction of properly paired reads and the insert-size distribution (for example with samtools stats).
>
> Tools such as MultiQC (Ewels et al. 2016) collect these statistics for many samples in one report, which makes outlier samples easy to see.

5.4.1.2 Mapping quality

A read from a repeat can align equally well to several locations. Each alignment is therefore given a **mapping quality**, a Phred-scaled probability that the reported location is wrong,

MAPQ $= -10 \log_{10} P(\text{wrong location})$ (Li et al. 2008). It is computed from the difference between the scores of the best and second-best hits: a read with two equally good hits gets a MAPQ of 0. Variant callers ignore or down-weight reads with low mapping quality, which means that variants in repeats and segmental duplications are often missed. Paired reads help, because one read in a unique region can anchor its mate in a repeat.

5.4.1.3 Reference bias and graph genomes

Mapping to a single linear reference genome introduces **reference bias**. Reads carrying the reference allele align slightly better than reads carrying a non-reference allele, so non-reference alleles are lost or under-counted, which distorts allele frequencies and allele-specific measurements. The effect is strongest around indels and in highly polymorphic or divergent regions, such as the HLA genes. Sequences absent from the reference, such as large insertions or population-specific sequence, cannot be mapped at all, and their reads may instead be mapped wrongly to a similar region elsewhere. Structural variants are therefore missed or mis-called.

Graph genomes, in which known variants are represented as alternative paths, reduce this bias (Garrison et al. 2018). This is no longer only a future idea. The draft human pangenome reference, a graph built from 47 phased diploid assemblies of individuals of diverse ancestry, was released in 2023 (Liao et al. 2023). Mapping short reads to it with graph-aware mappers in the vg toolkit (Garrison et al. 2018; Sirén et al. 2021) reduced small-variant errors by about a third and roughly doubled the number of structural variants detected per haplotype, compared with the linear GRCh38 reference (Liao et al. 2023). Linear references are still the default in most pipelines in 2026, but graph-based mapping and genotyping are in practical use and are expanding as more genomes are added.

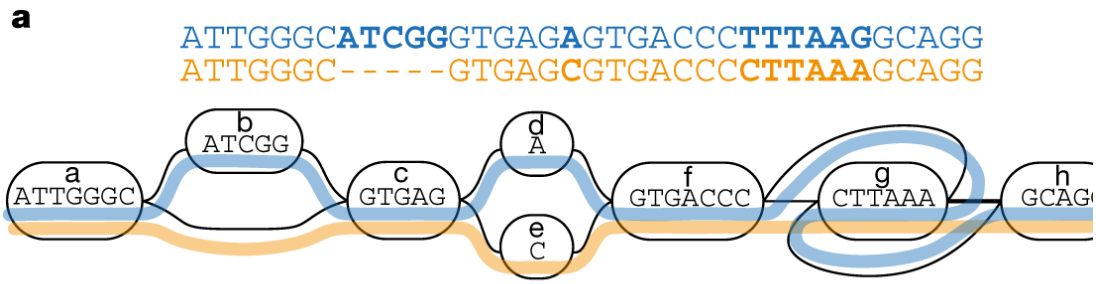

Figure 5.2: A sequence graph. Nodes hold DNA sequences and edges give the possible adjacencies; each haplotype is a walk through the graph (blue and orange), here differing by a deletion, a substitution and an inversion. Reproduced from Fig. 3a of Liao et al. (2023) (CC BY 4.0), as cropped in Matteo Tadiello, *Modern Bioinformatics: From Foundations to Frontiers*.

A graph reference is not free of bias either: it represents only the haplotypes and variants used to build it, its coordinates are harder to report than positions on a linear chromosome, and adding many similar paths can make mapping more ambiguous. The ancestry of the genomes in the graph therefore matters, and graph and linear workflows should be compared on benchmarks stratified by population and region.

5.4.2 Variant calling

Genetic variants are classified by size:

- **SNPs** (single-nucleotide polymorphisms, or SNVs): single-base substitutions, the most common kind; two human genomes differ at about 4–5 million sites (The 1000 Genomes Project Consortium 2015);
- **indels**: small insertions and deletions, up to about 50 bases;
- **structural variants** (SVs): larger deletions, insertions, duplications (copy-number variants), inversions and translocations. They are fewer than SNPs but affect more bases in total.

Calls are stored in the **VCF** format, with the position, the alleles, the genotype of each sample and quality measures.

5.4.2.1 The VCF record

A VCF file has a header of `##` lines that define the reference, the filters and every annotation field, followed by one line per variant site (Danecek et al. 2011). The fixed columns are CHROM, POS (1-based), ID (for example a dbSNP `rs` number), REF, ALT (one or more alternative alleles, comma-separated), QUAL (a Phred-scaled probability that the site is not variant), FILTER (`PASS` or the names of failed filters) and INFO, a list of site-level annotations such as the total depth (DP) or allele frequency (AF). Then follow a FORMAT column and one column per sample, for example

```
chr1  1234567  .  ATCT  A  812  PASS  DP=64  GT:AD:GQ:PL  0/1:33,31:99:850,0,920
```

for a heterozygous 3-base deletion (an invented example). FORMAT names the per-sample fields: the genotype (GT, with 0 for REF and 1 for the first ALT allele; `/` for unphased and `|` for phased genotypes), the read depth for each allele (AD), the genotype quality (GQ) and the Phred-scaled genotype likelihoods (PL) described below. An indel is written with the preceding reference base included in both REF and ALT. The same indel in a repeat can be placed at several equivalent positions, so call sets must be **normalised** (left-aligned and split into one allele per line) before they are compared or looked up in databases.

5.4.2.2 Genotype likelihoods

Calling a SNP is a statistical problem, because sequencing errors are frequent compared with true variants. A heterozygous site is expected to show the alternative allele in about half of the reads, but with 10 reads, and an error rate of 1%, distinguishing a heterozygote from an error is not trivial. Modern callers use a probabilistic model (Marth et al. 1999; Li et al. 2008; Li 2011; Nielsen et al. 2011). For each possible genotype G at a site (for two alleles A and B in a diploid: AA, AB, BB) the **genotype likelihood** is the probability of the observed read bases D:

$$P(D \mid G = \{A_1, A_2\}) = \prod_i \left[\tfrac{1}{2} P(b_i \mid A_1) + \tfrac{1}{2} P(b_i \mid A_2) \right],$$

where b_i is the base in read i and $P(b_i \mid A) = 1 - e_i$ if $b_i = A$ and $e_i/3$ otherwise, with e_i the error probability given by the base quality (and, often, the mapping quality). The posterior probability of each genotype follows from Bayes' theorem with a prior, for example the expected heterozygosity, about 0.001 per site in humans. The genotype quality reported in the VCF file expresses the confidence in the called genotype.

It helps to keep three steps apart: the **read evidence** (the aligned bases with their base and mapping qualities), the **genotype likelihoods** computed from it, and the **genotype or variant call**, which also depends on the prior, on the assumed ploidy and on filters. A difference between the reads and the

reference is not automatically a biological variant. It may come from sequencing errors, from reads of a paralogous region mapped to the wrong place, from contamination with another sample or organism, or from a mixture of cells, as in a tumour or a pooled sample, where the diploid model with allele fractions of 0, ½ and 1 does not apply. When many individuals are sequenced, information can be shared between them through allele frequencies, which is particularly important at low coverage. Genotype likelihoods are also used directly in downstream population-genetic analyses, without calling genotypes at all.

5.4.2.3 GATK and haplotype-based calling

The **Genome Analysis Toolkit** (GATK) (McKenna et al. 2010; DePristo et al. 2011) defined the standard "best practices" pipeline for short-read data: duplicate marking, base-quality recalibration, variant calling, joint genotyping of many samples, and statistical filtering of the raw calls with a model trained on known variants (variant quality score recalibration). Its **HaplotypeCaller** does not call variants column by column. In regions that show evidence of variation, it locally re-assembles the reads into candidate haplotypes with a de Bruijn graph, aligns each read to each haplotype with a pair HMM, and then computes genotype likelihoods. This makes it much better at indels, which are often misaligned by the mapper. Similar tools include FreeBayes and the samtools/bcftools caller (Danecek et al. 2021). Somatic mutations in cancer, which may be present in only a small fraction of the cells, require specialised callers that compare tumour and normal samples (see below).

5.4.2.4 Deep-learning callers

DeepVariant (Poplin et al. 2018) recast variant calling as image classification. The reads around a candidate site are encoded as a multi-channel image (bases, base qualities, mapping qualities, strand), and a convolutional neural network, trained on genomes with known variants, predicts the genotype. DeepVariant outperformed the hand-crafted models, and it can be retrained for new technologies such as PacBio HiFi and ONT reads without changing the method. Variant callers are benchmarked against the high-confidence call sets of the Genome in a Bottle consortium, for which the true variants are known from many technologies (Zook et al. 2019).

5.4.2.5 Structural variants

Structural variants, including copy-number variants (CNVs), are biologically important: they cause many genetic diseases, are frequent driver events in cancer, and differ in more base pairs between two human genomes than SNPs do. They cannot be found by examining one alignment column at a time, as small variants are, because reads that cross an SV breakpoint often fail to align or align only in part. They are therefore detected from different kinds of evidence, four kinds of signal in short-read data (Mahmoud et al. 2019):

- **read depth**: deletions and duplications change the number of reads mapped to a region;
- **discordant read pairs**: pairs that map too far apart, too close or in the wrong orientation indicate deletions, insertions or inversions;
- **split reads**: reads whose two parts map to different locations show the exact breakpoint;
- **assembly**: local or whole-genome assembly and comparison with the reference.

Each signal sees only some kinds of SV. Read depth detects copy-number changes but not balanced events, such as inversions and translocations, and gives only approximate breakpoints. Discordant pairs and split reads locate breakpoints, but cannot reveal the content of insertions longer than the fragment, and fail when the breakpoint lies in a repeat. Short-read SV callers therefore combine several signals.

With short reads, SV calling is much less accurate than SNP calling, and many SVs in repeats are missed entirely. Long reads span most SVs, and long-read callers such as Sniffles (Sedlazeck et al. 2018) and comparisons of haplotype-resolved assemblies have shown that each human genome carries more than 20,000 SVs, most of which were invisible to short reads.

5.4.2.6 Phasing

A diploid genotype such as A/G at one site and C/T at another does not say which alleles lie on the same chromosome. **Phasing** assigns alleles to the two *haplotypes*. This matters biologically: for a recessive disorder, two loss-of-function mutations in the same gene cause disease if they are on different copies (*compound heterozygosity*), but not if they are on the same copy, since the other copy is then intact. Haplotypes are also needed for allele-specific expression, for imputation of untyped variants, and for studies of recombination and selection. There are three main approaches:

- **read-backed phasing**: reads or read pairs that cover two or more heterozygous sites show directly which alleles occur together. Long reads give phased blocks of many kilobases to megabases (Patterson et al. 2015);
- **pedigree (trio) phasing**: the alleles inherited from each parent are determined from the parents' genotypes;
- **statistical (population) phasing**: haplotypes are inferred from patterns of linkage disequilibrium in a large reference panel of haplotypes, using hidden Markov models of how a new haplotype is a mosaic of the haplotypes in the panel. This works well for common variants but not for rare or private ones (Delaneau et al. 2019).

Read-backed phasing can be formulated as a combinatorial problem. In a matrix with one row per read and one column per heterozygous site, each entry gives the allele the read shows. With error-free reads the rows split cleanly into two groups, one per haplotype. With errors, the **minimum error correction** (MEC) problem asks for the partition that requires the fewest changes to the matrix, with each change weighted by the base quality. MEC is NP-hard, but WhatsHap solves it exactly in time exponential only in the read coverage, not in the number of reads or sites, which makes it practical for long reads at moderate depth (Patterson et al. 2015).

Phasing produces *phase blocks*, within which the relative phase is known, and its errors are measured as *switch errors* between adjacent sites. Long blocks with many switch errors can be worse than short accurate ones, so block length and switch error rate should be reported together. Haplotype-resolved assembly (Section 5.3) gives phasing over whole chromosomes.

5.4.3 Targeted and exome sequencing

Much clinical and cancer sequencing does not cover the whole genome. In **exome sequencing**, the protein-coding exons, about 1–2% of the genome, are enriched by **hybrid capture**: the DNA library is hybridised to biotinylated oligonucleotide baits complementary to the targets, which are pulled down with streptavidin beads before sequencing (Gnirke et al. 2009). Smaller **gene panels** use the same principle, or amplify the targets by PCR (amplicon sequencing). Targeting makes high depth affordable, which is needed for rare variants in tumours, but brings its own biases:

- **uneven coverage**: capture efficiency depends on GC content, bait design and the mappability of the target, so some exons are covered at hundreds of times the depth of others, and some, such as GC-rich first exons, hardly at all. The fraction of the target covered at, say, 20-fold is a more useful summary than the mean depth;
- **off-target reads**: a substantial fraction of reads come from outside the baits. They are wasted for small-variant calling, but give low-coverage information on copy number genome-wide;

- **reference bias in capture**: baits designed from the reference capture divergent alleles and large indels less efficiently;
- **duplicates**: with little input DNA, many reads come from the same molecule, and unique molecular identifiers are used to tell them apart.

Variants outside the targets, including most regulatory and structural variants, are invisible, and copy-number calling from exome data is noisier than from genomes, because the depth varies so much between targets. As sequencing costs fall, genome sequencing is replacing exome sequencing in many clinical settings.

5.4.4 Copy-number analysis

Copy-number variants (CNVs), deletions and duplications from about a kilobase to whole chromosome arms, are detected from sequencing **read depth**. The genome (or the targets) is divided into bins, reads are counted in each, and the counts are corrected for GC content and mappability and normalised against a reference, a matched normal sample or a panel of normal samples, which removes biases shared by all samples. The resulting log ratios are then **segmented** into regions of constant copy number, with change-point methods such as circular binary segmentation or with hidden Markov models whose states are copy numbers. Tools such as CNVkit use both on-target and off-target reads from targeted sequencing (Talevich et al. 2016).

Before sequencing became cheap, CNVs were measured with SNP arrays, which remain common in clinical genetics and in biobanks. Each SNP gives two quantities (Peiffer et al. 2006). The **log R ratio** (LRR) is the log of the total intensity of both alleles relative to that expected for two copies, and falls with deletions and rises with duplications. The **B-allele frequency** (BAF) is the fraction of the signal from one allele, and takes the values 0, ½ and 1 for the three genotypes of a normal diploid region. A heterozygous deletion removes the ½ band; a duplication splits it into ⅓ and ⅔; and **copy-neutral loss of heterozygosity**, in which a region is inherited from one parent twice or a tumour has lost one homologue and duplicated the other, removes the ½ band without changing the LRR. The same two signals are computed from read depth and allele fractions in sequencing data, and are the basis of copy-number analysis in cancer.

5.4.5 Somatic variants in cancer

A tumour sample differs from a germline sample in three ways: it is a mixture of tumour and normal cells, it is often aneuploid, and the tumour cells themselves are genetically heterogeneous. The diploid genotype model of the previous sections does not apply, and **somatic variant calling** compares a tumour with a **matched normal** sample from the same person, usually blood, so that germline variants can be removed. Callers such as Mutect (Cibulskis et al. 2013) ask whether the alternative allele in the tumour is better explained by a somatic mutation present at some unknown fraction than by sequencing error, and whether it is absent from the normal.

The **variant allele fraction** (VAF), the fraction of reads that carry the variant, depends on the tumour **purity** p, the copy number C_T at the locus in the tumour, the number of copies carrying the mutation m, and the fraction of tumour cells with the mutation. For a clonal mutation,

$$\mathrm{VAF} = \frac{p\,m}{p\,C_T + 2(1-p)}.$$

A heterozygous clonal mutation in a diploid region of a tumour with 40% purity is thus seen in only 20% of reads, and subclonal mutations at even lower fractions, which requires high depth. Purity and ploidy are estimated jointly from the copy-number profile and the allele fractions, for example by ABSOLUTE

(Carter et al. 2012); together they turn VAFs into the fraction of cancer cells carrying each mutation, which is the starting point for reconstructing subclones and tumour evolution (Section 7.7).

Somatic calls are dominated by artefacts unless they are filtered. A **panel of normals**, a set of unrelated normal samples processed in the same way, removes recurrent technical artefacts and common germline variants missed in the matched normal. Other artefacts come from sample preparation, such as C>T changes from formalin fixation and G>T changes from oxidative damage, and many are strand- or read-position-specific. Normal tissue is also not truly normal: blood can carry clonal haematopoiesis mutations, and a normal sample contaminated with tumour cells hides real somatic variants.

5.4.5.1 Drivers, passengers and mutational signatures

A typical adult tumour carries thousands of somatic point mutations, but only a handful are **drivers** that confer a growth advantage; the rest are **passengers** that happened to be present in the clone that expanded (Stratton et al. 2009; Vogelstein et al. 2013). Drivers are identified statistically, as genes mutated more often than expected from the background mutation rate. This rate varies along the genome with expression and replication timing, and failing to model it produced many false cancer genes (Lawrence et al. 2013). An alternative is to apply the ratio of non-synonymous to synonymous mutations, dN/dS (Section 3.6), to somatic mutations, which shows positive selection in drivers and nearly no negative selection in most of the tumour genome (Martincorena et al. 2017). Curated lists of driver genes are kept in the Cancer Gene Census of COSMIC (Section 2.9).

Passengers are not useless: they record the mutational processes that acted on the tumour. Each single-base substitution is classified into one of 96 types, six substitution classes (C>A, C>G, C>T, T>A, T>C, T>G, with the pyrimidine of the base pair as reference) times sixteen combinations of flanking bases. The mutation counts of many tumours form a matrix that is decomposed by non-negative matrix factorisation into **mutational signatures** and their activity in each tumour (Alexandrov et al. 2013). Several signatures have known causes: C>A changes from tobacco smoke in lung cancer, C>T changes at dipyrimidines from ultraviolet light in melanoma, a clock-like C>T signature at CpG sites from deamination of methylated cytosine, and signatures of APOBEC cytidine deaminases and of defective DNA repair. The current COSMIC catalogue, extended to doublet substitutions and indels from thousands of whole genomes (Alexandrov et al. 2020), is used to infer exposures and, for example, defects in homologous recombination that predict response to PARP inhibitors.

5.5 Regulatory and epigenomic sequencing data

Sequencing is used not only to read genomes, but also to measure where proteins bind DNA and RNA, which parts of the genome are accessible, and which bases are chemically modified. These assays turn a biochemical property into a set of sequenced DNA fragments, which are mapped to the reference with the same tools as genomic reads (Section 5.4). The computational problem is then to find regions where

reads are enriched, or bases where the sequence has been altered, against a background that is far from uniform. The regulatory elements found in this way are described in Section 6.9.

5.5.1 ChIP-seq

Chromatin immunoprecipitation followed by sequencing (ChIP-seq) maps the binding sites of a transcription factor, or the positions of a histone modification, across the genome (Johnson et al. 2007). Proteins are cross-linked to DNA, the chromatin is fragmented, fragments bound by the protein are pulled down with an antibody, and the DNA is sequenced. Reads pile up around the binding sites.

The background is not uniform: open chromatin fragments more easily, some regions map better than others, and amplified regions in the sample give more reads. Every experiment therefore needs a **control**, usually the **input** DNA taken before immunoprecipitation. **Peak callers** such as MACS (Zhang et al. 2008) find regions where the ChIP signal exceeds the control. MACS uses the fact that reads from the two strands form two peaks shifted by about one fragment length on either side of the binding site, shifts the reads by half this distance to centre them, and tests for enrichment against a *local* Poisson background estimated from the control in the surrounding kilobases. Transcription factors give sharp, narrow peaks; histone marks such as H3K27me3 cover broad domains and need different settings.

Biological replicates rarely agree perfectly. The **irreproducible discovery rate** (IDR) ranks peaks in two replicates and estimates which part of the ranked list is reproducible, much as a false discovery rate estimates which part is significant (Li et al. 2011). The ENCODE guidelines use IDR, the **fraction of reads in peaks** and other measures to judge the quality of experiments and antibodies (Landt et al. 2012). Finally, the sequences under the strongest peaks are searched for enriched motifs, both to confirm that the experiment worked (the factor's own motif should be at the centre of the peaks) and to find co-binding partners (Section 1.6) (Heinz et al. 2010). A peak shows where the protein is cross-linked, directly or indirectly, not that the binding regulates a gene.

5.5.2 Chromatin accessibility: DNase-seq and ATAC-seq

Active regulatory elements are depleted of nucleosomes, which makes them accessible to enzymes. **DNase-seq** digests chromatin lightly with DNase I and sequences the cut sites (Boyle et al. 2008). **ATAC-seq** uses the Tn5 transposase, which inserts sequencing adapters preferentially into open chromatin, and works with tens of thousands of cells or fewer, and also in single cells (Buenrostro et al. 2013). Peak calling resembles that of ChIP-seq, but no antibody is needed and one experiment finds all accessible elements at once. The fragment lengths reveal nucleosome positions, and short protected *footprints* within peaks can indicate bound transcription factors, although enzyme sequence bias complicates footprinting. Typical quality checks are the enrichment of reads at transcription start sites and the fraction of reads from mitochondrial DNA, which is accessible and often dominates poor libraries.

5.5.3 DNA methylation

In mammals, DNA methylation occurs mainly as 5-methylcytosine in CpG dinucleotides and is associated with silenced promoters and repeats (Section 6.7). In **bisulfite sequencing**, sodium bisulfite converts unmethylated cytosines to uracil, read as thymine after PCR, while methylated cytosines are protected (Frommer et al. 1992). Methylation is thus turned into a C/T difference between reads and reference.

This complicates mapping. Converted reads contain almost no C (or, from the other strand, no G) and match the reference poorly. Aligners such as Bismark convert both reads and genome *in silico* (C to T, and G to A for the opposite strand), map to the converted genomes, and then compare the original read with the reference (Krueger and Andrews 2011). The **methylation level** of a cytosine is the

fraction of reads that show C rather than T at that position. Whole-genome bisulfite sequencing gave the first base-resolution methylomes, which revealed widespread non-CpG methylation in embryonic stem cells (Lister et al. 2009). Pitfalls include incomplete conversion, which mimics methylation, C-to-T SNPs, which mimic unmethylated sites, and the inability of bisulfite to distinguish 5-methylcytosine from 5-hydroxymethylcytosine. Bisulfite also degrades DNA, and enzymatic conversion methods are a gentler alternative. Cheaper alternatives are reduced-representation bisulfite sequencing, which covers CpG-rich regions, and methylation arrays.

Long reads measure methylation without conversion (Section 5.2). In nanopore data a methylated base changes the current signal, and methylation is called by comparing the signal with models of methylated and unmethylated *k*-mers (Simpson et al. 2017), now usually with neural networks built into the basecaller. PacBio detects methylation from the kinetics of the polymerase. Because each read comes from one molecule, long reads also give methylation on each haplotype, for example at imprinted genes.

5.5.4 RNA–protein interactions: CLIP-seq

CLIP-seq (cross-linking and immunoprecipitation) maps the binding sites of RNA-binding proteins. Cells are irradiated with UV light, which cross-links proteins to the RNA they touch; the protein is immunoprecipitated, the RNA trimmed and sequenced (Licatalosi et al. 2008). The cross-linked amino acid leaves a trace in the reads, a mutation or a truncation of the reverse transcription, which locates binding sites with nucleotide resolution. As in ChIP-seq, a control is essential, and in eCLIP a size-matched input sample serves as background (Van Nostrand et al. 2016). Enrichment must be judged against the abundance of the RNA itself, since highly expressed transcripts give reads in any experiment.

5.6 Gene prediction

A genome sequence becomes useful only when its genes have been found. **Gene prediction** (gene finding) identifies the regions that encode proteins or functional RNAs, and **genome annotation** adds the gene structures, their products and their functions (Yandell and Ence 2012). This section concentrates on protein-coding genes. The prediction of non-coding RNA genes is discussed in Section 1.7, and functional annotation in Chapter 10.

5.6.1 Signals and content

Gene finders combine two kinds of information:

- **Signals**: short sequence motifs at defined positions, such as start and stop codons, splice sites (almost all introns start with GT and end with AG), ribosome-binding sites and promoters. They are modelled with position weight matrices or similar models (Section 1.6).

- **Content**: statistical differences between coding and non-coding sequence. Because the genetic code is read in triplets and codon usage is biased, coding sequence has a characteristic three-base periodicity and hexamer composition. Fickett showed in 1982 that such statistics can recognise coding regions (Fickett 1982).

The **open reading frame** (ORF), a stretch without stop codons in one reading frame, is the simplest content feature. In random sequence a stop codon appears on average every 21 codons, so ORFs longer than a few hundred codons are unlikely to occur by chance.

5.6.2 Prokaryotic gene finding

Prokaryotic genomes are dense, with about 85–90% of the sequence coding, and genes are not interrupted by introns. Gene finding therefore reduces to deciding which long ORFs are real genes and where they start. Statistical methods use **Markov models** of coding sequence: the probability of each base depends on the preceding k bases and on its position in the codon (a *three-periodic*, or inhomogeneous, Markov chain). **GeneMark** (Borodovsky and McIninch 1993) used fifth-order Markov chains for each of the six reading frames, and **GeneMark.hmm** (Lukashin and Borodovsky 1998) embedded them in a hidden Markov model of the whole genome, which also models ribosome-binding sites and gene overlaps. **Glimmer** (Delcher 1999) uses *interpolated* Markov models, which combine models of different orders depending on how much training data are available for each context. **Prodigal** (Hyatt et al. 2010) improved the prediction of translation start sites and is widely used in pipelines, including for metagenomes.

A simple way to score an ORF x is the log-likelihood ratio of a coding and a non-coding model,

$$S(x) = \log \frac{P(x \mid \text{coding})}{P(x \mid \text{non-coding})} = \sum_{i} \log \frac{P(x_i \mid x_{i-k} \dots x_{i-1}, \phi_i)}{P(x_i \mid x_{i-k} \dots x_{i-1})},$$

where ϕ_i is the codon position of base i. Scores for start codons, ribosome-binding sites, length and overlaps are added, and a dynamic programming pass along the genome selects a compatible set of genes. The score is relative to the model: a real gene with unusual composition can score poorly.

These programs are trained on the genome itself (*self-training*), since long ORFs are almost certainly genes. Glimmer, for example, first collects long non-overlapping ORFs, trains its interpolated Markov model on them, and then scores all candidate ORFs. Training on long ORFs biases the model against short genes, and the minimum gene length is a trade-off between sensitivity and false positives. A pile-up of predictions at exactly the minimum length is a sign that this threshold, rather than the biology, shapes the result. They find well over 95% of genes. The remaining errors are mostly in start sites, very short genes, genes acquired by horizontal transfer with an unusual composition (Section 3.7), and genes that are pseudogenised. Production pipelines, such as the NCBI prokaryotic genome annotation pipeline (Tatusova et al. 2016), combine ab initio predictions with protein homology.

5.6.3 Eukaryotic gene finding

Eukaryotic gene prediction is much harder. Genes are split into exons separated by introns that can be hundreds of kilobases long, coding sequence makes up only about 1–2% of the human genome, and most genes have several alternatively spliced transcripts (Section 3.5). A gene finder must predict not only where a gene is, but the exact boundaries of every exon. Eukaryotic gene prediction is therefore not simply ORF detection plus splice-site recognition. A complete gene model also includes the untranslated regions (UTRs) and the alternative isoforms of each gene, and a genome also contains many non-coding RNA genes. Classical ab initio gene finders predict one coding structure per locus and no UTRs, so these

features must come from transcript evidence, which is itself often incomplete, for example when cDNA or assembled transcripts lack their 5' ends.

Generalised hidden Markov models. The breakthrough came with **GENSCAN** (Burge and Karlin 1997), which models the structure of a whole gene with a *generalised* (semi-Markov) hidden Markov model. Each state represents a whole segment, such as an initial, internal or terminal exon, an intron in one of three phases, an intergenic region or a promoter, and emits a sequence of variable length with an explicit length distribution. Exon states use codon-position-specific Markov models of content, and the transitions between states are scored with signal models for splice sites and start and stop codons. The most probable parse of the sequence into gene structures is found with a Viterbi-like dynamic programming algorithm (Section 1.6). Explicit length distributions are important because real exons and introns have length distributions far from the geometric distributions of ordinary HMM states. Earlier, GeneID had shown how candidate exons could be scored and assembled into genes by dynamic programming (Guigó et al. 1992). Successors include **AUGUSTUS** (Stanke and Waack 2003), with an improved intron model and the ability to integrate external evidence, and **SNAP**, designed to be trained easily on new genomes (Korf 2004).

Accuracy. Gene finders are evaluated at the nucleotide, exon and gene levels, with sensitivity (the fraction of true features predicted) and specificity (the fraction of predictions that are true) (Burset and Guigó 1996). Note that "specificity" in the gene-finding literature means what is elsewhere called *precision*, not the true-negative rate (4). At the nucleotide level, accuracy is high. At the gene level, where every exon must be exactly right, purely ab initio predictions of human genes are correct for only a minority of genes. Small exons, untranslated regions, alternative splicing and genes within genes are the hardest parts.

5.6.4 Evidence-based annotation

Since ab initio prediction alone is not accurate enough for eukaryotes, genome annotation pipelines combine it with external **evidence**:

- **Transcript evidence**: cDNA and EST sequences, and now RNA-seq reads aligned with spliced aligners or assembled into transcripts, and full-length transcripts from long-read sequencing (Iso-Seq or direct RNA), which show exon–intron structures directly.
- **Protein evidence**: proteins from related species aligned to the genome with *spliced* protein-to-genome alignment, which identifies exons by homology even when the genes are not expressed in the sampled tissues.
- **Comparative evidence**: conservation between related genomes, since coding exons evolve more slowly and show the three-periodic pattern of synonymous changes.

Before gene prediction, **repeats** are identified and masked, since transposable elements contain ORFs that would otherwise be predicted as genes. Pipelines such as MAKER (Holt and Yandell 2011) and BRAKER (Brůna et al. 2021) align the evidence, use it to train and guide gene finders such as AUGUSTUS and GeneMark, and combine the results into consensus gene models. BRAKER3 combines RNA-seq and protein evidence in one pipeline (Gabriel et al. 2024). MAKER also reports for each gene model an *annotation edit distance* (AED), from 0 for complete agreement with the aligned evidence to 1 for no agreement (Holt and Yandell 2011). AED measures agreement with the evidence, not correctness: a real gene that is not expressed in the sampled tissues gets a poor score. Figure 5.3 summarises such a pipeline.

The evidence sources are not fully independent. A protein in a database may itself be a computational prediction, so using it to support another prediction can propagate an error from genome to genome. A predicted gene is well supported when RNA-seq reads confirm its splice junctions, a protein from a related species aligns along its whole length, and its domains occur in the expected order. A protein

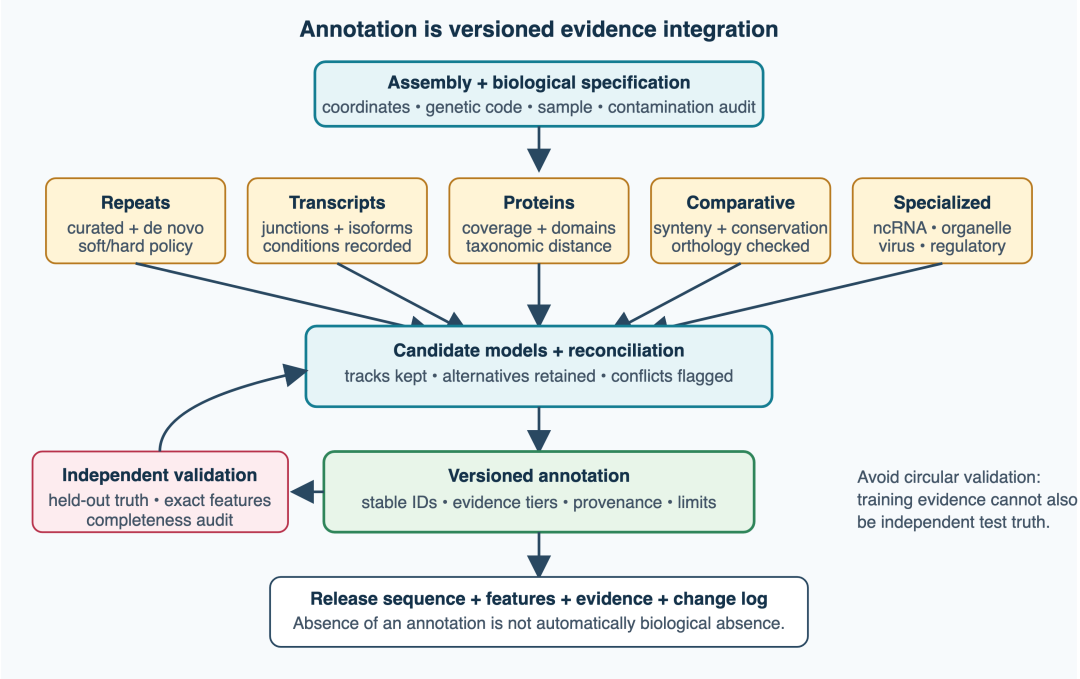

Figure 5.3: Genome annotation integrates several kinds of evidence (repeats, transcripts, proteins, conservation, specialised predictors for non-coding RNAs and other features) into candidate gene models, which are reconciled and released as versioned annotations. Evidence used to train the gene finders cannot also serve as independent test data. Figure: Matteo Tadiello, *Modern Bioinformatics: From Foundations to Frontiers* (CC BY 4.0).

match that covers only one domain, an internal stop codon or a frameshift suggests an incomplete or wrong gene model. Equally, the absence of a gene from an annotation does not show that the gene is absent from the genome, since it may lie in a gap of the assembly or have been missed by the pipeline. The Ensembl, RefSeq and GENCODE annotations of the human genome are curated with such pipelines and manual review. **Deep learning** has entered this field too: Helixer predicts gene structures directly from the genome sequence with a neural network and needs no species-specific training (Stiehler et al. 2020).

Even for the human genome, the number of protein-coding genes was debated for years: estimates before the genome project ranged up to 100,000, the first drafts predicted about 30,000–40,000, and the number in current annotations (2026) is about 20,000 (Chapter 6).

5.7 Metagenomics

Metagenomics is the study of genetic material recovered directly from an environment, without first isolating and culturing the organisms. Most microbes cannot be grown in the laboratory, so metagenomics has changed our view of microbial diversity, from the oceans and soil to the human gut, and of the tree of life itself (Section 4.5). It also raises its own algorithmic problems, because the data are a mixture of many genomes in unknown proportions (Quince et al. 2017).

5.7.1 History

In the 1980s Norman Pace and colleagues began to sequence ribosomal RNA genes amplified directly from environmental samples, which showed that microbial diversity was vastly greater than that of cultured species (Pace 1997). The term *metagenome* was introduced in 1998 for the collective genomes of the microbes in soil (Handelsman et al. 1998). The first large shotgun metagenomes followed in 2004: nearly complete genomes were reconstructed from a simple community in acid mine drainage (Tyson et al. 2004), and Venter's Sargasso Sea project reported more than a million new genes (Venter et al. 2004). Large projects then characterised the human gut (Qin et al. 2010) and the human microbiome at many body sites (The Human Microbiome Project Consortium 2012), and the Tara Oceans expedition the global ocean microbiome (Sunagawa et al. 2015). Catalogues of hundreds of thousands of genomes assembled from metagenomes now describe most of the species in the human gut (Almeida et al. 2019; Pasolli et al. 2019) and many environments on Earth (Nayfach et al. 2020).

5.7.2 Amplicon sequencing

The simplest approach is **amplicon** (marker-gene) sequencing: a variable region of the 16S rRNA gene (for bacteria and archaea), or of the 18S rRNA or ITS region (for eukaryotes and fungi), is amplified with universal primers and sequenced. It is cheap and sensitive, and is still the most common way to describe community composition.

Reads were traditionally clustered into **operational taxonomic units** (OTUs) at 97% identity, a rough proxy for species. Since clustering merges real variants with sequencing errors, modern methods instead infer the exact **amplicon sequence variants** (ASVs) in the sample, using a model of the sequencing errors to decide which sequences are real (Callahan et al. 2016). ASVs are reproducible across studies. Pipelines such as QIIME 2 (Bolyen et al. 2019) assign taxonomy by comparison with reference rRNA databases and compute diversity measures: *alpha diversity* within a sample and *beta diversity* between samples, using distances that may take phylogeny into account.

Amplicon data have well-known limitations. PCR primers do not amplify all taxa equally, the number of rRNA operons differs between genomes, a short region of 16S often cannot distinguish species or strains, and the data tell nothing about the functions encoded in the genomes.

5.7.3 Shotgun metagenomics

In **shotgun metagenomics**, all DNA in the sample is sequenced. This gives access to all organisms (including viruses and eukaryotes) and to their genes, but the analysis is much harder (Quince et al. 2017). The main tasks are:

- **Taxonomic profiling**: which organisms are present, and in what proportions. Read classifiers such as **Kraken** (Wood and Salzberg 2014; Wood et al. 2019) assign each read to the lowest common ancestor of the genomes that share its *k*-mers (Section 1.5). Marker-gene profilers such as **MetaPhlAn** (Blanco-Míguez et al. 2023) map reads to a set of clade-specific genes, which gives more accurate abundances. Profiling is limited by the reference database: organisms without sequenced relatives are invisible or misclassified.
- **Functional profiling**: which genes and pathways are present. Reads or predicted genes are compared with protein databases, usually with fast translated search such as DIAMOND or MMseqs2 (Section 1.4), and summarised by gene families and pathways (Chapter 10). Gene catalogues, such as the 3.3 million non-redundant genes of the first MetaHIT study of the gut (Qin et al. 2010), serve as references.
- **Assembly**: reconstructing genomes without a reference. Metagenome assembly is harder than single-genome assembly (Section 5.3), because coverage varies by orders of magnitude between species, closely related strains create bubbles and tangles in the graph, and repeats are shared between genomes. Assemblers such as metaSPAdes (Nurk et al. 2017) and MEGAHIT (Li et al. 2015) are adapted to these problems.
- **Binning**: grouping contigs that come from the same genome, described below.

Profiling and assembly answer different questions. A profiler estimates which *known* taxa are present and in what proportions, by comparing reads with reference genomes or marker genes, and does not reconstruct genomes. Assembly and binning reconstruct genome sequences, including those of organisms with no sequenced relatives, but only for organisms with enough coverage, and they say less about the rare members of the community.

Genes are predicted on the contigs, mostly with prokaryotic gene finders such as Prodigal (Section 5.6). The proteins found in metagenomes now far outnumber those from cultured organisms, and are a main source of sequences for protein families, structure prediction and protein language models (Section 1.10).

5.7.4 Binning and metagenome-assembled genomes

Binning groups contigs into putative genomes, **metagenome-assembled genomes** (MAGs). It uses two kinds of signal:

- **sequence composition**: different genomes have different GC content and oligonucleotide (typically tetranucleotide) frequencies, while contigs from the same genome are similar;
- **coverage**: contigs from the same genome have similar coverage within a sample, and, more powerfully, their coverage varies in the same way across many samples (*co-abundance*).

Tools such as MetaBAT 2 (Kang et al. 2019) combine the two signals to cluster contigs. The quality of each MAG is then estimated from sets of single-copy marker genes: the fraction of expected markers present gives the *completeness*, and the fraction present in multiple copies the *contamination* (Parks et al. 2015). By community standards, a high-quality draft MAG is more than 90% complete with less than 5% contamination and contains the rRNA genes and most tRNAs (Bowers et al. 2017). A MAG is not equivalent to the genome of an isolate. It is typically a consensus of closely related strains in the sample, it often lacks mobile elements, plasmids and rRNA operons, which are hard to assemble and bin, and it may contain contigs from other organisms that the marker-gene estimates do not detect. Long-read sequencing increasingly produces complete, circular genomes directly from metagenomes.

MAGs have changed microbial phylogeny: much of the diversity in current trees of life, including the candidate phyla radiation and the Asgard archaea, is known only from metagenomes (Section 4.5). The Genome Taxonomy Database includes MAGs in its classification (Parks et al. 2018).

5.7.5 Benchmarking

As in other fields, community challenges have been used to compare methods. The Critical Assessment of Metagenome Interpretation (CAMI) provides realistic simulated and mock communities with known composition, and has evaluated assemblers, binners and profilers (Sczyrba et al. 2017; Meyer et al. 2022). The results show that methods work well for species with a single strain at high coverage, and poorly for closely related strains and for low-abundance organisms.

5.8 Human genetics: finding disease genes and variants

Variant calling (Section 5.4) produces a list of differences between a genome and the reference. Human genetics asks which of these differences affect a trait or cause a disease. Two very different strategies are used. For common, complex diseases, millions of variants are tested for statistical association in large populations. For rare, Mendelian diseases, the genome or exome of a patient, often with the parents, is searched for one or two variants that explain the disease. Both depend on how variants are inherited together along the chromosome.

5.8.1 Linkage disequilibrium and haplotype structure

Alleles at nearby sites are not inherited independently. A new mutation arises on one particular haplotype, and only recombination, a few events per chromosome per generation, separates it from its neighbours. The non-random association of alleles at different sites is called **linkage disequilibrium** (LD). For two biallelic sites with alleles A/a and B/b, it is measured by

$$D = p_{AB} - p_A p_B,$$

the difference between the observed frequency of the AB haplotype and the frequency expected if the sites were independent. Because the range of D depends on the allele frequencies, two normalised measures are used. $D' = D/D_{\max}$ is 1 when at most three of the four haplotypes are present, which shows that no recombination (or recurrent mutation) has been observed between the sites. The squared correlation

$$r^2 = \frac{D^2}{p_A p_a p_B p_b}$$

is 1 only when the two sites carry the same information, so that one predicts the other perfectly. r^2 is what matters for association studies: a variant in LD r^2 with a causal variant captures its effect with a sample size about $1/r^2$ times larger.

LD decays with distance, but not smoothly. In humans most recombination occurs in **hotspots** of one or two kilobases, positioned largely by the DNA-binding protein PRDM9 (Myers et al. 2005). Between hotspots, the genome forms **haplotype blocks** of tens of kilobases, within which only a few common

haplotypes exist (Gabriel et al. 2002). The International HapMap Project mapped these patterns in several populations ("A Haplotype Map of the Human Genome" 2005). A few **tag SNPs** chosen from each block capture most of the common variation (Carlson et al. 2004), which is why a genotyping array with half a million SNPs can survey the common variation of a whole genome. LD extends further in populations that have passed through bottlenecks, such as Europeans and East Asians, than in African populations, which affects both the design and the transferability of genetic studies.

5.8.2 Genetic architecture of disease

In **Mendelian** (monogenic) diseases, such as cystic fibrosis or Huntington's disease, a variant in a single gene is sufficient to cause the disease. Such variants are rare, because selection keeps them at low frequency, and have large effects. **Complex** diseases and traits, such as type 2 diabetes, schizophrenia or height, are influenced by many variants of small effect together with the environment. In between lie variants with incomplete **penetrance**, the probability that a carrier develops the disease, such as *BRCA1* mutations in breast cancer. Effect size and allele frequency are therefore inversely related: common variants have small effects, and large effects are found mostly in rare variants. The methods differ accordingly: association studies find common variants of small effect, and sequencing of families finds rare variants of large effect.

Heritability is the fraction of the variance of a trait in a population that is explained by genetic differences. Twin studies estimate it to be about 80% for height, yet the first GWAS hits together explained only a few per cent, the problem of **missing heritability** (Manolio et al. 2009). Much of it was later found to be hidden in very many common variants, each too weak to reach significance: fitting all SNPs together explained about half of the heritability of height (Yang et al. 2010). The rest is thought to lie in rare variants, poorly tagged variants and, possibly, overestimated twin heritability.

5.8.3 Linkage analysis

Before association studies, disease genes were mapped by **linkage analysis** in families. Markers spread over the genome are genotyped in affected and unaffected relatives, and one tests whether a marker is co-inherited with the disease more often than expected for an unlinked locus. The evidence is summarised as a **LOD score**, the base-10 logarithm of the ratio between the likelihood of the data at a recombination fraction $\theta < 0.5$ and at $\theta = 0.5$ (no linkage). A LOD score of 3, odds of 1000 to 1, was the classical threshold, and thresholds for genome-wide scans were later formalised (Lander and Kruglyak 1995). Linkage analysis found the genes for hundreds of Mendelian diseases, such as *CFTR* and *HTT*, but it has low power for complex diseases and low resolution, since a family has few recombinations and a linked region can contain hundreds of genes.

5.8.4 Genome-wide association studies

A **genome-wide association study** (GWAS) tests each of millions of variants for association with a trait in unrelated individuals, either in a **case–control** design, comparing allele frequencies between patients and controls with logistic regression, or for a **quantitative trait** with linear regression of the trait on the number of alternative alleles (0, 1 or 2). The Wellcome Trust Case Control Consortium study of 14,000 cases of seven diseases and 3,000 shared controls established the design in 2007 (Burton et al. 2007), and tens of thousands of associations with thousands of traits have since been reported (Visscher et al. 2017; Uffelmann et al. 2021) and collected in the GWAS Catalog (Section 2.9).

Most GWAS genotype samples with **SNP arrays** (Section 7.2) rather than by sequencing. The missing variants are then **imputed**: each individual's haplotypes are modelled as a mosaic of haplotypes in a

sequenced **reference panel**, such as 1000 Genomes or TOPMed, with the same kind of hidden Markov model used for statistical phasing (Section 5.4), which predicts genotypes at millions of untyped sites (Marchini and Howie 2010). Imputation works well for common variants in populations represented in the panel, and poorly for rare variants.

Multiple testing. The conventional genome-wide significance threshold is $P < 5 \times 10^{-8}$. It is a Bonferroni correction of 0.05 for about one million independent tests, the effective number of independent common variants in the genome of European-ancestry populations, estimated from LD (Pe'er et al. 2008). It is not tied to the number of variants actually tested: imputing more variants adds tests, but few independent ones. Because the threshold is strict, true associations of small effect need very large samples, and modern GWAS include hundreds of thousands to millions of individuals. Associations must be **replicated** in an independent sample, and the first reported effect size is usually inflated (the *winner's curse*).

Population stratification. If cases and controls differ in ancestry, every variant whose frequency differs between the ancestral groups will appear associated with the disease. **EIGENSTRAT** corrects for this by computing principal components of the genotype matrix, which capture ancestry, and including them as covariates (Price et al. 2006). **Linear mixed models** go further by modelling the genetic relatedness between all pairs of individuals as a random effect, which also handles cryptic relatedness, and scale to biobanks (Loh et al. 2015).

Manhattan and QQ plots. The results are shown as a **Manhattan plot**, with $-\log_{10} P$ for each variant against its position, where associated loci appear as towers of variants in LD with each other. A **quantile–quantile (QQ) plot** compares the observed P-values with the uniform distribution expected under the null hypothesis. A curve that leaves the diagonal only at the tail indicates true associations; a curve lifted from the start indicates inflation, measured as the **genomic inflation factor** λ_{GC}, the median observed χ^2 statistic divided by its expected value of 0.455 (Devlin and Roeder 1999). For highly polygenic traits in large samples, true signal also inflates λ_{GC}, and LD score regression separates polygenicity from confounding (Bulik-Sullivan et al. 2015).

5.8.5 From association to causal variants and genes

A GWAS locus is a region, not a variant. Because of LD, dozens of variants are almost equally associated, and the strongest is often not the causal one. **Statistical fine-mapping** computes, from the association statistics and the LD between variants, the posterior probability that each variant is causal, and reports a **credible set**, the smallest set of variants that contains the causal one with, say, 95% probability (Schaid et al. 2018). Methods such as FINEMAP and SuSiE allow several causal variants per locus. Fine-mapping depends on accurate LD, ideally from the study itself, and is helped by combining populations with different LD patterns, and by functional annotation of the variants.

About 90% of GWAS variants lie outside protein-coding sequence, presumably in regulatory elements (Section 6.9), so the target gene is not obvious and is often not the nearest one. **Colocalisation** tests whether the association with a disease and with the expression of a gene (an eQTL, Section 7.5) are likely to be due to the same causal variant rather than to two distinct variants in LD (Giambartolomei et al. 2014). Overlap with open chromatin and histone marks from the methods of Section 5.5 adds further evidence.

5.8.6 Polygenic scores

A **polygenic score** (PGS or PRS) sums the effects of many variants, $\text{PGS} = \sum_i \hat{\beta}_i x_i$, with x_i the number of alleles and $\hat{\beta}_i$ the effect sizes from a GWAS, after pruning or shrinking the effects to account for LD (Choi et al. 2020). Polygenic scores can identify individuals with a risk comparable to that of carriers

of Mendelian variants, but they predict poorly for individuals, and their accuracy depends strongly on ancestry. Most GWAS participants are of European ancestry, and because LD patterns and allele frequencies differ between populations, scores derived in Europeans are several times less accurate in people of African ancestry (Martin et al. 2019). Using them in the clinic without larger, more diverse studies could widen existing health disparities.

5.8.7 Finding Mendelian disease genes by sequencing

Exome sequencing changed the search for Mendelian disease genes. In 2010, the gene for Miller syndrome was found by sequencing the exomes of only four affected individuals (Ng et al. 2009), and exome and genome sequencing have since become first-line tests for rare disease (Bamshad et al. 2011). Each exome contains about 20,000 variants, and each genome four to five million, so the problem is to filter them down to a few candidates:

- **Annotation.** Each variant is annotated with its consequence (missense, stop-gain, frameshift, splice site, synonymous) in every overlapping transcript, by tools such as VEP (McLaren et al. 2016) and SnpEff (Cingolani et al. 2012). A variant can be a missense change in one transcript and intronic in another, so the transcript set (for example MANE Select) must be stated.
- **Population frequency.** A variant that causes a rare, severe disease cannot be common in the general population. Variants above a frequency cut-off in gnomAD (Section 2.9), adapted to the prevalence and inheritance of the disease, are removed.
- **Inheritance model.** For a recessive disease, the candidate gene must carry two damaging alleles, either homozygous or compound heterozygous, which requires phasing (Section 5.4). For a dominant disease one allele suffices.
- **Trios and de novo mutations.** Each person carries roughly 70 new single-nucleotide variants not present in either parent, on average about one in the exome. Counting also indels, structural variants and changes in tandem repeats, which only long-read assemblies detect reliably, a four-generation pedigree gave about 100–200 de novo mutations per transmission, most of them inherited from the father (Porubsky et al. 2025). Sequencing patient and parents (a *trio*) finds these **de novo** variants directly, and they explain a large fraction of severe developmental disorders and intellectual disability (Veltman and Brunner 2012). Apparent de novo calls are, however, enriched for errors, such as low coverage in a parent.
- **Homozygosity mapping.** In consanguineous families, a recessive disease allele lies in a long run of homozygosity inherited from a common ancestor, which narrows the search to these regions (Lander and Botstein 1987).
- **Phenotype-driven prioritisation.** The patient's clinical features are coded with the Human Phenotype Ontology (HPO) (Köhler et al. 2020), and tools such as Exomiser (Smedley et al. 2015) rank the remaining candidates by combining variant scores with the similarity between the patient's phenotype and those of known diseases and model organisms.

Even so, exome sequencing gives a diagnosis in only about a quarter to two-fifths of patients, depending on the cohort; in critically ill neonates and infants, a meta-analysis found a yield of about 40% for both exome and genome sequencing (Yang et al. 2026). The remainder may have variants in non-coding regions, structural variants, repeat expansions, or variants in genes not yet linked to disease, which is why genome sequencing, long reads and RNA sequencing are increasingly added, and why unsolved cases are reanalysed as knowledge grows.

5.8.8 Interpreting variants in the clinic

Finding a candidate is not the same as proving that it causes the disease. Clinical laboratories classify variants with the ACMG/AMP guidelines into five classes, from *benign* to *pathogenic*, by combining

weighted criteria: population frequency, the predicted consequence (null variants in genes where loss of function causes disease), segregation in the family, de novo occurrence, functional assays and computational predictions (Richards et al. 2015). Many variants end up as *variants of uncertain significance*. The databases used in this process are described in Section 2.9, and the computational prediction of variant effects, which counts only as supporting evidence, in Section 10.6.

5.9 Key concepts

A checklist for revision.

- **Sequencing technologies:** Sanger chain termination and its automation; Phred quality scores; pyrosequencing and 454; Illumina sequencing by synthesis; Ion Torrent; PacBio (CLR and HiFi); Oxford Nanopore (simplex and duplex); read lengths, error profiles and cost, and why quoted accuracies date quickly; detection of base modifications; base qualities as calibrated model estimates; random vs. systematic (context-dependent) errors and why consensus removes only the former; long-read transcriptomics (Iso-Seq, direct RNA sequencing)
- **Shotgun sequencing:** clone-by-clone vs. whole-genome shotgun; coverage and the Lander–Waterman model ($c = NL/G$, uncovered fraction e^{-c}); coverage bias; paired-end and mate-pair reads; read length vs. insert size
- **Assembly paradigms:** shortest common superstring and greedy assembly; overlap–layout–consensus; string graphs and transitive reduction; de Bruijn graphs, Eulerian paths, tips and bubbles, the choice of k; long-read assemblers (Canu, Flye, hifiasm); polishing (Racon) and how it can homogenise repeats or erase heterozygous sites; why "de Bruijn for short, overlap for long reads" is a simplification
- **Repeats** as the central problem of assembly; contigs and scaffolds; scaffolding with read pairs, long reads, optical maps and Hi-C
- **Assembly quality:** contiguity, completeness and correctness as separate axes; N50 and NG50; BUSCO; k-mer based evaluation and QV; reference-based evaluation (QUAST) and why differences from a reference are not always errors; Assemblathon; haplotigs, primary/alternate and haplotype-resolved assemblies; chromosome-scale and telomere-to-telomere assemblies; pangenome references
- **Read mapping:** seed and extend; hash-based mappers vs. Burrows–Wheeler/FM-index (Bowtie, BWA); minimizers and chaining (minimap2); mapping quality; SAM/BAM/CRAM and the SAM record (FLAG, CIGAR, MAPQ); 1- vs. 0-based coordinates; quality control (base quality, adapters, duplicates, contamination, coverage, mapping statistics); reference bias, graph genomes and the human pangenome reference, and the biases of graph references
- **Variant calling:** SNPs, indels and structural variants; the VCF record (REF, ALT, QUAL, FILTER, INFO, FORMAT, GT, AD, PL) and indel normalisation; read evidence vs. genotype likelihood vs. genotype call, and why a difference from the reference is not always a variant; genotype likelihoods and priors; joint calling; GATK and haplotype-based calling; DeepVariant; Genome in a Bottle benchmarks; SV and CNV signals (depth, discordant pairs, split reads, assembly) and what each can detect; long-read SV calling; phasing (read-backed, trio, statistical); minimum error correction (WhatsHap); phase blocks and switch errors
- **Targeted sequencing, copy number and cancer:** hybrid capture and exome sequencing; uneven coverage and off-target reads; CNVs from read depth (binning, GC correction, panel

of normals, segmentation) and from SNP arrays (log R ratio, B-allele frequency, copy-neutral LOH); tumour–normal somatic calling (Mutect); variant allele fraction, purity and ploidy; panel of normals and artefacts; clonal vs. subclonal mutations; drivers vs. passengers, background mutation rate and dN/dS; mutational signatures (96 trinucleotide contexts, NMF, COSMIC signatures)
- **Regulatory and epigenomic sequencing:** ChIP-seq and the input control; peak calling (MACS), narrow vs. broad peaks; IDR and FRiP; motif analysis of peaks; DNase-seq and ATAC-seq, footprints; bisulfite sequencing, bisulfite-aware alignment (Bismark), methylation level and its pitfalls; long-read methylation calling; CLIP-seq
- **Gene prediction:** signals and content; ORFs; why eukaryotic gene prediction is more than ORFs plus splice sites (UTRs, isoforms, non-coding genes); Markov models of coding sequence (GeneMark, Glimmer, Prodigal); coding log-likelihood scores; self-training on long ORFs and its bias against short genes; generalised HMMs (GENSCAN, AUGUSTUS); evaluation at nucleotide, exon and gene level; repeat masking; evidence-based annotation (RNA-seq, protein alignments, MAKER, BRAKER); annotation edit distance; circular evidence and why absence from an annotation is not absence from the genome; deep-learning gene finders
- **Metagenomics:** history (Pace, Handelsman, Sargasso Sea, MetaHIT, HMP, Tara Oceans); 16S amplicon sequencing, OTUs vs. ASVs, diversity; shotgun metagenomics; taxonomic profiling (Kraken, MetaPhlAn) and functional profiling; metagenome assembly; profiling vs. assembly and binning as different questions; binning by composition and coverage; MAG quality (completeness, contamination, MIMAG); MAGs vs. isolate genomes; CAMI
- **Human genetics:** linkage disequilibrium (D, D', r^2), recombination hotspots, haplotype blocks and tag SNPs; Mendelian vs. complex disease, penetrance, allele frequency vs. effect size; heritability and missing heritability; linkage analysis and LOD scores; GWAS design, arrays and imputation; the 5×10^{-8} threshold; population stratification, PCA and mixed models; Manhattan and QQ plots, genomic inflation; replication and winner's curse; fine-mapping and credible sets; colocalisation with eQTLs; polygenic scores and their portability across ancestries; exome/genome sequencing for rare disease: annotation per transcript (VEP), gnomAD frequency filtering, inheritance models, trios and de novo mutations, homozygosity mapping, HPO and Exomiser; ACMG/AMP classification

5.10 Recommended reading

These papers are recommended for reading in full:

- Goodwin et al. (2016) — ten years of next-generation sequencing; how the technologies work and what their errors are.
- Compeau et al. (2011) — how to apply de Bruijn graphs to genome assembly; the key algorithmic idea, very clearly explained.
- Langmead et al. (2009) — Bowtie; read mapping with the Burrows–Wheeler transform.
- Nielsen et al. (2011) — genotype and SNP calling from sequencing data; the probabilistic framework.
- Yandell and Ence (2012) — a beginner's guide to eukaryotic genome annotation.
- Quince et al. (2017) — shotgun metagenomics from sampling to analysis.

Titles, abstracts, links and the full texts are in Section A.5; a longer list of further papers is in Section B.5.

5.11 Background reading (open access)

- **DNA sequencing (Wikipedia)** — DNA sequencing is the process of determining the nucleic acid sequence – the order of nucleotides in DNA. It includes any method or technology that is

used to determine the order of the four bases: adenine, thymine, cytosine, and guanine.
https://en.wikipedia.org/wiki/DNA_sequencing

- **Massive parallel sequencing (Wikipedia)** — Massively parallel sequencing (MPS) is any of several high-throughput approaches to DNA sequencing using the concept of massively parallel processing; it is also called next-generation sequencing (NGS) or second-generation sequencing.
https://en.wikipedia.org/wiki/Massive_parallel_sequencing
- **Nanopore sequencing (Wikipedia)** — Nanopore sequencing is a third generation approach used in the sequencing of biopolymers — specifically, polynucleotides in the form of DNA or RNA.
https://en.wikipedia.org/wiki/Nanopore_sequencing
- **Sequence assembly (Wikipedia)** — In bioinformatics, sequence assembly refers to aligning and merging fragments from a longer DNA sequence in order to reconstruct the original sequence.
https://en.wikipedia.org/wiki/Sequence_assembly
- **De Bruijn graph (Wikipedia)** — In graph theory, an n-dimensional De Bruijn graph of m symbols is a directed graph representing overlaps between sequences of symbols. It has mn vertices, consisting of all possible length-n sequences of the given symbols; the same symbol may appear multiple times in a sequence.
https://en.wikipedia.org/wiki/De_Bruijn_graph
- **N50, L50, and related statistics (Wikipedia)** — In computational biology, N50 and L50 are statistics of a set of contig or scaffold lengths. The N50 is similar to a mean or median of lengths, but has greater weight given to the longer contigs. It is used widely in genome assembly, especially in reference to contig lengths within a draft assembly.
https://en.wikipedia.org/wiki/N50,_L50,_and_related_statistics
- **Burrows–Wheeler transform (Wikipedia)** — The Burrows–Wheeler transform (BWT) rearranges a character string into runs of similar characters, in a manner that can be reversed to recover the original string.
https://en.wikipedia.org/wiki/Burrows%E2%80%93Wheeler_transform
- **A tutorial on Burrows–Wheeler indexing methods** — A step-by-step blog tutorial (The Grand Locus) on the Burrows–Wheeler transform, the FM-index and backward search, the data structures behind read mappers such as BWA and Bowtie.
http://blog.thegrandlocus.com/2016/07/a-tutorial-on-burrows-wheeler-indexing-methods
- **SNV calling from NGS data (Wikipedia)** — SNV calling from NGS data is any of a range of methods for identifying the existence of single nucleotide variants (SNVs) from the results of next generation sequencing (NGS) experiments.
https://en.wikipedia.org/wiki/SNV_calling_from_NGS_data
- **Structural variation (Wikipedia)** — Genomic structural variation is the variation in structure of an organism's chromosome, such as deletions, duplications, copy-number variants, insertions, inversions and translocations.
https://en.wikipedia.org/wiki/Structural_variation
- **Gene prediction (Wikipedia)** — In computational biology, gene prediction or gene finding refers to the process of identifying the regions of genomic DNA that encode genes. This includes protein-coding genes as well as RNA genes, but may also include prediction of other functional elements such as regulatory regions.
https://en.wikipedia.org/wiki/Gene_prediction
- **Metagenomics (Wikipedia)** — Metagenomics is the study of all genetic material from all organisms in a particular environment, providing insights into their composition, diversity, and functional potential.
https://en.wikipedia.org/wiki/Metagenomics

5.12 Student recommendations

Recommended by students preparing for the exam: papers, reviews, online lectures, tutorials and short explanations. To suggest something, use the suggestion form (SU login).

No recommendations yet.

5.13 Review problems

These problems are adapted from Matteo Tadiello, *Modern Bioinformatics: From Foundations to Frontiers* (CC BY 4.0), used with permission. For a longer treatment of this topic, see the chapters "Sequencing, Mapping, Assembly, and Variation" and "Genome Architecture, Representation, and Annotation" of that book. In the HTML version, click a box to show the extensions, solution outline and common errors.

5.13.1 Design sequencing for a repeat-rich diploid genome

You have a highly heterozygous, repeat-rich diploid organism with a genome of 1.2 Gb and no close reference. How would you design the genome project?

Extensions, solution outline and common errors

Extensions:

1. Why are accurate short reads alone insufficient?
2. How do read length and molecule length differ?
3. Would you use Hi-C, parental data or both?
4. What do you mean by "the genome": which output do you deliver?
5. How would you know that both haplotypes were recovered?

Solution outline:

- Define the deliverable first: a collapsed primary assembly, a primary assembly with alternate haplotigs, or two haplotype-resolved assemblies. Estimate genome size, ploidy, heterozygosity and repeat content, for example from a k-mer spectrum.
- Extract high-molecular-weight DNA; long-read sequencing cannot recover long-range information from sheared molecules.
- Use accurate long reads (HiFi) to span repeats and link nearby heterozygous sites. Add parental reads for trio binning if the parents are available, or Hi-C for chromosome-scale phasing and scaffolding; ultra-long nanopore reads help with the longest repeats.
- Assemble with a haplotype-aware method such as hifiasm. Keep bubbles in the graph until the evidence shows whether they are alleles, repeat copies or errors.
- Polish each haplotype separately, so that alleles are not mixed, and be careful with short reads in paralogous regions.
- Evaluate contiguity (N50, NG50), consensus quality (k-mer QV), assembly size relative to the expected genome size, gene completeness (BUSCO), structural correctness (Hi-C contact maps, read support at joins), phasing (haplotype-specific k-mers, switch errors) and contamination.
- Report unresolved regions and gaps rather than forcing a single path.

Common errors:

- Saying “30× coverage” without stating whether it is per haplotype, raw or mapped, and what the read-length distribution is.
- Treating scaffold N50 as proof that the chromosomes are correct.
- Treating all bubbles as sequencing errors.
- Calling a primary assembly “haploid” when it is a mosaic of both homologues.

Connections: Section 5.3; repeats and genome organisation in Section 6.7 and Section 6.4; phasing in Section 5.4.

5.13.2 Explain read mapping

How does a read mapper find the location of a read, and what does mapping quality mean? Avoid simply saying that “the read matches the reference”.

Extensions, solution outline and common errors

Extensions:

1. Compare an FM-index mapper with a minimizer-based mapper.
2. Why is mapping quality not the same as base quality?
3. What is a supplementary alignment?
4. Can a unique alignment still be wrong?
5. What happens if the sample contains sequence that is absent from the reference?

Solution outline:

- Candidate generation: backward search in an FM-index, or seed look-up in a hash table, narrows the reference down to a few positions that are worth an expensive alignment.
- In minimizer mapping (minimap2), representative k-mers chosen from windows become anchors; compatible anchors are chained by order and spacing, and the chain is then aligned base by base.
- The alignment score measures fit under the substitution and gap costs. Mapping quality is a Phred-scaled estimate of the probability that the reported position is wrong, and its computation is specific to each mapper.
- Base quality concerns the decoding of a base; mapping quality concerns the location of the whole read. A read of perfect base quality can map ambiguously, and a unique mapping can contain poor bases.
- Secondary alignments are alternative placements of the same read; supplementary alignments are the parts of a chimeric or rearranged read that map to different places.
- A unique alignment can still be wrong if the heuristic missed alternatives or if the true origin is missing from the reference.
- Diagnose with pair consistency, soft clipping, alternative references, graph mapping and local assembly.

Common errors:

- Interpreting MAPQ 60 as a universal empirical error rate of 10^{-6}.
- Removing all multi-mapping reads and then concluding that a difficult locus has no coverage.
- Assuming that an indexed search evaluates every gapped alignment.
- Taking a high alignment score as proof of biological origin.

Connections: Section 5.4; exact matching and heuristic search in Section 1.4; dynamic programming in Section 1.3.

5.13.3 Compare de Bruijn and string graphs

Explain genome assembly with de Bruijn graphs and with overlap and string graphs, including how each fails.

Extensions, solution outline and common errors

Extensions:

1. What does changing k do in a de Bruijn graph?
2. Why are transitive overlaps removed in a string graph?
3. What are tips and bubbles?
4. When is a repeat resolvable?
5. Why might the graph be a more truthful result than the contigs?

Solution outline:

- In a de Bruijn graph, reads are broken into k-mers; in the usual form, $(k-1)$-mers are nodes and observed k-mers are directed edges. Non-branching paths are compacted into unitigs.
- A small k keeps the graph connected where coverage is low but collapses more repeats; a large k resolves more repeats but breaks at errors and coverage gaps. Assemblers such as SPAdes combine several values of k.
- In overlap–layout–consensus, reads are nodes connected by overlaps. A string graph removes contained reads and transitive edges, which carry no extra information.
- Long reads reduce the number of nodes and span repeats, but overlap detection must tolerate errors.
- Tips may be errors or real sequence with low coverage; bubbles may be errors, heterozygous alleles, strains or paralogues. Removing them is an inference, not housekeeping.
- A repeat is resolved when reads connect each copy to its own unique flanks. Average read length alone does not show this.
- If several paths are equally supported, the graph represents the uncertainty correctly; choosing one contig invents information.

Common errors:

- Saying that de Bruijn nodes are always k-mers without stating the convention used.
- Equating high coverage with repeat resolution.
- Assuming that every long-read assembler literally performs classical overlap–layout–consensus.
- Removing all low-coverage branches in a metagenome, where they may be rare strains.

Connections: Section 5.3; metagenome assembly in Section 5.7; repeats in Section 6.7.

5.13.4 Diagnose an impressive but suspicious assembly

Assembly A has an N50 of 80 Mb and assembly B an N50 of 20 Mb. Is A better?

Extensions, solution outline and common errors

Extensions:

1. Define N50 and NG50 precisely.
2. How can N50 be inflated?
3. What would Merqury and BUSCO tell you?
4. How do you detect a collapsed or duplicated haplotype?
5. How would you validate a chromosome-scale scaffold?

Solution outline:

- N50 is the length such that contigs of that length or longer contain half of the assembly; NG50 uses half of an independent estimate of the genome size instead.
- N50 measures only contiguity. Chimeric joins, collapsed repeats, missing small chromosomes or duplicated haplotigs can all increase it.
- Compare the assembly size with independent genome-size estimates and inspect the *k*-mer spectrum. Merqury compares the *k*-mers of the assembly with those of accurate reads to estimate consensus quality (QV), completeness and, with parental data, phasing.
- BUSCO measures the recovery and duplication of conserved single-copy genes, but says nothing about intergenic sequence or structural correctness.
- Test the structure with read support across joins, Hi-C contact maps, optical or genetic maps, and comparison with a reference where a suitable one exists.
- For haplotypes, examine haplotype-specific *k*-mers, read depth, allele balance and switch errors: a collapsed region has double depth, a duplicated one half depth.
- Conclude only after comparing all these dimensions in relation to the intended use.

Common errors:

- Defining N50 relative to the known genome size rather than the assembly size.
- Calling every difference from a related reference a misassembly.
- Interpreting duplicated BUSCO genes as either always an error or always biological.
- Evaluating a polished consensus only with the reads used for polishing.

Connections: Section 5.3; genome duplication in Section 3.4 and Section 6.4; circular evaluation in 4.

5.13.5 Call and validate small variants

How is a heterozygous SNP inferred from sequencing reads?

Extensions, solution outline and common errors

Extensions:

1. Where do base quality and mapping quality enter?
2. What does local haplotype assembly add?
3. Why might the allele balance differ from 0.5?
4. How does a learned caller such as DeepVariant change the inference?
5. What is a fair benchmark?

Solution outline:

- Define candidate alleles, compute genotype likelihoods $P(D \mid G)$ from the reads under an error model, and combine them with genotype priors to obtain posterior probabilities $P(G \mid D) \propto P(D \mid G)\,P(G)$.
- Base quality gives the probability of a wrong base; mapping quality the probability that the read comes from elsewhere. Strand, position in the read, duplicates and sequence context also matter.
- Local haplotype assembly (as in GATK HaplotypeCaller) represents nearby substitutions and indels jointly and aligns reads to candidate haplotypes, rather than scoring each pileup column on its own.
- A learned caller estimates the decision function from labelled truth data; its performance depends on how well the technology, coverage and ploidy match its training data.
- Allele balance departs from 0.5 because of reference bias, copy number, tumour purity, mosaicism, sampling, amplification or contamination.
- Benchmark only within the confident regions of a truth set such as Genome in a Bottle, and report precision and recall separately by variant type and genomic context.
- Validate important calls with an assay that does not share the same failure modes.

Common errors:

- Taking depth alone as evidence for a heterozygote.
- Treating genotype quality as clinical pathogenicity.
- Counting calls outside the truth set as false positives, although the truth there is unknown.
- Tuning filters on the same benchmark used for the final score.

Connections: Section 5.4; Bayesian reasoning and evaluation in 4; interpretation of variants in Section 10.6.

5.13.6 Detect a structural variant and phase it

A patient may carry a 12 kb insertion in a segmental duplication. How would you detect, reconstruct, phase and validate it?

Extensions, solution outline and common errors

Extensions:

1. What can paired short reads contribute?
2. Why are split reads helpful but sometimes insufficient?
3. How would reference bias appear?
4. How do long reads enable phasing?
5. Which validation assay would you choose?

Solution outline:

- State why the locus is difficult: a 12 kb novel insertion is longer than a short-read fragment, and the segmental duplication makes the anchors ambiguous.
- Short reads give discordant pairs, a change in depth and split reads at the breakpoints, but cannot reconstruct the insertion and may not place it without unique flanks.
- Obtain long reads that span unique sequence on both sides. Keep supplementary alignments and assemble the locus locally rather than trusting a single alignment.
- Compare linear and graph references; check whether reads that support the insertion get low mapping quality or are lost.

- Phase the insertion by linking it to flanking heterozygous sites on the same reads, and report the support for the phase block.
- Reconstruct the inserted sequence, its orientation and copy number, and the breakpoints.
- Validate with long-range PCR or targeted sequencing if possible, or optical mapping for large structures.

Common errors:

- Reporting a symbolic VCF allele as a complete reconstruction.
- Using only total read depth in a duplicated locus.
- Claiming an exact length from reads that end inside the insertion.
- Using a second aligner on the same short reads as the only validation.

Connections: Section 5.4; segmental duplications in Section 6.7; gene duplication in Section 3.4.

5.13.7 Analyse a low-biomass metagenome

Design a shotgun metagenomics study of a clinical sample with little microbial DNA, and explain how you would defend the claim that a rare pathogen is present.

Extensions, solution outline and common errors

Extensions:

1. Why are extraction blanks essential?
2. Compare read classification with assembly-first analysis.
3. What does a lowest-common-ancestor label from Kraken mean?
4. Why does a single mean coverage make little sense?
5. When is a metagenome-assembled genome credible?

Solution outline:

- Randomise cases and controls across extraction and library batches; include extraction and library blanks, positive controls and a mock community.
- Measure the fraction of host DNA. With little microbial DNA, contaminating DNA from reagents and cross-talk between samples matter much more.
- Read classification depends on the database and on k-mers shared between taxa; record the database version and check for reads in regions unique to the organism, not only read counts.
- Assembly can recover novel sequence and genomic context, but uneven abundance, strains, repeats and mobile elements fragment the graph or cause misjoins. Abundance varies over orders of magnitude between organisms, so there is no single coverage.
- A credible bin has coherent composition and abundance across samples, high completeness and low contamination estimated from marker genes, and sufficient read support; it is still a reconstruction.
- For a rare pathogen, require a much weaker signal in the controls, reads from several organism-specific regions, and confirmation with a targeted assay.
- Absence of classified reads is not proof of absence.

Common errors:

- Removing every organism found in any blank without considering its abundance.

- Treating database labels as direct observations of living organisms.
- Removing host reads without documenting the host reference used.
- Reporting species-level abundance when only conserved genus-level sequence is observed.

Connections: Section 5.7; sequence databases in Section 2.3; horizontal gene transfer in Section 3.7.

5.13.8 Decide whether to use a pangenome graph

What problem does a pangenome graph solve, and how would you show that it improves variant calling?

Extensions, solution outline and common errors

Extensions:

1. What are the nodes, edges and paths of the graph?
2. How does a graph reduce reference bias?
3. Can a graph introduce new biases?
4. How are coordinates reported?
5. How would you avoid testing on genomes that were used to build the graph?

Solution outline:

- A single linear reference favours one sequence and lacks sequence specific to other populations. A pangenome graph stores sequences in nodes and alternative adjacencies in edges; paths record the observed haplotypes and the reference.
- Reads with non-reference alleles can align to a matching path instead of paying mismatch and gap penalties or remaining unmapped.
- The graph still depends on which samples and variants were included. Under-represented ancestries and rare sequence remain at a disadvantage, and many similar paths can make mapping more ambiguous.
- Record the graph release, the haplotypes it contains, how coordinates are projected to a linear reference, and the versions of the mapper and caller.
- Compare with a linear workflow on the same reads, and report precision and recall separately by ancestry, region, variant class and repeat context.
- Hold out samples that were not used to build the graph to measure generalisation.
- Conclude that a graph is a broader model of the reference, not an unbiased truth.

Common errors:

- Describing the pangenome as a list of variants without explaining paths and sequences.
- Testing only on individuals that are already represented in the graph.
- Claiming that graph mapping removes all reference bias.
- Ignoring the consequences for coordinates and reproducibility.

Connections: Section 5.4; genome variation within species in Section 6.6; data leakage in 4.

5.13.9 A workflow for prokaryotic genome annotation

A high-contiguity bacterial assembly contains one main chromosome and two circular contigs that may be plasmids. Outline an annotation and validation workflow, and state the evidence needed to trust

each major kind of prediction.

Extensions, solution outline and common errors

Extensions:

1. Why is a long open reading frame not necessarily a gene?
2. What is the role of the coding and background models in the score of a gene?
3. How do short genes, horizontally acquired genes and a wrong genetic code affect the prediction?
4. How should operons and pseudogenes be inferred?
5. How would you distinguish plasmids from circular chromosomal contigs or mobile elements?

Solution outline:

- Fix the assembly version, sample information and genetic code before predicting genes. Check contamination, depth, topology and read support for each replicon.
- For a candidate sequence x, the log-likelihood ratio $\log[P(x \mid C)/P(x \mid N)]$ compares a coding model C with a non-coding model N. Start codons, ribosome-binding sites, length, strand and overlaps add further terms, and dynamic programming selects a compatible set of genes.
- Add protein-family profiles, models for structural RNAs, annotation of mobile elements, and explicit rules for partial genes, pseudogenes, selenoproteins and programmed frameshifts.
- Infer transcription units from strand, spacing, promoters and terminators, conserved gene order and transcript data, and report them as predictions with evidence rather than as certain operons.
- Assess plasmids by replication and partition genes, mobility genes, copy number, topology, read linkage and comparison with known plasmids; circularity alone is not enough.
- Validate representative genes with curated homologues, ribosome profiling or proteomics, transcript boundaries, conserved gene order and manual inspection.

Common errors:

- Reporting every open reading frame from start to stop codon as a gene.
- Assuming that all bacteria use the same ribosome-binding signal.
- Labelling a region with unusual composition as contamination without phylogenetic or read evidence.
- Treating adjacency as proof of co-transcription.
- Naming a protein from a single best hit without checking alignment coverage and domain architecture.

Connections: Section 5.6; profile HMMs in Section 1.6; horizontal gene transfer in Section 3.7; proteomic evidence in Chapter 8; functional annotation in Section 10.4.

5.13.10 Annotating a non-model eukaryotic genome

Design a workflow for the structural annotation of a repeat-rich eukaryotic genome, with stranded short-read RNA-seq, a smaller set of long-read transcripts and proteins from related species as evidence.

Extensions, solution outline and common errors

Extensions:

1. How should repeat annotation precede and inform gene prediction?
2. Explain the role and assumptions of a generalised hidden Markov model.
3. Compare the information from short and long transcript reads.
4. What evidence would you require to keep an alternative isoform?
5. How would you validate the annotation without a complete reference annotation?

Solution outline:

- Start with quality control of the assembly, removal of contamination and organelle sequence, discovery of repeats for the lineage, and a documented choice of soft or hard masking.
- A generalised HMM represents the genome as a path through intergenic, untranslated, exon and intron states, with splice-site and coding signals, length distributions for each segment and reading-frame constraints; the Viterbi algorithm finds the most probable path under the model.
- Short reads measure expression and support individual splice junctions; long reads connect distant exons and show transcript ends, but can be truncated and have platform-specific errors. Aligned proteins from related species stabilise the coding structure.
- Train on complete, high-confidence genes and keep independent genes or evidence for evaluation. Keep the evidence tracks when combining ab initio, transcript and protein models.
- Keep isoforms only when distinct splice junctions, transcript ends, protein products or comparative evidence support them; flag partial, conflicting and unsupported models and those overlapping repeats.
- Report performance at nucleotide, exon, transcript and gene level on curated subsets, together with agreement between evidence types, BUSCO completeness and contamination.

Common errors:

- Hard-masking every repeat and so removing real exons.
- Treating the Viterbi path as biological truth.
- Turning every fragment of a transcript assembly into a gene model.
- Training and evaluating on the same evidence.
- Reporting only a BUSCO score.

Connections: Section 5.6; repeats in Section 6.7; RNA-seq in Section 7.3; data leakage in 4.

5.13.11 Auditing claims of annotation completeness

A genome release reports 98.5% BUSCO completeness, and RNA-seq support for 95% of the predicted genes. Do these figures justify the claim that the annotation is complete? What would a more informative validation report contain?

Extensions, solution outline and common errors

Extensions:

1. What does a benchmark of conserved single-copy orthologues measure?

2. How can RNA-seq support an incorrect gene model?
3. At which levels should precision and recall be measured?
4. How would you test a claim that a gene is absent?
5. How should uncertainty be represented in the released annotation?

Solution outline:

- BUSCO measures the recovery and apparent copy number of a set of genes that are single-copy orthologues in the lineage (taken from OrthoDB). It says nothing about isoform structure, lineage-specific genes, repeats, regulatory elements, chromosome completeness or contamination.
- RNA-seq reads can cover part of a locus while the strand, exon boundaries, merged genes or isoform structure are wrong. Highly expressed genes dominate, and evidence used to build the models is not independent validation.
- Report precision and recall at the level of nucleotides, exact exons, exact transcripts and genes, on curated or held-out data, together with protein evidence, partial genes, overlap with repeats and manual checks.
- To test an apparent absence, search the translated genome sequence and the raw reads with sensitive profiles, examine the syntenic region (Section 6.5), check for assembly gaps, and distinguish deletion, pseudogenisation, divergence and annotation failure.
- Release evidence tracks, confidence levels, stable identifiers, assembly and annotation versions, software and database versions, and known limitations.
- Completeness has many dimensions; the reported percentages support only specific, conditional claims.

Common errors:

- Treating completeness as a single number.
- Counting any overlapping read as support for a transcript.
- Evaluating with the same data that were used for training.
- Interpreting every duplicated BUSCO gene as a real duplication.
- Removing unsupported predictions instead of representing confidence explicitly.

Connections: Section 5.6; assembly quality in Section 5.3; orthology databases in Section 3.4; benchmarking in Section 1.11.

5.13.12 Interpret a genome-wide association study

A case–control GWAS of 20,000 cases and 30,000 controls, genotyped on an array and imputed, reports eight loci with $P < 5 \times 10^{-8}$, a genomic inflation factor $\lambda_{GC} = 1.15$, and a lead SNP at the strongest locus that lies in an intron of gene X. The authors conclude that gene X causes the disease, and propose a polygenic score for clinical screening. How would you evaluate these claims?

Extensions, solution outline and common errors

Extensions:

1. Why is the significance threshold 5×10^{-8}, and does it depend on the number of imputed variants?
2. Is $\lambda_{GC} = 1.15$ evidence of confounding?
3. How would you go from the lead SNP to a causal variant and a causal gene?

4. What does the QQ plot add to the Manhattan plot?
5. In which populations would the polygenic score work?

Solution outline:

- The threshold corrects for about one million independent common variants in European-ancestry genomes; imputation adds variants but few independent tests. Loci should be replicated in an independent cohort, with effect sizes expected to shrink (winner's curse).
- Inflation can come from population stratification, cryptic relatedness or batch effects between case and control genotyping, but also from true polygenic signal in a large sample. Check that principal components or a mixed model were used, and use LD score regression to separate the two.
- The lead SNP marks a region of LD. Statistical fine-mapping gives a credible set of candidate variants; their overlap with regulatory elements in relevant cell types, and colocalisation with eQTLs, suggests the target gene, which may not be X. Experimental perturbation is needed to show causality.
- A QQ plot shows whether the whole distribution of test statistics is inflated, or only its tail.
- A score derived in one ancestry is less accurate in others because of differences in LD and allele frequencies; individual-level prediction is usually weak even within the training population, so clinical value must be shown in independent, diverse cohorts.

Common errors:

- Equating the nearest gene, or the gene containing the lead SNP, with the causal gene.
- Treating the lead SNP as the causal variant.
- Interpreting every $\lambda_{GC} > 1$ as confounding, or ignoring it.
- Confusing a strong P-value with a large effect size.
- Applying a polygenic score across ancestries without validation.

Connections: Section 5.8; eQTLs in Section 7.5; regulatory elements in Section 6.9; the GWAS Catalog in Section 2.9.

5.13.13 Find the cause of a rare disease in a trio

A child has a severe developmental disorder; the parents are healthy and unrelated. Exome sequencing of the child and both parents gives about 25,000 variants per person. Describe how you would find the causal variant, and how you would decide whether a candidate should be reported.

Extensions, solution outline and common errors

Extensions:

1. Which inheritance models are plausible, and how does each use the parents' data?
2. Which population frequency cut-off would you use?
3. Why might an apparent de novo variant be an artefact?
4. How would the analysis change if the parents were first cousins?
5. What would you do if no candidate is found?

Solution outline:

- Check sample identity and relationships, coverage and call quality. Annotate variants per transcript with VEP or SnpEff, using a stated transcript set.

- With healthy, unrelated parents, consider de novo dominant variants (present in the child, absent from both parents), recessive variants (homozygous, or compound heterozygous with one allele from each parent, which the trio phases) and X-linked variants in a boy.
- Remove variants that are too common in gnomAD for a rare, severe disease (for a de novo dominant model, essentially absent), keep protein-altering and splice variants, and rank them by predicted effect, gene constraint and phenotype match using HPO terms and tools such as Exomiser.
- Check de novo candidates for adequate depth in both parents, mapping quality, and strand and position biases; confirm by an independent method.
- Classify the best candidate with the ACMG/AMP criteria: frequency, consequence, de novo status, segregation, functional data and computational evidence; report pathogenic and likely pathogenic variants in genes consistent with the phenotype, and handle variants of uncertain significance with care.
- With consanguinity, prioritise long runs of homozygosity. If nothing is found, consider genome sequencing for non-coding, structural and repeat-expansion variants, RNA sequencing, and periodic reanalysis.

Common errors:

- Treating absence from gnomAD as proof of pathogenicity.
- Accepting de novo calls without checking parental coverage.
- Ignoring the transcript in which a variant is annotated.
- Using computational predictions as the main evidence.
- Assuming that a negative exome excludes a genetic cause.

Connections: Section 5.8; variant calling and phasing in Section 5.4; variant databases in Section 2.9; variant effect prediction in Section 10.6.

6 Genomes

> **From the exam description**
>
> Fundamental differences in how different genomes are constructed. What is the difference between eukaryotic and prokaryotic genomes?

6.1 Overview

This chapter summarises what thirty years of genome sequencing have taught us about genomes: how large they are, how they are organised, how they vary within species, and what the non-coding majority of a eukaryotic genome does. The methods for obtaining genome sequences are covered in Chapter 5, and the evolutionary processes that shape genomes, such as duplication, horizontal transfer and selection, in Chapter 3. Gene expression, the topic of the next chapter (Chapter 7), builds on the regulatory elements introduced here.

- background: nucleic acids, the central dogma, cells and model organisms (Section 6.2);
- the genome projects, what a gene is and why the human gene count fell, genome size and gene number, and the C-value paradox (Section 6.3);
- the organisation of prokaryotic and eukaryotic genomes, genome duplications, organelle genomes and viral genomes (Section 6.4);
- gene order, synteny, dot plots and genome rearrangements (Section 6.5);
- genomes in populations: pan-genomes, from one reference genome to a pangenome, population-genetic explanations of genome complexity, and what ancient genomes have revealed about human evolution (Section 6.6);
- repeats, transposable elements, segmental duplications, the mechanisms that create structural variants, and the 3D organisation of the genome (Section 6.7);
- pseudogenes, the birth of new genes (including de novo from non-coding DNA), and small proteins missed by classical annotation (Section 6.8);
- non-coding RNAs, regulatory elements and the debate about how much of the genome is functional (Section 6.9).

6.2 Background: genes, genomes and cells

Bioinformatics at DBB is part of a PhD in biochemistry, and examiners expect you to know the molecules and cells that the methods describe. This section summarises the background on nucleic acids and genes, at the level of an undergraduate course in molecular biology. The corresponding background on proteins is given in Section 9.3.

6.2.1 Nucleic acids

DNA is a polymer of four nucleotides, each consisting of a deoxyribose sugar, a phosphate and one of four bases: the purines adenine (A) and guanine (G), and the pyrimidines cytosine (C) and thymine (T). Two antiparallel strands form the **double helix**, held together by **base pairing**, A with T (two hydrogen bonds) and G with C (three), and by stacking between the bases. Because the strands are complementary, each can serve as a template for the other, which is the basis of replication and of almost every experimental method in molecular biology: hybridisation, PCR and sequencing (Section 5.2). RNA differs by having a ribose sugar and uracil (U) instead of thymine. It is usually single-stranded but folds into secondary and tertiary structures through base pairing within the same molecule (Section 1.7), which allows it to act as a catalyst as well as a carrier of information (Section 3.2).

6.2.2 The central dogma and its exceptions

Francis Crick's **central dogma** describes the flow of sequence information in cells: DNA is **replicated**, **transcribed** into RNA, and messenger RNA is **translated** into protein. In eukaryotes, the primary transcript is **processed** before export from the nucleus: a 5' cap is added, introns are removed by **splicing** (Section 6.4), and a poly(A) tail is added at the 3' end. Translation by the ribosome reads the mRNA in triplets, using the **genetic code**, in which 61 codons specify the 20 amino acids and three are stop signals. The code is nearly universal, with small variations, for example in mitochondria. Because most amino acids are encoded by several codons, substitutions can be **synonymous** or **non-synonymous**, the basis of the dN/dS test for selection (Section 3.6).

The dogma has important exceptions and extensions. **Reverse transcription** copies RNA into DNA, in retroviruses and retrotransposons (Section 6.7). Many genes produce functional RNAs that are never translated (Section 6.9). Gene expression is regulated at every step, by transcription factors binding to promoters and enhancers, by chromatin, by RNA processing and stability, by microRNAs and by the regulation of translation and protein degradation, which is why mRNA levels predict protein levels only partly (Section 7.5).

6.2.3 Cells and organisms

All cellular life belongs to three domains, Bacteria, Archaea and Eukarya (Section 4.5). **Prokaryotic** cells (bacteria and archaea) have no nucleus, and transcription and translation are coupled in the cytoplasm. **Eukaryotic** cells have a nucleus, an endomembrane system (endoplasmic reticulum, Golgi apparatus, lysosomes) and organelles: **mitochondria**, and in plants and algae **chloroplasts**, which descend from bacterial endosymbionts (Section 6.4). Proteins are sorted to these compartments by signals in their sequence (3).

Much of what is known comes from a few **model organisms**, chosen because they are easy to grow and manipulate genetically: the bacterium *Escherichia coli*, the yeasts *Saccharomyces cerevisiae* and *Schizosaccharomyces pombe*, the nematode *Caenorhabditis elegans*, the fruit fly *Drosophila melanogaster*, the plant *Arabidopsis thaliana*, the zebrafish and the mouse. Their genomes were among the first sequenced (Section 6.3), and knowledge about their genes is transferred to other species by homology (Section 10.4).

6.2.4 Experimental methods

You should also understand, in outline, the experimental methods that produce the data you analyse: PCR and DNA sequencing (Section 5.2), microarrays and RNA-seq (Chapter 7), mass spectrometry

(Chapter 8), X-ray crystallography, NMR and cryo-EM (Section 9.4), and the methods for detecting protein interactions (Section 11.2). Knowing how data are generated is essential for knowing their errors and biases.

6.3 From the first genome projects

The first complete genomes, in the 1990s, turned genomics from the study of single genes into the comparison of whole gene repertoires. This section follows the main genome projects and summarises what they showed about how genomes differ in size and gene content. The technologies and algorithms behind them are described in Chapter 5.

6.3.1 The genome projects

The first DNA genome, that of the bacteriophage φX174 (5,386 bases), was sequenced in 1977, and the human mitochondrial genome (16,569 bases) followed in 1981 (Anderson et al. 1981). Sequencing a cellular genome seemed out of reach until the 1990s.

Table 6.1: Some landmark genome sequences. Sizes marked * are the euchromatic sequence only.

Year	Genome	Size	Genes	Notes
1995	*Haemophilus influenzae*	1.8 Mb	~1,700	first free-living organism; whole-genome shotgun (Fleischmann et al. 1995)
1995	*Mycoplasma genitalium*	0.58 Mb	~470	one of the smallest genomes of a cell that can be grown in culture; the "minimal gene set" (Fraser et al. 1995)
1996	*Saccharomyces cerevisiae*	12 Mb	~6,000	first eukaryote; international consortium (Goffeau et al. 1996)
1997	*Escherichia coli* K-12	4.6 Mb	~4,300	the model bacterium (Blattner et al. 1997)
1998	*Caenorhabditis elegans*	97 Mb	~19,000	first animal (The C. elegans Sequencing Consortium 1998)
2000	*Drosophila melanogaster*	120 Mb*	~13,600	whole-genome shotgun of a large genome (Adams et al. 2000; Myers et al. 2000)
2000	*Arabidopsis thaliana*	125 Mb	~25,500	first plant (The Arabidopsis Genome Initiative 2000)
2001	*Homo sapiens* (drafts)	2.9 Gb	~30,000–40,000 predicted	public and Celera drafts (International Human Genome Sequencing Consortium et al. 2001; Venter et al. 2001)
2002	*Mus musculus*	2.5 Gb	~30,000 predicted	first comparison of two mammals (Mouse Genome Sequencing Consortium 2002)
2004	*Homo sapiens* (finished)	2.85 Gb*	20,000–25,000	finished euchromatin (International Human Genome Sequencing Consortium 2004)

Year	Genome	Size	Genes	Notes
2022	*Homo sapiens* (T2T)	3.06 Gb	~19,000–20,000	first complete human genome (Nurk et al. 2022)

The **Human Genome Project** was launched in 1990 as an international public project, with an estimated cost of three billion dollars. It used a *hierarchical* (clone-by-clone) strategy: the genome was first cut into large bacterial artificial chromosome (BAC) clones, which were mapped to the chromosomes and then sequenced individually by shotgun. In 1998 the company Celera Genomics, led by Craig Venter, announced that it would sequence the genome faster with a *whole-genome shotgun* strategy (Weber and Myers 1997), relying on the assembly algorithms developed by Gene Myers (Section 5.3). The resulting race ended with the joint announcement of two draft sequences in 2000 and their publication in 2001 (International Human Genome Sequencing Consortium et al. 2001; Venter et al. 2001). One lasting legacy of the public project is the *Bermuda principles* of 1996, which required sequence data to be released within 24 hours, and which set the norm of open data in genomics (Chapter 2).

What counts as a *finished* genome has changed. The "finished" human sequence of 2004 covered about 99% of the euchromatin, with about one error per 100,000 bases, but it still had 341 gaps and left out the heterochromatin (International Human Genome Sequencing Consortium 2004). The reference assembly GRCh38 (2013) remained incomplete in the same places. About 8% of the genome, including the centromeres, the short arms of the acrocentric chromosomes with the ribosomal RNA gene arrays, and large segmental duplications, consists of long, nearly identical repeats (Section 6.7) that could not be assembled from BAC clones or short reads. Accurate long reads combined with ultra-long nanopore reads made it possible to assemble them, and in 2022 the Telomere-to-Telomere (T2T) consortium published the first gapless sequence of all human autosomes and the X chromosome, CHM13 (Nurk et al. 2022; Altemose et al. 2022); a complete Y chromosome followed in 2023 (Rhie et al. 2023) (Section 5.3). A finished genome now means a gapless sequence of every chromosome from telomere to telomere, ideally with both haplotypes resolved.

The early genomes produced several surprises. About a third of the genes in every new bacterial genome had no known function. Even *E. coli* and yeast, the best-studied organisms, had hundreds of uncharacterised genes. The human genome contained far fewer genes than expected: estimates before the project ranged up to 100,000, but the finished sequence suggested 20,000–25,000 (International Human Genome Sequencing Consortium 2004), and the current count of protein-coding genes is around 19,000–20,000 (as of 2026, depending on the annotation). This is about the same as in the nematode *C. elegans*. The high early estimates rested on the expectation that a more complex organism needs more genes; the genome projects showed that this expectation was wrong (see the G-value paradox below). The mouse genome showed that about 5% of the human genome is conserved between the two species, much more than the 1–2% that codes for protein (Mouse Genome Sequencing Consortium 2002), which gave the first evolutionary estimate of how much of the genome is functional (Section 6.9).

Gene counts come from a genome **annotation**, which is a separate product from the genome **assembly**, with its own versions and its own errors. The assembly is the sequence itself, released in versions such as GRCh37, GRCh38 (with minor patch releases) and T2T-CHM13; genomic coordinates refer to one assembly version and differ between versions. The annotation is the set of gene models placed on an assembly by pipelines that combine *ab initio* prediction, transcript and protein evidence and manual curation (Section 5.6). For the human genome, GENCODE (identical to the Ensembl annotation) and RefSeq annotate the same assembly independently and are updated several times a year. They differ in the number of genes, in the transcripts of each gene and in exon boundaries, which is why the MANE project selects one matching transcript per protein-coding gene that both agree on. Annotations of less-studied genomes are mostly automatic and contain more errors, such as split, fused, missing or spurious gene models, which propagate to the protein databases (Chapter 2). A result should therefore always state both the assembly and the annotation version.

6.3.2 What is a gene?

Counting genes requires a definition of a gene, and the definition has changed several times (Gerstein et al. 2007). For Mendel and the early geneticists, a gene was an abstract unit of inheritance, detected through a phenotype and placed on a linkage map. The *one gene, one enzyme* idea of the 1940s and the discovery of DNA turned it into a molecular object: a stretch of DNA that encodes one polypeptide. This molecular gene was soon complicated by split genes and alternative splicing (Section 6.4), by genes that overlap or lie inside the introns of other genes, by distant regulatory elements (Section 6.9), and by genes whose final product is an RNA rather than a protein.

The ENCODE pilot project of 2007 added another complication. Much of the genome is transcribed, transcripts often extend beyond the annotated genes or join exons of neighbouring genes, and many transcribed regions overlap no known gene. In response, Gerstein and colleagues proposed that a gene is "a union of genomic sequences encoding a coherent set of potentially overlapping functional products" (Gerstein et al. 2007). The unit is the *product* (a protein or a functional RNA), and the gene is the set of sequences that contribute to related products. In practice, annotations such as GENCODE are built from transcript models, and genes are clusters of transcripts that share exons on the same strand.

The count of human protein-coding genes has fallen as the evidence has improved (Pertea and Salzberg 2010). Before the genome was sequenced, estimates were often around 100,000, and some estimates based on expressed sequence tags were even higher. The drafts of 2001 predicted 30,000–40,000, the finished genome 20,000–25,000, and the count has drifted down to about 19,000–20,000 since. The reduction came from removing models that do not encode proteins: ORFs that are not conserved and have no protein-like features (Clamp et al. 2007), fragments of pseudogenes, and models without support from protein evidence or evolutionary constraint (Ezkurdia, Juan, et al. 2014). At the same time, the counts of non-coding genes and of transcripts per gene have grown.

The reference catalogues still differ (Amaral et al. 2023). GENCODE/Ensembl and RefSeq agree on most protein-coding genes but not on all, and CHESS, built from thousands of RNA-seq experiments (Pertea et al. 2018), gives other numbers again. The disagreements are concentrated in a few hundred to a few thousand loci: genes of uncertain coding status, which may be non-coding RNAs or pseudogenes (Abascal et al. 2018), readthrough transcripts that join two genes, and complex families in segmental duplications. Differences in how isoforms and UTRs are defined are much larger. MANE Select defines one matching transcript per protein-coding gene in Ensembl and RefSeq (Morales et al. 2022), which makes clinical reporting consistent but does not settle which loci are genes. Small protein-coding genes are a separate blind spot, discussed in Section 6.8. Whether a locus is "a gene" is therefore partly a decision of the annotation, and a gene count is only meaningful with the catalogue and release it came from.

6.3.3 Genome size and gene number

The **C-value** is the amount of DNA in a haploid (gametic) nucleus. It varies more than 100,000-fold among cellular organisms:

- **Bacteria and archaea** have genomes from about 0.1 to 16 Mb. The smallest belong to endosymbionts of insects, such as *Carsonella*, with 160 kb and fewer than 200 genes (Nakabachi et al. 2006). They have lost most genes needed for independent life. The smallest free-living organisms, such as the abundant marine bacterium *Pelagibacter*, have streamlined genomes of about 1.3 Mb (Giovannoni et al. 2005). The largest bacterial genomes, in soil bacteria such as myxobacteria and streptomycetes, are 10–16 Mb.

- **Eukaryotes** range from about 2 Mb in some microsporidian parasites to more than 100 Gb. The current record is the fork fern *Tmesipteris oblanceolata*, with about 160 Gb, some 50 times the human genome (Fernández et al. 2024). The lungfish, salamanders and lilies also have very large genomes.

In prokaryotes, genomes are densely packed with genes, about one gene per kilobase, and **gene number is proportional to genome size**. Larger bacterial genomes encode more regulatory and metabolic genes, reflecting more versatile lifestyles. In eukaryotes the relationship breaks down. Yeast has about one gene every 2 kb, while in the human genome protein-coding exons make up only about 1.5% of the sequence.

Genome size and gene number should therefore be kept apart. Among eukaryotes, differences in genome size are mostly differences in repetitive DNA, above all transposable elements (Section 6.7), and in the length of introns and intergenic regions, not in the number of protein-coding genes. **Polyploidy** is a further, independent factor. A recent polyploid, such as bread wheat (about 16 Gb, with three subgenomes), carries several copies of each chromosome set, which multiplies the DNA content and the number of gene copies without adding new kinds of genes (Section 6.4). For polyploids, the C-value, which includes all chromosome sets of a gamete, is therefore distinguished from the *monoploid* genome size, the DNA content of a single chromosome set.

6.3.4 The C-value paradox

Genome size is not correlated with organismal complexity: an onion has about five times more DNA than a human, and closely related species of amphibians or plants can differ several-fold in genome size. This was called the **C-value paradox** by C. A. Thomas in 1971 (Thomas 1971). The paradox was resolved, in part, by the discovery that most eukaryotic DNA does not code for proteins: differences in genome size are mostly differences in non-coding DNA, especially transposable elements (Section 6.7). What remains unexplained is *why* different species carry such different amounts of non-coding DNA, which Gregory called the **C-value enigma** (Gregory 2001). Genome size correlates with cell size, nucleus size and the rate of cell division, and it changes over time through a balance between gains, mainly by transposable elements and duplications, and losses by deletion (Kapusta et al. 2017). Population-genetic arguments for why non-coding DNA accumulates in some lineages are discussed in Section 6.6.

A similar observation applies to genes: the number of protein-coding genes does not track complexity either (sometimes called the *G-value paradox*). Humans have about as many genes as nematodes and fewer than many plants. Organismal complexity is itself hard to define, and the number of protein-coding genes is not a measure of it. The differences between, for example, humans and nematodes are thought to lie more in how genes are used: more elaborate regulation, alternative splicing (Section 6.4), combinations of protein domains (Section 3.5), and non-coding RNAs (Section 6.9).

6.4 Differences across the tree of life

The exam asks for the fundamental differences between prokaryotic and eukaryotic genomes. This section describes the organisation of each, the traces of whole-genome duplications, the genomes of

mitochondria and chloroplasts, which are remnants of bacteria living inside eukaryotic cells, and the genomes of viruses.

6.4.1 Prokaryotic genome organisation

Most bacteria and archaea have a single **circular chromosome**, often together with smaller circular **plasmids**. There are exceptions: *Vibrio cholerae* has two chromosomes, and *Borrelia* and *Streptomyces* have linear ones. The genome is not enclosed in a nucleus but folded into a compact *nucleoid*. Prokaryotic genomes are organised by replication, transcription and selection for compactness (Rocha 2008):

- **One origin of replication.** Replication starts at a single origin (*oriC*) and proceeds in both directions to the terminus, dividing the chromosome into two halves, *replichores*. Many archaea, in contrast, have several origins.
- **GC skew.** Because the leading and lagging strands are replicated differently, they accumulate different mutations: the leading strand becomes enriched in G over C. The GC skew, $(G-C)/(G+C)$ in a sliding window, therefore changes sign at the origin and the terminus, which is used to locate them in new genome sequences (Lobry 1996).
- **Gene orientation and position.** Genes, especially essential and highly expressed ones, tend to lie on the leading strand, so that the replication fork and RNA polymerase move in the same direction and do not collide head-on. Highly expressed genes, such as those for ribosomal proteins, cluster near the origin, where they are present in more copies in rapidly dividing cells.
- **Operons.** Functionally related genes are often transcribed together as one mRNA from a single promoter. The concept was introduced by François Jacob and Jacques Monod in 1961 with the *lac* operon (Jacob and Monod 1961). About half of bacterial genes are in operons. Operons are rearranged over evolution, but genes that remain neighbours in many genomes are usually functionally linked, which is used to predict function (Chapter 11).
- **Compactness.** About 85–90% of the genome codes for proteins, genes lack introns, intergenic regions are short (around 100 bp), and there are few pseudogenes. Prokaryotic genomes have a *deletional bias*: non-functional DNA is removed quickly.
- **A mobile gene pool.** Plasmids, prophages, transposons and *genomic islands* acquired by horizontal gene transfer make up a variable part of the genome (Section 6.6 and Section 3.7).

Archaea look like bacteria in this respect, with circular chromosomes, operons and compact genomes, but their machinery for replication, transcription and translation resembles that of eukaryotes, and some of them package DNA with histones.

6.4.2 Eukaryotic genome organisation

Eukaryotic genomes are organised very differently:

- **Linear chromosomes in a nucleus.** The genome is divided into several linear chromosomes (23 pairs in humans), packed with histones into chromatin (Section 6.7). Each chromosome is replicated from many origins.
- **Telomeres.** Linear chromosomes cannot be replicated to their very ends (the *end-replication problem*). They end in **telomeres**, tandem repeats of a short motif (TTAGGG in vertebrates) that are added by the enzyme **telomerase**, an RNA-containing reverse transcriptase discovered by Carol Greider and Elizabeth Blackburn (Greider and Blackburn 1985).
- **Centromeres** attach chromosomes to the spindle during cell division. They range from a 125 bp sequence in budding yeast to megabase arrays of satellite repeats in humans (Section 6.7).

- **Introns and splicing.** In 1977 two groups found that adenovirus mRNAs are assembled from separate segments of the genome (Berget et al. 1977; Chow et al. 1977). Most eukaryotic genes are split into **exons** and **introns**, which are removed from the pre-mRNA by the spliceosome. Intron density varies widely: budding yeast has only about 280 introns in total, while a typical human gene has about ten exons spread over tens of kilobases, and some genes, such as dystrophin, span more than 2 Mb. Whether introns were present in the earliest genes (*introns early*) or were inserted later (*introns late*) was long debated. Spliceosomal introns probably derive from self-splicing group II introns that entered with the mitochondrial endosymbiont.
- **Alternative splicing.** Exons can be combined in different ways, so one gene can produce several transcripts. RNA-seq showed that more than 90% of human multi-exon genes are alternatively spliced (Pan et al. 2008; Wang et al. 2008), although how many of these isoforms are functional is debated (Section 3.5).
- **Large intergenic regions and distant regulation.** Genes are separated by long stretches of non-coding DNA, much of it derived from transposable elements. Genes are regulated by promoters and by enhancers that can be far from the gene they control (Section 6.9), and transcription is influenced by chromatin and its 3D organisation (Section 6.7).

Table 6.2: Main differences between prokaryotic and eukaryotic genomes.

Feature	Prokaryotes	Eukaryotes (e.g. human)
Chromosomes	usually one, circular, plus plasmids	several, linear, in a nucleus
Replication origins	one (bacteria); one to a few (archaea)	many per chromosome
Ends	none	telomeres and telomerase
Genome size	0.1–16 Mb	2 Mb – 160 Gb
Coding fraction	85–90%	1–2% in humans (70% in yeast)
Introns	very rare	common; spliceosome
Gene organisation	operons, polycistronic mRNA	one gene per mRNA, alternative splicing
Repeats and transposons	few	often the majority of the genome
Gene content	highly variable within species (pan-genome)	relatively stable within species
Organelle genomes	none	mitochondria, plastids

6.4.3 Genome duplications

Whole-genome duplications (WGDs) have left clear traces in many eukaryotic genomes. Their mechanisms, the fates of duplicated genes and the evidence for the main events are described in Section 3.4. At the level of genome organisation, a WGD is recognised as large blocks of duplicated genes in the same order (**paralogous synteny**), and, when two related species are compared, as a pattern in which each region of one genome corresponds to two regions of the other. The budding yeast genome has such a 2:1 relationship with genomes that did not undergo its WGD about 100 million years ago (Wolfe and Shields 1997; Kellis et al. 2004). Two rounds of WGD early in vertebrate evolution (*2R*) explain why many human gene families have four members where invertebrates have one (Dehal and Boore 2005). Teleost fish had a third round, and flowering plants are particularly rich in polyploidy: the small genome of *Arabidopsis* contains the remnants of several ancient duplications (The Arabidopsis Genome Initiative 2000). Most duplicated genes are lost within a few million years, and genomes return towards their previous size, so ancient WGDs can be detected only through the retained duplicates and the conserved gene order.

Recent polyploids and hybrids are among the hardest genomes to analyse. In an *allopolyploid*, formed by hybridisation between species, as in bread wheat (subgenomes A, B and D) and many other crops, the subgenomes are similar but not identical. In an *autopolyploid*, such as cultivated potato (four copies of one genome), the copies are nearly identical. Assemblers designed for haploid or diploid genomes tend to collapse similar subgenomes or switch between them, and short reads map ambiguously between them, so separating them requires long reads and phasing (Section 5.3). Orthology is harder too. A gene of a diploid relative corresponds to two or more *homoeologues*, the copies inherited from the different parental genomes, so one-to-one orthology breaks down, and gene trees of an allopolyploid reflect hybridisation, a reticulate event, rather than a simple bifurcating species tree (Section 3.4; Section 4.4). Hybrid fungal genomes, such as that of the lager yeast *Saccharomyces pastorianus*, raise the same problems. Most genomics methods and benchmarks were developed on diploid model organisms, and their performance on polyploid and hybrid genomes should not be taken for granted.

6.4.4 Organelle genomes and endosymbiosis

Mitochondria and chloroplasts contain their own small genomes. The **endosymbiotic theory**, proposed for chloroplasts by Konstantin Mereschkowski in 1905 and developed by Lynn Margulis (then Sagan) in 1967 (Sagan 1967), explains them as the remnants of bacteria that were engulfed by an ancestral cell. Gene sequences confirmed the theory: mitochondria descend from alphaproteobacteria and plastids from cyanobacteria (Roger et al. 2017). The acquisition of the mitochondrion was probably part of the origin of eukaryotes themselves (Section 4.5).

- The **human mitochondrial genome** is a circle of 16,569 bp encoding 37 genes: 13 proteins of the respiratory chain, 22 tRNAs and 2 rRNAs (Anderson et al. 1981). It is very compact, has no introns, uses a slightly different genetic code (UGA codes for tryptophan) and is inherited from the mother. Its rapid evolution and lack of recombination made it the first molecular marker for human population history (Section 6.6).
- Mitochondrial genomes vary greatly. The most bacteria-like, in the protist *Reclinomonas americana*, encodes 97 genes (Lang et al. 1997), while plant mitochondrial genomes are large (hundreds of kilobases to megabases) but mostly non-coding.
- **Plastid genomes** are typically 120–160 kb with 100–130 genes.

Organelle genomes encode only a small fraction of the proteins the organelles need. Human mitochondria contain more than 1,000 proteins, almost all encoded in the nucleus, made in the cytoplasm and imported. Most of the genes of the original endosymbionts were lost or moved to the nucleus by **endosymbiotic gene transfer** (Timmis et al. 2004), and the transfer continues: fragments of mitochondrial DNA are still inserted in nuclear genomes (*NUMTs*). Why some genes remain in the organelle at all is still discussed; one explanation is that it allows each organelle to regulate the expression of the genes for its own respiratory or photosynthetic complexes. Endosymbiont genomes in general shrink. The bacterial endosymbionts of insects, which live inside host cells and are transmitted between generations, have some of the smallest genomes known (Nakabachi et al. 2006), a process driven by small population sizes and relaxed selection (Section 6.6).

6.4.5 Viral genomes

Viruses are not cells, but their genomes are the most varied of all. A viral genome can be DNA or RNA, single- or double-stranded, linear or circular, and in one piece or *segmented*, like the eight RNA segments of influenza virus. David Baltimore classified viruses by how they make their mRNA from the genome (Baltimore 1971); the resulting Baltimore classes (double-stranded DNA, single-stranded DNA, double-stranded RNA, positive- and negative-sense single-stranded RNA, and reverse-transcribing viruses with RNA genomes, to which reverse-transcribing DNA viruses were added later) are still used,

although they are not a taxonomy. Viruses share no universal genes, so the formal taxonomy of the International Committee on Taxonomy of Viruses groups them into realms by a few *hallmark* genes, such as those for capsid proteins and replication enzymes (Koonin et al. 2020).

Genome sizes range from under 2 kb in circoviruses to 2.5 Mb in the pandoraviruses of amoebae, larger than some bacterial and even eukaryotic genomes (Philippe et al. 2013). Small viral genomes are extremely compact. **Overlapping genes**, read in different frames of the same sequence, were discovered in the first DNA genome to be sequenced, that of bacteriophage φX174 (Sanger, Air, et al. 1977). Many RNA viruses translate their genome into one long *polyprotein* that is cleaved by viral proteases, and use programmed ribosomal frameshifting or subgenomic mRNAs to express further genes, as coronaviruses do. RNA viruses have mutation rates of about 10^{-6}–10^{-4} per nucleotide per cell infection, far higher than DNA viruses (Sanjuán et al. 2010). This is thought to limit their genome size: coronaviruses, among the largest RNA viruses at about 30 kb, encode a proofreading exonuclease.

These features matter for analysis. Gene prediction based on open reading frames misses overlapping genes, frameshifts and spliced transcripts; segmented genomes can exchange segments (*reassortment*) and RNA viruses recombine, so that different parts of a genome have different trees (Section 4.4); and the high mutation rate means that a sample from one host is a population of variants rather than a single sequence.

6.5 Gene order, synteny and genome rearrangements

Genomes change not only by substitutions, duplications and losses but also by rearrangements that move, invert and join large segments. The order of genes along the chromosomes is therefore a character in its own right. It decays more slowly than sequence in some lineages and much faster in others, and it provides evidence of homology, orthology, genome duplication and function that is independent of sequence similarity.

6.5.1 Synteny and collinearity

The word **synteny** originally meant that two loci lie on the same chromosome. In comparative genomics it is mostly used for conserved correspondence between regions of two genomes, and **collinearity** for the stricter case in which the genes are also in the same order and orientation. Because usage varies, it should be stated whether a claim concerns the same chromosome, a block of conserved gene content, or a collinear block.

From a few dozen genetic markers, Nadeau and Taylor estimated in 1984 that the human and mouse genomes are made up of about 180 conserved segments, broken by rearrangements since the two lineages diverged (Nadeau and Taylor 1984). The mouse genome sequence confirmed the picture: more than 90% of both genomes can be divided into a few hundred corresponding blocks of conserved synteny (Mouse Genome Sequencing Consortium 2002). Rates differ greatly between lineages. Gene order in mammals

and birds is relatively stable, whereas plant mitochondrial genomes rearrange so often that closely related species differ in gene order even though their sequences evolve slowly (Palmer and Herbon 1988). In bacteria, gene order beyond the operon is lost quickly, so that distantly related genomes retain little conserved order except for groups of functionally linked genes (Mushegian and Koonin 1996). Genes that remain neighbours across many bacterial genomes are therefore likely to work together, which is used to predict functional links (Section 10.4).

Conserved synteny is used in several ways:

- **Orthology.** Among several paralogues, the orthologue usually lies in the corresponding region of the other genome. Orthology databases use conserved gene order as independent support (Section 3.4).
- **Missing genes.** If a gene is absent from an otherwise conserved block, a search of the genome sequence in that region often finds a gene that the annotation missed, a pseudogene, or a gap in the assembly.
- **Genome duplications.** A whole-genome duplication leaves pairs of paralogous blocks, and each region of an unduplicated relative corresponds to two regions of the duplicated genome (Section 6.4).
- **Ancestral genomes.** Comparing many genomes makes it possible to reconstruct ancestral chromosomes. The amphioxus genome showed that chordate chromosomes descend from about 17 ancestral linkage groups (Putnam et al. 2008), and conserved synteny has been traced across animals as distant as sponges, cnidarians and bilaterians (Simakov et al. 2022). Patterns of synteny between amphioxus, lampreys and jawed vertebrates have also been used to time the two rounds of vertebrate genome duplication relative to the divergence of jawless and jawed vertebrates (Simakov et al. 2020).

6.5.2 Dot plots

The simplest way to compare the order of two sequences is the **dot plot**, introduced by Gibbs and McIntyre in 1970 (Gibbs and Mcintyre 1970). One sequence is placed along the horizontal axis and the other along the vertical axis, and a dot is drawn wherever the two are similar. With single residues the plot is dominated by random matches, so a dot is usually drawn only if a window of w residues contains at least t matches, or if its alignment score exceeds a threshold. A larger window or a stricter threshold removes noise but hides short or divergent similarities. Dotter displays the scores as a greyscale and lets the user change the threshold interactively (Sonnhammer and Durbin 1995). For whole genomes, the dots are matches found by a whole-genome aligner such as MUMmer (Kurtz et al. 2004), or pairs of orthologous genes.

Rearrangements have characteristic signatures (Figure 6.1):

- a **collinear** region gives a diagonal line with positive slope;
- an **inversion** gives a segment with the opposite slope, between two breakpoints, because the matching sequence is on the reverse strand. Both strands must therefore be compared for DNA;
- an **insertion or deletion** shifts the diagonal horizontally or vertically, leaving a gap;
- a **transposition** moves a segment of the diagonal to another position;
- a **duplication** gives two or more matches for one interval, and repeats give parallel lines or grids. Comparing a sequence with itself shows internal repeats as lines parallel to the main diagonal, and inverted repeats as lines perpendicular to it;
- with several chromosomes, a **translocation** moves a block to another chromosome, and **fusions** and **fissions** join or split blocks.

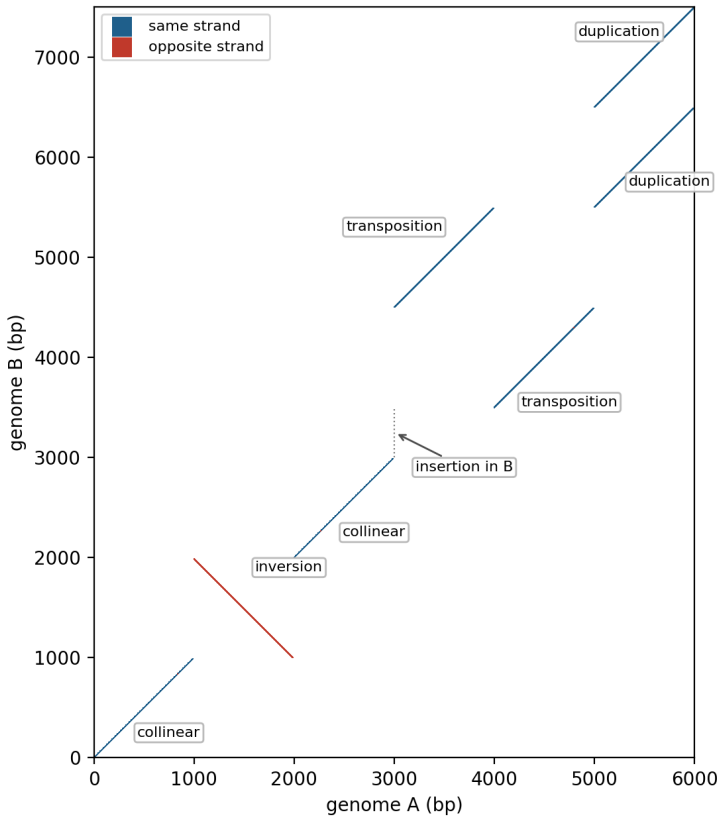

Figure 6.1: A dot plot of two synthetic genomes. Genome B was made from genome A (six blocks of 1 kb) by inverting the second block, inserting 500 bp of new sequence, swapping the order of the fourth and fifth blocks, and duplicating the last block. Dots mark identical 12-mers on the same strand (blue) or the opposite strand (red).

A dot plot proposes events but does not prove them. It shows similarity, not ancestry, so a clean diagonal can join paralogous repeats. It does not show which genome changed, which requires an outgroup. And assembly errors, such as misjoined contigs or a contig in the wrong orientation, produce exactly the same patterns as real rearrangements. A breakpoint should therefore be confirmed with reads or long molecules spanning it (Section 5.3) and, ideally, in an independent assembly.

6.5.3 Rearrangement distances

For computation, a genome is represented as an ordered list of genes or conserved blocks, each with a sign for its orientation. An inversion reverses the order of a segment and flips the signs. Inverting genes 2 to 4 of

$$(+1, +2, +3, +4, +5)$$

gives

$$(+1, -4, -3, -2, +5).$$

A **breakpoint** is an adjacency present in one genome but not in the other; this inversion created two, between $+1$ and -4 and between -2 and $+5$. The **breakpoint distance** counts them. The **reversal distance** is the smallest number of inversions that transforms one genome into the other. For signed permutations it can be computed in polynomial time, as Hannenhalli and Pevzner showed, using the example of the mitochondrial genomes of cabbage and turnip, which differ mainly by a few inversions (Hannenhalli and Pevzner 1999). The *double-cut-and-join* (DCJ) model treats inversions, translocations, fusions and fissions as special cases of one operation, which cuts two adjacencies and rejoins the ends in a new way, and gives particularly simple distances (Yancopoulos et al. 2005).

These distances are parsimony estimates, with the usual limitations: the true number of events can be larger than the minimum, repeated events at the same place overwrite each other, and duplications and gene losses violate the assumption that each gene occurs once in each genome. Whether breakpoints are scattered at random, as in the *random breakage model* of Nadeau and Taylor, was questioned when Pevzner and Tesler found that many human–mouse breakpoints have been reused, suggesting fragile regions that break repeatedly (Pevzner and Tesler 2003). Comparative maps of many mammals support breakpoint reuse and show that rates of rearrangement vary between lineages and over time (Murphy et al. 2005).

6.5.4 Detecting synteny at genome scale

Synteny is detected by finding **anchors**, usually pairs of homologous or orthologous genes, or local matches from a whole-genome alignment, and chaining them into blocks. The rules decide the result: how many anchors a block needs, how large a gap is allowed between them, whether order and orientation must be conserved, and how tandem duplicates are handled. MCScanX (Wang et al. 2012) is widely used for plant and animal genomes, and Mauve aligns bacterial genomes into collinear blocks while allowing rearrangements (Darling et al. 2004). Because a few genes in the same order can occur by chance, the significance of a block can be tested by comparison with randomised gene orders. Blocks can only be as long as the assembly allows, so fragmented assemblies give apparent breaks in synteny, and coordinates from different assembly versions should not be combined.

6.6 Genomes in populations

A single genome sequence is a sample from a population. Sequencing many individuals of the same species shows how much genomes vary, why they have the architecture they have, and, for our own species, how we are related to extinct humans.

6.6.1 Pan-genomes

When several strains of the same bacterial species were sequenced, they turned out to differ dramatically in gene content. Tettelin and colleagues, comparing eight genomes of *Streptococcus agalactiae*, introduced the **pan-genome**: the set of all genes found in a species, divided into a **core genome** present in all strains and an **accessory** (dispensable) genome present in only some, including strain-specific genes (Tettelin et al. 2005; Medini et al. 2005). In *E. coli*, each genome has about 4,500–5,000 genes, but only about 2,000 are shared by all strains, and 20 genomes together contain about 18,000 gene families (Touchon et al. 2009). Every new genome adds new genes. Such a pan-genome is called **open**, as opposed to a **closed** pan-genome, which stops growing after a few genomes have been sequenced. Open pan-genomes are typical of species with large populations that live in varied environments and exchange genes frequently, while specialised intracellular bacteria have small, closed pan-genomes.

The accessory genome is acquired by **horizontal gene transfer** and lost by deletion (Section 3.7). It contains many genes for niche-specific functions, such as antibiotic resistance, virulence and the use of particular nutrients, but also a large number of genes of unknown function, mobile elements and phages. Whether pan-genomes are mainly *adaptive*, with accessory genes maintained because they are useful in some environments, or mainly *neutral*, a by-product of transfer and drift in large populations, is debated (McInerney et al. 2017). Core genes are used to build species phylogenies, while accessory genes are used to type strains and to find genes associated with traits such as virulence.

6.6.2 From one reference genome to a pangenome

The concept has spread to eukaryotes, where it has changed what a reference genome is. Plant species such as maize show extensive presence–absence variation of genes between individuals, so no single individual contains all the genes of the species. For humans, the reference assembly GRCh38 is a single linear sequence, a mosaic of DNA from a few donors, about 70% of it from one individual, with alternative sequences for only a few highly variable regions such as the MHC. T2T-CHM13 is complete but represents one haploid genome (Section 6.3). Neither represents human diversity. Every person differs from the reference at millions of sites and carries more than 20,000 structural variants, some alleles common in populations under-represented among the donors are missing, and sequence absent from the reference cannot be analysed at all. Mapping reads to a single linear reference therefore causes *reference bias* (Section 5.4).

The Human Pangenome Reference Consortium instead represents the species as a collection of phased, near-complete assemblies of individuals from diverse populations, 47 in its first release, combined into a *pangenome graph* in which shared sequence is stored once and variants form alternative paths. Compared with GRCh38, mapping to the graph reduced errors in small-variant calls by about a third and

roughly doubled the number of structural variants detected per haplotype (Liao et al. 2023). GRCh38 remains important: it is the coordinate system of most annotations, variant databases and clinical pipelines, and graph-based coordinates are still being standardised. The conceptual change is that a linear reference is a convenient coordinate system, not a description of the species.

The word pangenome thus has two meanings (Figure 6.2). The *gene-content* pangenome of bacteria is a table of gene families against genomes; the *sequence* pangenome of humans and plants is a graph of alternative sequences. Both describe a particular sample. Whether a gene is "core" depends on the genomes included, the clustering of genes into families and the presence threshold (often 95% or 99% of genomes rather than all), and incomplete assemblies or missed gene calls make core genes look accessory. Whether a pan-genome is open or closed is likewise an estimate from the sample, not a fixed property of the species.

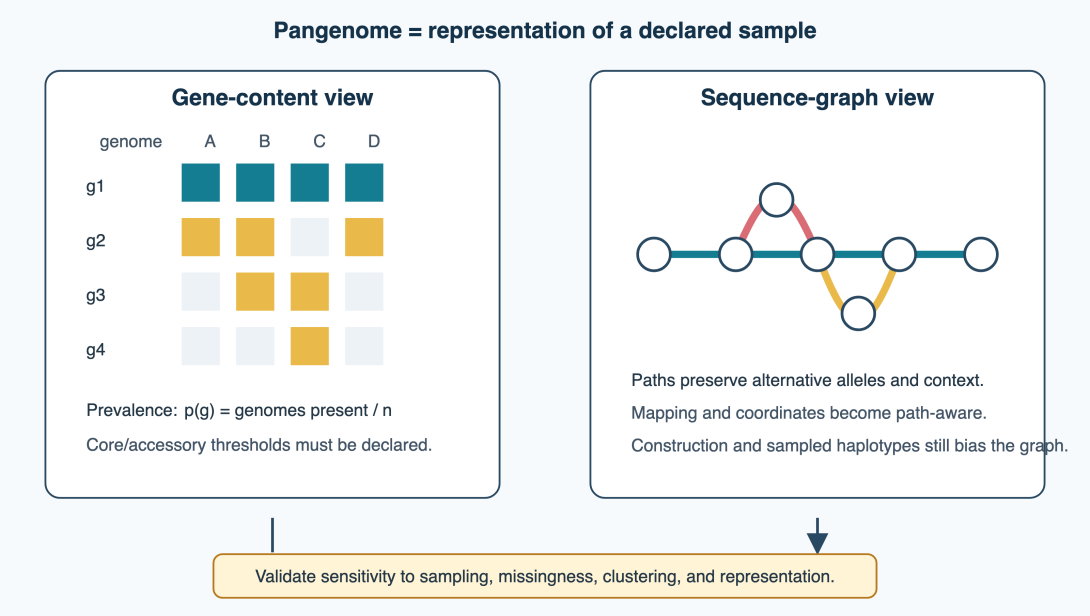

Figure 6.2: Two views of a pangenome. The gene-content view records which gene families are present in which genomes, and divides them into core and accessory families by a declared prevalence threshold. The sequence-graph view stores shared sequence once and represents variants as alternative paths, so that the haplotypes and their context are kept. Both depend on which genomes were sampled and how the data were processed. Figure: Matteo Tadiello, *Modern Bioinformatics: From Foundations to Frontiers* (CC BY 4.0).

6.6.3 Population-genetic explanations of genome complexity

Why do prokaryotic genomes remain compact, while multicellular eukaryotes accumulate introns, transposable elements and non-coding DNA? Michael Lynch and John Conery proposed that the answer lies in population genetics rather than in adaptation (Lynch and Conery 2003). The argument builds on the nearly neutral theory (Section 3.3):

1. Most of the "extra" DNA of eukaryotes is slightly harmful. An intron, for example, adds splice sites that can mutate and cause mis-splicing, and a transposable element can disrupt genes when it moves. Lynch called this the **mutational hazard**: each additional element is a target for harmful mutations, so its selective disadvantage s is roughly proportional to the mutation rate u per site times the number of sites that must be maintained.
2. Selection can remove such elements only if s is larger than about $1/N_e$, where N_e is the effective population size.

3. Prokaryotes have very large effective population sizes (often above 10^8), so even slightly harmful DNA is removed and the genome remains streamlined. Large multicellular eukaryotes have much smaller ones (around 10^4–10^5), so drift lets introns, mobile elements and duplicate genes accumulate passively.

In this view, genome complexity is not an adaptation but a consequence of weak selection, which may later have been exploited. For example, introns made alternative splicing possible, and duplicated genes provided material for new functions. Lynch supported the theory with correlations between genome features and estimates of $N_e u$ across species, and later extended it to explain the evolution of mutation rates (the drift-barrier hypothesis; Section 3.3) (Lynch et al. 2016).

The theory is influential but debated. The correlations are confounded by phylogeny and by other variables, such as cell size and metabolic rate, and estimates of N_e are uncertain. In prokaryotes, the size of the genome seems to be set by a balance between a deletional bias and selection for acquired genes that are useful, rather than by drift alone (Sela et al. 2016). Two cases fit the theory well: endosymbiotic bacteria, whose tiny populations and bottlenecks at each host generation lead to the accumulation of harmful mutations and to genome decay (Nakabachi et al. 2006), and the streamlined genomes of the most abundant free-living bacteria, such as *Pelagibacter*, which live in enormous populations (Giovannoni et al. 2005).

6.6.4 Neanderthals and human evolution

The evolution of humans and the other great apes, as seen in phylogenetic trees, is described in Section 4.5. Genomics has added a detailed picture of the last few hundred thousand years.

Out of Africa. In 1987 a tree of mitochondrial DNA from people around the world traced all human mitochondria to a common ancestor in Africa about 200,000 years ago, the so-called "mitochondrial Eve" (Cann et al. 1987). Together with fossils, this supported the *out-of-Africa* model, in which modern humans arose in Africa and replaced other human populations elsewhere. Fossils from Jebel Irhoud in Morocco push the origin of *Homo sapiens* back to about 300,000 years ago (Hublin et al. 2017). Genome-wide data showed that genetic diversity is highest in Africa and decreases with distance from Africa, as expected from a series of founder events as humans spread across the world from about 60,000 years ago. Humans are genetically unusually homogeneous: two people differ at about one site in a thousand, and most of the variation is found within, rather than between, populations (The 1000 Genomes Project Consortium 2015).

Ancient DNA. DNA survives in bones for tens of thousands of years, but it is degraded into short fragments, carries characteristic damage (deamination of cytosine, which appears as C⟶T changes near the ends of the molecules), and is mixed with DNA from bacteria and modern humans. Svante Pääbo's group developed methods to deal with these problems. The first Neanderthal mitochondrial sequence, in 1997, fell outside the range of modern human variation, consistent with replacement (Krings et al. 1997). The draft Neanderthal nuclear genome in 2010 brought the surprise: Neanderthals share more variants with present-day non-Africans than with Africans, which shows that the ancestors of non-Africans **interbred with Neanderthals**, and that a few percent of the genome of present-day people outside Africa derives from Neanderthals (Green et al. 2010); current estimates are about 2%. Admixture was detected with statistics that count how often derived alleles are shared between pairs of populations in a four-taxon configuration, the D-statistic or ABBA–BABA test, a genome-scale cousin of the phylogenetic tests in Section 4.4.

The same year, DNA from a finger bone from Denisova Cave in Siberia revealed a previously unknown group of archaic humans, the **Denisovans**, known almost only from their genome (Reich et al. 2010). Present-day populations in Oceania carry several percent Denisovan ancestry. High-coverage genomes of a Denisovan (Meyer et al. 2012) and of a Neanderthal from the Altai mountains (Prüfer et al. 2013)

revealed several episodes of gene flow between archaic and modern groups, and the genome of "Denny", a girl with a Neanderthal mother and a Denisovan father, showed that the groups met and mixed directly (Slon et al. 2018). Pääbo was awarded the 2022 Nobel Prize in Physiology or Medicine for this work.

Consequences of admixture. Archaic DNA is not uniformly distributed in our genomes. It is depleted on the X chromosome and in genes expressed in the testes, which suggests that selection removed many archaic variants, possibly because they reduced fertility in hybrids (Sankararaman et al. 2014). Some archaic variants were instead favoured by selection (*adaptive introgression*): a Denisovan-like version of the gene *EPAS1* helps Tibetans live at high altitude (Huerta-Sánchez et al. 2014), and archaic variants in immune genes are common in many populations.

6.7 Repeats and the 3D genome

Most of a large eukaryotic genome consists of repeated sequences, and the genome is not a linear string but a molecule folded in three dimensions inside the nucleus. Both aspects matter for bioinformatics: repeats are the main problem in assembly and mapping (Chapter 5), and 3D folding brings regulatory elements into contact with the genes they control.

6.7.1 Transposable elements

Transposable elements (TEs) are DNA sequences that can move or copy themselves to new positions in the genome. Barbara McClintock discovered them in maize in the 1940s, from the unstable colour patterns of kernels (McClintock 1950), and received the Nobel Prize for the discovery in 1983. TEs are classified by their mechanism (Wells and Feschotte 2020):

- **Class I, retrotransposons**, move by "copy and paste": they are transcribed into RNA, reverse-transcribed into DNA and inserted at a new site, so each transposition adds a copy.
  - *LTR retrotransposons* and *endogenous retroviruses* have long terminal repeats, like retroviruses, and make up about 8% of the human genome.
  - *LINEs* (long interspersed nuclear elements) encode their own reverse transcriptase. **L1** makes up about 17% of the human genome, and about a hundred copies are still active.
  - *SINEs* (short interspersed nuclear elements) are short, non-autonomous elements that use the LINE machinery. The primate-specific **Alu** element, about 300 bp long, has more than a million copies and makes up about 10% of the human genome.
- **Class II, DNA transposons**, move by "cut and paste" using a transposase. They make up about 3% of the human genome and are no longer active in humans.

Altogether, recognisable TEs cover about half of the human genome, and more than 80% of the maize genome. Many older elements have decayed beyond recognition. Most insertions are neutral or slightly harmful: TEs can disrupt genes, and recombination between copies causes deletions and rearrangements. Genomes defend themselves with DNA methylation, repressive chromatin, small RNAs (piRNAs in the germline) and TE-silencing proteins. But TEs are also a source of novelty (Bourque et al. 2018): they provide promoters, enhancers and splice sites, and some have been *domesticated* into host genes. The RAG recombinase that drives the rearrangement of antibody genes derives from a DNA transposon, and the syncytin proteins essential for the placenta come from the envelope genes of endogenous retroviruses.

TEs are identified with libraries of consensus sequences or profile HMMs, such as Dfam (Storer et al. 2021), searched with tools such as RepeatMasker, and new families are found *de novo* from repeated sequence in a new genome. Masking repeats is the first step in gene annotation (Section 5.6).

6.7.2 Tandem repeats and segmental duplications

Tandem repeats are copies placed head to tail. **Microsatellites** (short tandem repeats, with units of 1–6 bp) mutate rapidly by replication slippage. They are used in forensics and population genetics, and their expansion causes diseases such as Huntington's disease (CAG repeats). **Satellite DNA** consists of long arrays of longer units. Human centromeres are built from megabase arrays of the 171 bp *alpha satellite*, organised in higher-order repeats. They were the largest gaps in the human reference until the complete T2T genome made it possible to map them (Nurk et al. 2022; Altemose et al. 2022).

Segmental duplications are copies of more than 1 kb with more than 90% identity, often at different chromosomal positions. They make up about 5–7% of the human genome, are enriched near centromeres and telomeres, and are particularly frequent in great apes (Bailey et al. 2002). They are a source of new genes, including several human-specific genes involved in brain development, but recombination between copies also causes recurrent deletions and duplications associated with disease. Because the copies are nearly identical, segmental duplications were the regions most often collapsed or misassembled in reference genomes (Section 5.3).

6.7.3 How structural variants arise

Structural variants (SVs), such as deletions, duplications, inversions and translocations, arise when DNA breaks or replication goes wrong and the pieces are joined incorrectly. The main mechanisms leave different signatures at the breakpoint junctions, so the junction sequence, which long reads often resolve (Section 5.4), tells how an SV was formed (Hastings, Lupski, et al. 2009; Carvalho and Lupski 2016).

- **Non-allelic homologous recombination** (NAHR) is recombination between two similar copies at different positions, such as segmental duplications or, at a smaller scale, Alu and L1 elements. Between copies in direct orientation on the same chromosome it deletes or duplicates the region between them, as reciprocal products; between inverted copies it inverts the region; between chromosomes it gives translocations. Because the duplications define the breakpoints, NAHR produces *recurrent* rearrangements with the same size and breakpoints in unrelated individuals (Lupski 1998).
- **Non-homologous end joining** (NHEJ) repairs double-strand breaks by joining the ends directly, with no or only a few bases of homology (*microhomology*), often with small deletions or insertions at the junction (Lieber 2010). The resulting SVs are *non-recurrent*: each has its own breakpoints.
- **Replication-based mechanisms.** When a replication fork stalls or collapses, the end of the new strand can invade another template nearby, using microhomology, copy some sequence, and

switch again. This *fork stalling and template switching* (FoSTeS) (Lee et al. 2007), or *microhomology-mediated break-induced replication* (MMBIR) (Hastings, Ira, et al. 2009), explains non-recurrent duplications with complex junctions, short inserted sequences copied from elsewhere, and patterns such as duplication–triplication–duplication.

- **Chromothripsis** ("chromosome shattering") is a single catastrophic event in which one or a few chromosomes, or chromosome arms, break into many pieces that are rejoined in random order and orientation, with some pieces lost (Stephens et al. 2011). Its signature is tens to hundreds of breakpoints clustered in a region whose copy number oscillates between two states. It was discovered in cancer genomes, where it occurs in a few per cent of tumours overall and more often in some types, and is thought to follow when a chromosome is trapped in a micronucleus or a chromatin bridge. It also occurs in the germline.

Retrotransposition of L1 and Alu elements and of processed mRNAs (see above and Section 6.8) adds a further class of insertions.

Genomic disorders are diseases caused by such rearrangements (Lupski 1998). Many recurrent ones are flanked by segmental duplications and caused by NAHR. In 17p12, a 1.4 Mb duplication that includes *PMP22* causes Charcot–Marie–Tooth disease type 1A, and the reciprocal deletion causes a different neuropathy (HNPP). The 22q11.2 deletion syndrome and Williams–Beuren syndrome (7q11.23) arise in the same way. The phenotype follows from **dosage sensitivity**: some genes cause disease when one copy is lost (*haploinsufficiency*) or when an extra copy is present (*triplosensitivity*), often genes whose products work in balanced complexes or networks (Section 3.4). Most genes tolerate a change in copy number, and population catalogues of SVs, such as gnomAD-SV (Collins et al. 2020), help to separate deletions and duplications that are common, and therefore probably harmless, from rare ones in constrained genes. How SVs are detected from sequencing data is described in Section 5.4.

6.7.4 Chromatin and 3D genome organisation

The DNA in a human cell is about 2 m long and must fit into a nucleus a few micrometres across. It is wrapped around histone octamers in **nucleosomes**, about 147 bp each, which are further compacted into chromatin. Loosely packed, active **euchromatin** is distinguished from dense, mostly silent **heterochromatin**, with differences in histone modifications and DNA methylation, the main carriers of *epigenetic* information. Each chromosome occupies its own *territory* in the nucleus.

The 3D organisation inside these territories was revealed by **chromosome conformation capture** methods. In 3C, chromatin is cross-linked, cut with a restriction enzyme and religated, so that pieces of DNA that were cross-linked to each other, usually because they were close in space, are joined and can be detected (Dekker et al. 2002). **Hi-C** sequences all such ligation junctions, giving a genome-wide matrix of contact frequencies (Lieberman-Aiden et al. 2009).

A contact frequency is not a measurement of physical distance. It counts how often two regions were cross-linked and ligated together in a population of millions of cells. A high frequency can mean that the regions are close in most cells or in contact in only a few, and single-cell Hi-C and microscopy show that the structure varies greatly from cell to cell. Frequencies also depend on the efficiency of cross-linking and ligation, on the density of restriction sites, on GC content and on mappability. They are dominated by genomic distance: as in any polymer, sites that are close along the chromosome are in contact far more often than distant ones. Contact maps are therefore normalised and compared with this expected decay before structures are inferred. With these caveats, Hi-C data showed several levels of organisation:

- **Compartments.** The genome is divided into an active *A* compartment and an inactive *B* compartment, which segregate in the nucleus. They are found with principal component analysis of the contact matrix (Lieberman-Aiden et al. 2009).

- **Topologically associating domains** (TADs). At the sub-megabase scale, the genome consists of domains within which contacts are frequent and across which they are rare. TADs are largely shared between cell types, and many are conserved between species (Dixon et al. 2012; Nora et al. 2012). Like other Hi-C structures, they describe the average of a cell population.
- **Loops.** High-resolution maps showed about 10,000 loops in the human genome, mostly between pairs of binding sites for the protein CTCF in convergent orientation (Rao et al. 2014). They are explained by **loop extrusion**: the cohesin complex extrudes a loop of DNA until it meets CTCF bound in the right orientation (Fudenberg et al. 2016).

TADs and loops constrain which enhancers can contact which promoters. Deletions or inversions that remove a TAD boundary can let an enhancer activate the wrong gene, which causes several developmental disorders. Analysing Hi-C data is itself a computational field: contact matrices must be normalised for the biases above, and domains and loops are called with dedicated algorithms. Hi-C is also used to scaffold genome assemblies, since contacts are much more frequent within than between chromosomes (Section 5.3).

6.8 Pseudogenes, new genes and small proteins

A gene catalogue (Section 6.3) is not fixed. Genes die and become pseudogenes, new genes are born, and some real genes are missing from the catalogues because they are too short to be found by the usual methods. All three matter in practice: pseudogenes confuse mapping and quantification, young genes have no homologues to annotate them from, and small proteins fall below the length cut-offs of gene prediction.

6.8.1 Pseudogenes

A **pseudogene** is a copy of a gene that has lost its ability to encode a functional protein, through stop codons, frameshifts, loss of a promoter or truncation. The human genome contains more than 10,000 recognisable pseudogenes, about as many as protein-coding genes, and the GENCODE annotation distinguishes three main types (Pei et al. 2012):

- **Processed pseudogenes** (retrocopies) arise when an mRNA is reverse-transcribed by the L1 machinery and inserted elsewhere (Section 6.7). They lack introns and promoters, often carry the remains of a poly(A) tail, and are the majority in mammals. Highly expressed genes, such as those for ribosomal proteins and GAPDH, have dozens of them.
- **Duplicated (unprocessed) pseudogenes** arise from a DNA-level duplication (Section 3.4) followed by loss of function of one copy. They keep the exon–intron structure and often lie near their parent.
- **Unitary pseudogenes** are former single-copy genes that were disabled in place, without a functional copy remaining. A classic example is *GULO*, needed for vitamin C synthesis, which is a pseudogene in primates (and in guinea pigs); humans must therefore obtain vitamin C from their diet.

Pseudogenes are a practical problem in bioinformatics. A processed pseudogene looks like the spliced mRNA of its parent, so RNA-seq reads from the parent can align to it without splitting, and reads from the pseudogene, if it is transcribed, can be assigned to the parent. Expression estimates for such genes depend on how multi-mapping reads are handled (Section 7.3). In DNA sequencing, a variant in a pseudogene can be mistaken for a variant in the gene, and true variants can be lost because reads map with low quality to both copies (Section 5.4). Clinical genes with close pseudogenes, such as *PMS2*, *CYP21A2* and *GBA1*, need special methods, and gene conversion between gene and pseudogene can move pathogenic variants into the functional copy. Retrocopies that are present in only some individuals appear as apparent intron deletions in DNA sequence. Annotation pipelines must also avoid calling pseudogenes as genes: a disrupted ORF can come from a sequencing error in a real gene, and a pseudogene can be mistaken for a gene if the disruption falls in a gap.

Most pseudogenes are thought to have no function and evolve neutrally, which makes them useful for estimating mutation rates. A minority are transcribed, and some of these have functions. The best-known proposal is that the transcript of *PTENP1* acts as a decoy that binds microRNAs targeting the tumour suppressor *PTEN* (Poliseno et al. 2010), although how general such "competing endogenous RNA" effects are is debated. Other pseudogenes produce small interfering RNAs, or are translated into short proteins (Cheetham et al. 2019). As for non-coding RNAs (Section 6.9), transcription alone does not show function.

6.8.2 How new genes are born

New genes arise in several ways (Long et al. 2003):

- **Duplication** of an existing gene, which is the main source of new genes in eukaryotes, followed by neo- or subfunctionalisation (Section 3.4).
- **Retroposition.** A retrocopy usually becomes a processed pseudogene, but occasionally it lands near a promoter or recruits one and becomes a functional *retrogene* (Kaessmann et al. 2009). In mammals, retrogenes copied from X-linked genes are often expressed in the testis, where they replace their parents when the X chromosome is silenced during male meiosis.
- **Gene fusion and fission** join parts of genes or split them, and rearrange protein domains (Section 3.5).
- **Horizontal gene transfer**, dominant in prokaryotes (Section 3.7).
- **Domestication** of transposable elements and viral genes, such as the RAG recombinase and the syncytins (Section 6.7).
- **De novo gene birth** from sequence that was not previously a gene.

The last mechanism was long considered improbable, but comparative genomics has found convincing cases in yeast, flies, plants and primates, including human genes with no counterpart in chimpanzee that arose from non-coding DNA (Knowles and McLysaght 2009; Van Oss and Carvunis 2019). Non-coding DNA contains many short ORFs, and much of it is transcribed (Section 6.9), so the raw material is plentiful. Using ribosome profiling in yeast, Carvunis and colleagues found that many short, non-conserved ORFs are translated, and that their properties, such as length, codon usage and expression, lie between those of random non-genic ORFs and those of established genes (Carvunis et al. 2012). They proposed a continuum of **proto-genes**, from which a few gain a function, are retained by selection and become genes. In most cases, a transcript gains an ORF, or an ORF gains transcription, and the order in which these happen differs between cases.

De novo genes are a subset of **orphan genes**, or *taxonomically restricted genes*: genes with no detectable homologues outside a lineage. Every newly sequenced genome has many of them, often 10–30% of the genes (Tautz and Domazet-Lošo 2011). Not every orphan is new, however. A gene that evolves fast or is short can lose detectable similarity to its homologues, so that sequence searches miss them (1).

Simulations suggest that such *homology detection failure* explains many apparent orphans (Weisman et al. 2020), while analyses that use conserved gene order to find the corresponding region in related genomes show that only a minority of orphans can be explained in this way (Vakirlis et al. 2020). A convincing de novo gene is therefore shown by finding the orthologous region in related species, demonstrating that it is non-coding there, and identifying the mutations that created the ORF or its expression. Methods that date genes by the most distant species in which a homologue is found (*phylostratigraphy*) are biased by the same problem, since short and fast genes appear younger than they are.

6.8.3 Small proteins and smORFs

Small proteins, or **microproteins**, are usually defined as those shorter than about 100 amino acids, encoded by **small ORFs** (smORFs). They were systematically missed by genome annotation (Storz et al. 2014; Couso and Patraquim 2017). In random sequence an ORF of 50 codons is common (Section 5.6), so early annotations set a minimum length, typically 100 codons, to keep the false positives down. Short genes also give weak statistical signals for gene finders, have few or no homologues in the databases, and give few peptides in proteomics. Some well-known small proteins were nevertheless found early, by biochemistry: phospholamban and sarcolipin, which regulate the calcium pump SERCA in muscle, are 52 and 31 residues long.

Small ORFs come in several classes (Couso and Patraquim 2017): short genes on their own transcripts; *upstream ORFs* (uORFs) in the 5' UTRs of mRNAs, which mostly regulate the translation of the main ORF; ORFs in transcripts annotated as long non-coding RNAs; and *alternative ORFs* that overlap known coding sequence in another frame. Three kinds of evidence are used to find them:

- **Ribosome profiling** (Ribo-seq) sequences the fragments of mRNA protected by ribosomes, and so shows which regions are translated, at single-nucleotide resolution (Ingolia et al. 2009). Translated ORFs show a three-nucleotide periodicity of the footprints. Ribo-seq has revealed thousands of translated smORFs in human cells and tissues (Chothani et al. 2022), but ribosome binding does not prove that a stable protein is made.
- **Proteomics and peptidomics.** Mass spectrometry can confirm the protein, but small proteins are often of low abundance and give one or two tryptic peptides. Enrichment of small proteins, searches without digestion and immunopeptidomics, which detects peptides presented by HLA molecules, increase sensitivity (Slavoff et al. 2012). Searches against databases of all possible ORFs are proteogenomic searches with a large search space and need strict error control (Section 8.3).
- **Evolutionary conservation.** Codon substitution patterns in alignments of related genomes show whether an ORF evolves like protein-coding sequence. PhyloCSF (Lin et al. 2011) compares the likelihoods of the observed codon substitutions under coding and non-coding models. It works for conserved smORFs but, by design, not for young ones.

Several small proteins with important functions were found in transcripts annotated as non-coding. *Myoregulin* (46 residues) (Anderson et al. 2015) and *DWORF* (34 residues) (Nelson et al. 2016) are single transmembrane helices that inhibit or activate SERCA in muscle. Other microproteins act in mitochondria, for example in the respiratory chain, and the peptides of the *polished rice* (*tarsal-less*) gene in *Drosophila*, 11–32 residues long, control development (Kondo et al. 2010). In bacteria, small proteins regulate membrane transporters, kinases and cell division (Storz et al. 2014), and the human microbiome encodes thousands of families of small proteins (Sberro et al. 2019).

How many of the translated smORFs encode functional proteins is the open question. A CRISPR screen found that disrupting some non-canonical ORFs affected cell growth (Chen et al. 2020), but most translated smORFs are short, young and not conserved, and many may be translational noise or regulatory uORFs. To bring them into the reference annotation, GENCODE has started to include a

curated set of about 7,000 Ribo-seq ORFs, annotated with the strength of their evidence (Mudge et al. 2022).

Structure prediction (Section 9.8) is increasingly applied to small proteins, to find out whether they fold and with what they interact. It is harder than for ordinary proteins. Many microproteins are single helices, often transmembrane, or are disordered, and young ones have few or no homologues, so the multiple sequence alignments that AlphaFold relies on are shallow. Predictions therefore often have low confidence, and a confident model of a short peptide is not by itself evidence that it folds. Language-model predictors that work on single sequences (Section 9.9) avoid the alignment problem, but not the underlying lack of information. The most promising use is to predict complexes between microproteins and candidate partners, as for the SERCA regulators. Interfaces of short peptides are, however, predicted less reliably than folds, and screens of many pairs produce false positives that need experimental testing (Section 9.8).

6.9 RNA genes and regulatory elements

Protein-coding exons are a small part of a eukaryotic genome. Much of the rest is transcribed, and some of it encodes functional RNAs or regulates the expression of genes. How much of the non-coding genome is functional is one of the most debated questions in genomics.

6.9.1 Non-coding RNAs

Genes whose product is an RNA rather than a protein are called non-coding RNA (ncRNA) genes. The search for them, and the prediction of their structures, is described in Section 1.7. The main classes are:

- **Housekeeping RNAs**, present in all cells and essential for basic functions: ribosomal RNAs (rRNAs) and transfer RNAs (tRNAs) in translation, small nuclear RNAs (snRNAs) in the spliceosome, small nucleolar RNAs (snoRNAs) that guide the modification of other RNAs, and the RNA components of ribonuclease P, the signal recognition particle and telomerase. Several of them are catalytic, a possible relic of the RNA world (Section 3.2).
- **MicroRNAs** (miRNAs), about 22 nucleotides long, regulate gene expression by base pairing with the 3' untranslated regions of mRNAs, which leads to their degradation or reduced translation. The first, *lin-4*, was found in *C. elegans* in 1993 (Lee et al. 1993). The human genome encodes hundreds of conserved miRNAs, which together regulate a large fraction of protein-coding genes (Bartel 2018). Victor Ambros and Gary Ruvkun received the 2024 Nobel Prize for their discovery.
- **Small interfering RNAs** (siRNAs) and **piRNAs** silence viruses and transposable elements; piRNAs protect the germline (Section 6.7).
- **Long non-coding RNAs** (lncRNAs), longer than 200 nucleotides and not translated. Tens of thousands are annotated in the human genome. A few are well studied, such as *XIST*, which silences one X chromosome in females. Most are expressed at low levels, are poorly conserved and have no known function, and it is debated how many are functional and how many are transcriptional noise (Mattick et al. 2023; Palazzo and Lee 2015).
- In bacteria, small regulatory RNAs, *riboswitches* (structures in mRNAs that bind metabolites and control expression) and the CRISPR RNAs of bacterial immunity.

6.9.2 Regulatory elements

Gene expression is controlled by DNA sequences that bind transcription factors and other proteins:

- **Promoters**, at the start of a gene, where RNA polymerase and the general transcription factors assemble. Many human promoters lie in *CpG islands*, regions that escaped the general depletion of CpG dinucleotides caused by the mutation of methylated cytosines.
- **Enhancers**, which increase transcription and can lie up to a megabase away from their target gene, in introns or in intergenic regions. They act by contacting the promoter through chromatin loops (Section 6.7).
- **Silencers**, which repress transcription, and **insulators**, which block the action of enhancers across boundaries, often by binding CTCF.

Regulatory elements are short and degenerate, so they are hard to find from sequence alone. They are mapped experimentally from their biochemical signatures: open chromatin (DNase-seq, ATAC-seq), specific histone modifications (such as H3K27ac at active enhancers and H3K4me3 at active promoters), and transcription-factor binding (ChIP-seq). Evolutionary conservation provides an independent signal. Some non-coding elements, the *ultraconserved elements*, are identical over hundreds of bases between human, mouse and rat, more conserved than most protein-coding genes. The ENCODE project has catalogued close to a million candidate regulatory elements in the human genome (The ENCODE Project Consortium 2020). The analysis of the corresponding expression data is described in Chapter 7.

6.9.3 How much of the genome is functional?

The term *junk DNA* was popularised by Susumu Ohno in 1972 for DNA, such as the decayed copies of duplicated genes, that had accumulated without a function. The C-value paradox (Section 6.3) was a strong argument for it: if an onion needs five times more DNA than a human, or one species of amphibian much more than a close relative, most of that DNA can hardly be essential.

Junk DNA means DNA with no known *selected* function: mutating or deleting it would not affect the fitness of the organism. It does not mean DNA without biochemical activity. Junk DNA may be transcribed, bound by proteins or carry chromatin marks, because these activities also occur by chance. Conversely, transcription or protein binding alone does not show that a sequence has a function for the organism. That requires evidence of evolutionary constraint or of a phenotypic effect when the sequence is mutated or deleted.

In 2012 the ENCODE project reported that about 80% of the human genome had a "biochemical function", meaning that it was transcribed, bound by proteins or marked by specific chromatin features in at least one cell type (The ENCODE Project Consortium 2012). The press reported the death of junk DNA. Evolutionary biologists responded sharply (Eddy 2012; Graur et al. 2013; Doolittle 2013). They argued that ENCODE confused two meanings of function: *causal-role* function, an activity that can be measured, and *selected-effect* function, an activity that is maintained by natural selection. Much transcription and protein binding may be biochemical noise, and DNA can be active without being needed. ENCODE scientists later acknowledged that the different definitions give very different numbers (Kellis et al. 2014).

Evolutionary estimates of the functional fraction measure how much of the genome is under purifying selection, from the deficit of substitutions compared with neutral expectations. Comparisons of mammalian genomes give estimates of about 8% for the human genome (Rands et al. 2014), and the Zoonomia alignment of 240 mammals identified at least 3% of human bases as significantly constrained and estimated that around 10% are under constraint (Christmas et al. 2023). These estimates miss recently evolved and rapidly turned-over functional elements, but they are hard to reconcile with 80%. A population-genetic argument points in the same direction: each human inherits about 60–70 new

mutations (Section 3.3), and if most of the genome were sensitive to mutation the load of harmful mutations would be very high. Taken together, these arguments suggest that perhaps 10–15% of the human genome is functional in the selected-effect sense, but the question is far from settled, and it is a typical exam topic because it connects genome biology, evolution and the interpretation of large-scale data.

6.10 Key concepts

A checklist for revision.

- **Background:** DNA and RNA structure and base pairing; replication, transcription, RNA processing and translation; the genetic code; reverse transcription; levels of gene regulation; prokaryotic and eukaryotic cells; model organisms
- **Genome projects:** the first genomes (*H. influenzae*, yeast, *E. coli*, *C. elegans*, *Drosophila*, *Arabidopsis*, human, mouse); clone-by-clone vs. whole-genome shotgun; the public–Celera race; Bermuda principles; what "finished" means and the complete T2T genome; assembly vs. annotation and their versions
- **What is a gene?** Mendelian, molecular and post-ENCODE definitions (a union of sequences encoding related functional products); why the human protein-coding count fell from ~100,000 guesses to ~19,000–20,000; GENCODE/Ensembl, RefSeq, CHESS and MANE, and where they disagree (uncertain coding status, readthrough, duplicated families, isoforms)
- **Genome size and gene number:** C-value; range across bacteria, archaea and eukaryotes; smallest and largest genomes; gene density; gene number proportional to genome size in prokaryotes but not in eukaryotes; genome size dominated by repeats, not gene number; polyploidy and monoploid genome size; the C-value paradox and C-value enigma; the G-value paradox (gene number does not measure complexity)
- **Prokaryotic genome organisation:** circular chromosomes and plasmids; single origin and replichores; GC skew; strand bias and gene position; operons; compactness and deletional bias; genomic islands; archaea as a mix
- **Eukaryotic genome organisation:** linear chromosomes, telomeres and telomerase, centromeres; multiple origins; introns, splicing and the discovery of split genes; introns early vs. late; alternative splicing; large intergenic regions and distal regulation
- **Genome duplications:** paralogous synteny and 2:1 patterns; yeast WGD, vertebrate 2R, teleost and plant polyploidy; allo- and autopolyploids, homoeologues, and why polyploid and hybrid genomes are hard to assemble and to analyse for orthology
- **Organelle genomes:** endosymbiotic theory; origins of mitochondria and plastids; human mtDNA; variation in organelle genomes; endosymbiotic gene transfer and NUMTs; genome reduction in endosymbionts
- **Viral genomes:** DNA or RNA, single- or double-stranded, segmented genomes; Baltimore classes vs. taxonomy; hallmark genes and realms; genome sizes from circoviruses to pandoraviruses; overlapping genes (φX174), polyproteins, frameshifting; high mutation rates of RNA viruses; consequences for gene prediction and phylogeny

- **Synteny and rearrangements:** synteny vs. collinearity; conserved segments (Nadeau and Taylor) and differing rates of rearrangement; uses of synteny (orthology, missing genes, WGD, ancestral linkage groups); dot plots, window and threshold, and the signatures of inversions, indels, transpositions, duplications and translocations; assembly errors that mimic breakpoints; signed permutations, breakpoint and reversal distances, DCJ; random breakage vs. breakpoint reuse; anchors and chaining (MCScanX, Mauve)
- **Pan-genomes:** core and accessory genomes; open vs. closed pan-genomes; HGT; adaptive vs. neutral explanations; gene-content vs. sequence pangenomes; core defined by a sampling-dependent threshold; eukaryotic and human pangenomes; linear reference (GRCh38, CHM13) vs. pangenome graph; reference bias
- **Population genetics of genome complexity:** Lynch and Conery; the mutational hazard; N_e and the efficiency of selection; criticism; endosymbionts and streamlined free-living bacteria
- **Human evolution:** mitochondrial Eve and out of Africa; low human diversity; ancient DNA and its damage; Neanderthal and Denisovan genomes; admixture and the D-statistic; introgression deserts and adaptive introgression
- **Repeats:** classes of transposable elements (LTR, LINE, SINE, DNA transposons); L1 and Alu; host defences and domestication; repeat masking; microsatellites, satellites and centromeres; segmental duplications
- **Mechanisms of structural variation:** NAHR between segmental duplications (recurrent, reciprocal deletions and duplications); NHEJ and microhomology; replication-based FoSTeS/MMBIR and complex junctions; chromothripsis; junction signatures; genomic disorders (CMT1A/HNPP, 22q11.2); haploinsufficiency, triplosensitivity and population SV catalogues
- **Pseudogenes and new genes:** processed, duplicated and unitary pseudogenes (GULO); how they confuse read mapping, variant calling and quantification; occasional functions (PTENP1) and the ceRNA debate; gene birth by duplication, retroposition (retrogenes), fusion/fission, HGT, TE domestication and de novo origin; proto-genes; orphan genes and homology detection failure; synteny-based evidence; phylostratigraphy bias
- **Small proteins:** microproteins and smORFs (<100 aa); why ORF-length cut-offs missed them; uORFs, lncRNA ORFs, alternative ORFs; Ribo-seq and its caveats; peptidomics and proteogenomic error control; PhyloCSF and conservation; myoregulin, DWORF, polished rice; GENCODE Ribo-seq ORFs; structure prediction of microproteins and its limits
- **3D genome:** nucleosomes and chromatin; eu- and heterochromatin; chromosome territories; 3C and Hi-C; contact frequency is not distance (population averaging, biases, polymer effects); A/B compartments, TADs and CTCF loops; loop extrusion
- **Non-coding RNAs:** housekeeping RNAs; miRNAs, siRNAs and piRNAs; lncRNAs and the debate about their function; bacterial sRNAs and riboswitches
- **Regulatory elements:** promoters and CpG islands; enhancers, silencers and insulators; how they are mapped; ultraconserved elements
- **The function debate:** junk DNA (no selected function, not no biochemical activity); ENCODE 2012 and its critics; causal-role vs. selected-effect function; estimates from evolutionary constraint; the mutational-load argument

6.11 Recommended reading

These papers are recommended for reading in full:

- International Human Genome Sequencing Consortium et al. (2001) — the human genome draft; what a genome looks like, and how it was obtained.
- Lynch and Conery (2003) — why prokaryotic and eukaryotic genomes differ; the population-genetic theory of genome complexity.

- McInerney et al. (2017) — why prokaryotes have pan-genomes; core and accessory genes, and adaptive vs. neutral explanations.
- Green et al. (2010) — the draft Neanderthal genome and the discovery of admixture with modern humans.
- Bourque et al. (2018) — ten things you should know about transposable elements.
- Eddy (2012) — the C-value paradox, junk DNA and ENCODE, in two pages.

Titles, abstracts, links and the full texts are in Section A.6; a longer list of further papers is in Section B.6.

6.12 Background reading (open access)

- **What is a genome? (YourGenome)** — An introduction for a general audience, from Wellcome Connecting Science, to genomes: DNA, genes, chromosomes and how genome sizes differ between organisms.
  https://www.yourgenome.org/theme/what-is-a-genome/
- **Genome (Wikipedia)** — In the fields of molecular biology and genetics, a genome is all the genetic information of an organism. It consists of nucleotide sequences of DNA.
  https://en.wikipedia.org/wiki/Genome
- **Genome size (Wikipedia)** — Genome size is the total amount of DNA contained within one copy of a single complete genome. It is typically measured in terms of mass in picograms or less frequently in daltons, or as the total number of nucleotide base pairs, usually in megabases. One picogram is equal to 978 megabases.
  https://en.wikipedia.org/wiki/Genome_size
- **C-value (Wikipedia)** — C-value is the amount, in picograms, of DNA contained within a haploid nucleus or one half the amount in a diploid somatic cell of a eukaryotic organism.
  https://en.wikipedia.org/wiki/C-value
- **Human genome (Wikipedia)** — The human genome is a complete set of DNA sequences for each of the 22 autosomes and the two distinct sex chromosomes. A small DNA molecule is found within individual mitochondria. These are usually treated separately as the nuclear genome and the mitochondrial genome.
  https://en.wikipedia.org/wiki/Human_genome
- **Human Genome Project (Wikipedia)** — The Human Genome Project (HGP) was an international scientific research project with the goal of determining the base pairs that make up human DNA, and of identifying, mapping and sequencing all of the genes of the human genome from both a physical and a functional standpoint.
  https://en.wikipedia.org/wiki/Human_Genome_Project
- **Operon (Wikipedia)** — In genetics, an operon is a functioning unit of DNA containing a cluster of genes under the control of a single promoter.
  https://en.wikipedia.org/wiki/Operon
- **Intron (Wikipedia)** — An intron is any nucleotide sequence within a gene that is not expressed or operative in the final RNA product. The word intron is derived from the term intragenic region, i.e., a region inside a gene. The term intron refers to both the DNA sequence within a gene and the corresponding RNA sequence in RNA transcripts.
  https://en.wikipedia.org/wiki/Intron
- **Mitochondrial DNA (Wikipedia)** — Mitochondrial DNA is the DNA located in the mitochondria organelles in a eukaryotic cell that converts chemical energy from organic compounds into adenosine triphosphate (ATP).
  https://en.wikipedia.org/wiki/Mitochondrial_DNA
- **Pan-genome (Wikipedia)** — In the fields of molecular biology and genetics, a pan-genome is the entire set of genes from all strains within a clade. More generally, it is the union of all the

genomes of a clade.
https://en.wikipedia.org/wiki/Pan-genome

- **Interbreeding between archaic and modern humans (Wikipedia)** — Interbreeding between archaic humans and anatomically modern humans took place during the Middle Paleolithic and early Upper Paleolithic.
https://en.wikipedia.org/wiki/Interbreeding_between_archaic_and_modern_humans
- **Transposable element (Wikipedia)** — Transposable elements (TEs), also known as transposons, jumping genes, or mobile genetic elements, are DNA sequences that can change their position, or translocate, within a genome.
https://en.wikipedia.org/wiki/Transposable_element
- **Topologically associating domain (Wikipedia)** — A topologically associating domain (TAD) is a self-interacting genomic region, meaning that DNA sequences within a TAD physically interact with each other more frequently than with sequences outside the TAD.
https://en.wikipedia.org/wiki/Topologically_associating_domain
- **Non-coding DNA (Wikipedia)** — Non-coding DNA (ncDNA) sequences are components of an organism's DNA that do not encode protein sequences. Some non-coding DNA is transcribed into functional non-coding RNA molecules.
https://en.wikipedia.org/wiki/Non-coding_DNA
- **Junk DNA (Wikipedia)** — Junk DNA is a DNA sequence that has no known biological function. Most organisms have some junk DNA in their genomes—mostly pseudogenes and fragments of transposons and endogenized viruses—but it is possible that some organisms have substantial amounts of junk DNA.
https://en.wikipedia.org/wiki/Junk_DNA

6.13 Student recommendations

Recommended by students preparing for the exam: papers, reviews, online lectures, tutorials and short explanations. To suggest something, use the suggestion form (SU login).

No recommendations yet.

6.14 Review problems

These problems are adapted from Matteo Tadiello, *Modern Bioinformatics: From Foundations to Frontiers* (CC BY 4.0), used with permission. For a longer treatment of this topic, see the chapters "Genome Architecture, Representation, and Annotation" and "Gene Order, Synteny, and Rearrangements" of that book. In the HTML version, click a box to show the extensions, solution outline and common errors.

6.14.1 Comparing genome architectures without stereotypes

Compare the organisation of bacterial, archaeal, eukaryotic nuclear, organelle and viral genomes. Show how the differences determine which computational representations and analyses are appropriate.

Extensions, solution outline and common errors

Extensions:

1. Why need a bacterial chromosome be neither single nor circular?
2. Distinguish an operon from a set of neighbouring genes.
3. Which features of archaea resist a simple division into bacteria and eukaryotes?
4. Why can organelle genomes not be treated as miniature bacterial chromosomes?
5. Which properties of viral genomes change the strategy for assembly and annotation?

Solution outline:

- Compare genomes along independent axes: DNA or RNA and strandedness, topology, the number of molecules or segments, ploidy and copy number, packaging, coding strategy, repeats, and diversity within a sample.
- Treat the differences between domains as tendencies, not definitions. Bacterial and archaeal genomes are usually compact but can have several or linear replicons. Eukaryotic nuclear chromosomes are linear and packed in chromatin. Organelle genomes are reduced but vary in structure, genetic code and RNA processing. Viral genomes can be DNA or RNA, single- or double-stranded and segmented, and use overlapping genes, frameshifts and polyproteins.
- An operon is defined by a shared transcript. Adjacent genes on the same strand are only a prediction, because internal promoters and terminators and condition-specific boundaries occur.
- The architecture determines the choice of genetic code, assembler, mapping strategy, gene predictor, treatment of repeats and validation data.
- An assembly or annotation is a model of a sampled genome, not the genome itself.

Common errors:

- Stating that all bacteria have one circular chromosome.
- Treating all eukaryotic transcripts as monocistronic, or all viral genomes as unspliced.
- Taking a circular contig as proof that the molecule is a single circle in the cell.
- Using the Baltimore classification as if it were a taxonomy of viruses.
- Equating compactness with simplicity.

Connections: Section 6.4; assembly in Section 5.3; gene prediction in Section 5.6; phylogenetic classification in Section 4.5.

6.14.2 Introns in bacteria and archaea

Correct the statement that prokaryotes lack introns, and explain how the corrected picture changes sequence analysis and annotation.

Extensions, solution outline and common errors

Extensions:

1. Compare spliceosomal introns with self-splicing group I and group II introns.
2. Why can similarity of primary sequence fail to detect self-splicing introns?
3. How would you distinguish an intron from an insertion error in an assembly?
4. How can introns disrupt the annotation of protein-coding and RNA genes?

Solution outline:

- Spliceosomal introns are a feature of eukaryotic nuclear pre-mRNAs. Introns in bacteria and archaea are rare and of other kinds: self-splicing group I and group II introns, and archaeal introns in tRNA and rRNA genes that are removed by a dedicated enzyme. Group II introns are thought to be the ancestors of spliceosomal introns.
- The RNA secondary structure and catalytic core are more conserved than the primary sequence, so covariance models, which score base-pair covariation as well as sequence, detect them better than sequence similarity alone.
- An intron should be supported by spliced transcripts, an alignment of the flanking exons with the host gene in related species, a plausible RNA structure and splice boundaries, and consistent read support, after excluding misassembly and contamination.
- An intron can split an open reading frame, obscure an rRNA or tRNA gene, or be mistaken for an inserted mobile element.
- A low frequency does not mean absence; classify each intron only as far as the evidence allows.

Common errors:

- Replacing one universal claim with another, that all prokaryotes contain self-splicing introns.
- Calling all introns spliceosomal.
- Treating sequence similarity alone as sufficient evidence of homology for structured RNAs.
- Ignoring the homing endonucleases encoded by many self-splicing introns, which make them mobile.
- Inferring an intron from an unexplained gap in a protein alignment.

Connections: Section 6.4; RNA structure and covariance models in Section 1.7; gene prediction in Section 5.6.

6.14.3 Interpreting regulatory and chromatin evidence

A distal region is accessible, enriched for the histone mark H3K27ac, bound by a transcription factor, and in contact with a promoter in Hi-C data. Which conclusions are justified, and which experiments would show that it is an enhancer of that gene?

Extensions, solution outline and common errors

Extensions:

1. What does each assay measure, and what does it not measure?
2. Why is contact frequency not the same as regulation?
3. What is a candidate cis-regulatory element?
4. Distinguish tests of necessity, sufficiency and target assignment.
5. How do cell type, developmental stage and mixtures of cells affect the interpretation?

Solution outline:

- Interpret each signal separately: accessibility shows open chromatin; H3K27ac is a mark associated with active elements; factor binding is measured in the conditions assayed; contact frequency shows that the regions are close more often than expected in a population of cells.
- None of these alone shows that the region regulates the promoter. The signals can reflect a shared cell state, or be a consequence of transcription rather than its cause.

- *Candidate* keeps the distinction between a biochemical annotation and a demonstrated function. State the cell type, genome build, processing pipeline and thresholds.
- Test necessity at the endogenous locus by deletion, CRISPR interference or mutation of the binding motif; test sufficiency by targeted activation or reporter assays, remembering that an ectopic context can change activity.
- Assign the target gene through the response to perturbation, allele-specific effects and genetic evidence, with positive and negative controls and alternative candidate promoters.
- Report a graded conclusion: biochemically active candidate, putative target, perturbation-supported regulator, or mechanistically resolved enhancer.

Common errors:

- Calling every accessible region an enhancer.
- Treating histone modifications as definitive functional labels.
- Assigning the nearest gene as the target without further evidence.
- Treating reporter activity as proof of function at the endogenous locus.
- Pooling tissues or cells without accounting for the mixture.

Connections: Section 6.9; 3D genome organisation in Section 6.7; expression data in Chapter 7.

6.14.4 Biological repeats and repeat-induced artefacts

Explain why repeated sequence is both a major component of genome biology and a source of errors in assembly, mapping and annotation. Outline a strategy for repeat-aware gene annotation.

Extensions, solution outline and common errors

Extensions:

1. Distinguish tandem repeats, interspersed repeats, segmental duplications and transposable elements.
2. What are autonomous and non-autonomous transposable elements?
3. How do repeats affect short-read mapping and genome assembly?
4. Compare hard and soft masking.
5. How would you avoid annotating a transposable element as a host gene?

Solution outline:

- Define repeat classes by arrangement, homology and mechanism. Repeated sequence need not be mobile, and a duplicated host gene is not a transposable element.
- Autonomous elements encode the proteins needed for their own movement, such as L1; non-autonomous elements, such as Alu, depend on proteins encoded elsewhere. Most copies in a genome are inactive, decayed or nested, and some have been domesticated.
- Similar copies cause reads to map to several places, assemblies to collapse or fragment, and false duplications and ambiguous variant calls. Long accurate reads help but do not resolve every array.
- Hard masking removes repeats from many analyses, improving specificity at the cost of missed genes; soft masking keeps the sequence but lets gene predictors down-weight repeat-derived candidates.
- Combine a curated repeat library for the lineage with de novo discovery of repeat families, and examine terminal repeats, transposase or reverse-transcriptase domains, copy number, splicing, conservation and protein evidence.

- Keep host genes that overlap repeats only when there is evidence for a distinct transcript and coding structure; transcription alone does not show function.

Common errors:

- Treating repeats as uniformly non-functional.
- Interpreting transcription as proof of a host-gene function.
- Assuming that every copy of a transposable element is active.
- Treating a repeat library from a distant species as complete.
- Ignoring genes that overlap or evolved from transposable elements.

Connections: Section 6.7; assembly in Section 5.3; mapping in Section 5.4; gene annotation in Section 5.6.

6.14.5 Building and interpreting a bacterial pangenome

You build a pangenome from 500 bacterial isolates. Explain how sampling, assembly quality, the clustering of genes into families and population structure affect its interpretation.

Extensions, solution outline and common errors

Extensions:

1. Define core and accessory gene families operationally.
2. How do annotation errors inflate the accessory genome?
3. Compare a table of gene content with a sequence graph.
4. Evaluate a claim that the pangenome is open or closed.
5. Design an analysis of association between accessory genes and virulence.

Solution outline:

- A gene-content pangenome is the union of gene families in a stated sample; a sequence pangenome represents alternative sequence paths. They answer different questions.
- Use consistent assembly and annotation, then cluster proteins with rules that consider coverage, domains and orthology. Build presence–absence and copy-number tables, and inspect difficult families with trees and conserved gene order.
- For n genomes, the prevalence of family g is $p_g = \frac{1}{n}\sum_i \mathbf{1}(A_{gi} > 0)$, where A_{gi} is the number of copies in genome i; state the threshold used for core genes. Missing sequence, fragmented genes and split or merged clusters all change p_g.
- Estimate the uncertainty of the accumulation curve by repeated subsampling or permutation of the genome order. Whether a pangenome is open or closed depends on the sample, the fitted model and the technical errors.
- Use a graph when haplotypes, genomic context or mapping are central, and gene tables for questions about family presence and copy number. Neither removes sampling bias.
- For an association with virulence, model population structure, relatedness, recombination, environment, missing data and multiple testing, and follow the association with genetic and phenotypic validation.

Common errors:

- Treating a 95% prevalence threshold as universal.

- Clustering proteins by percentage identity alone.
- Interpreting every singleton as a new gene.
- Assuming that a graph is unbiased because it is not linear.
- Ignoring clonal population structure in association studies.

Connections: Section 6.6; horizontal gene transfer in Section 3.7; pangenome graphs and mapping in Section 5.4; multiple testing in Section 7.4.1.

6.14.6 Interpreting conserved synteny

Two genes lie in corresponding genomic neighbourhoods in human and in a fish. Which evolutionary inferences does this observation support?

Extensions, solution outline and common errors

Extensions:

1. Is synteny the same as identical gene order?
2. Can orthologues lack conserved synteny?
3. How does synteny reveal a whole-genome duplication?
4. How would you score a syntenic block?
5. Which technical artefact can mimic a breakpoint?

Solution outline:

- Define the terms: synteny may mean correspondence of chromosomes or regions, whereas collinearity also requires conserved order and orientation.
- Corresponding neighbours support shared positional ancestry and help to identify the orthologue among paralogues and to find missed genes, but rearrangements can move true orthologues.
- Choose orthologous anchors, chain them into blocks with stated rules for orientation and gaps, and compare the result with randomised gene orders. Use chromosome-scale assemblies and outgroups.
- An ancient whole-genome duplication leaves pairs of paralogous segments with complementary retained genes, even after most duplicates have been lost; teleost fish had an additional duplication, so one human region often corresponds to two fish regions. Conserved synteny has helped to resolve the early vertebrate duplications (Simakov et al. 2020).
- Confirm breakpoints with long reads, maps or independent assemblies, because misjoined scaffolds and gaps mimic rearrangements.

Common errors:

- Using “synteny” without an operational definition.
- Treating one neighbouring gene as a convincing block.
- Requiring conserved order for all orthologues.
- Ignoring tandem duplicates when chaining anchors.
- Comparing coordinates from different assembly releases.

Connections: Section 6.5; genome duplications in Section 6.4 and Section 3.4; orthology databases in Section 3.4; long-read assembly in Section 5.3.

6.14.7 A short ORF without homologues

Ribosome profiling of human heart tissue shows translation of a 40-codon ORF in a transcript annotated as a long non-coding RNA. A BLAST search finds no homologues outside primates. Is this a new protein-coding gene, and is it a *de novo* gene?

Extensions, solution outline and common errors

Extensions:

1. Why was the ORF not in the protein-coding annotation?
2. What does the Ribo-seq signal show, and what does it not show?
3. How would you show that the protein exists?
4. How would you distinguish *de novo* origin from homology detection failure?
5. What can a predicted structure contribute?

Solution outline:

- Classical annotation used minimum ORF lengths, often 100 codons, because short ORFs are common in random sequence, and short ORFs give weak gene-finder and conservation signals.
- Check the Ribo-seq evidence: three-nucleotide periodicity in frame, footprints across the whole ORF, a defined start, and reproducibility across samples. Translation shows that ribosomes engage the ORF, not that a stable, functional protein is made; it may be a regulatory uORF-like event or noise.
- Look for the protein with mass spectrometry (targeted or peptidomic searches, immunopeptidomics), with strict, separate error control for non-canonical peptides, or with tagging of the endogenous locus.
- For function, use knockouts or knockdowns that disrupt the ORF but not the RNA (for example a start-codon mutation), and evolutionary signals such as PhyloCSF or dN/dS within primates.
- For origin, find the orthologous region in other mammals by conserved gene order and whole-genome alignment, check whether the ORF is absent (disrupted or untranscribed) there, and identify the enabling mutations. Absence of BLAST hits alone is not evidence of *de novo* origin.
- A structure prediction with low confidence is expected for a short, young protein; a confident complex prediction with a plausible partner is a hypothesis to test experimentally.

Common errors:

- Treating ribosome footprints as proof of a functional protein.
- Treating absence of BLAST hits as proof of a *de novo* origin.
- Accepting a single non-canonical peptide at the global FDR.
- Interpreting a confident structure model of a short peptide as evidence that it folds or functions.

Connections: Section 6.8; gene prediction in Section 5.6; proteogenomics and error control in Section 8.3; structure prediction in Section 9.8; homology detection in 1.

6.14.8 Inferring how a deletion arose

Long-read sequencing of two unrelated patients with the same neurological disorder shows a deletion in each. In one, the deletion is 1.4 Mb and its ends lie in two nearly identical 24 kb repeats. In the other, the deletion is 600 kb, its junction shows a 3 bp microhomology, and a 150 bp segment copied from a nearby region is inserted at the junction. Which mechanisms are likely, and what do they imply?

Extensions, solution outline and common errors

Extensions:

1. Which mechanism produces recurrent rearrangements, and why?
2. Why is the exact junction hard to determine in the first patient?
3. Which gene could explain the shared phenotype?
4. How would you decide whether a new deletion in a third patient is likely to be pathogenic?

Solution outline:

- The first deletion, flanked by segmental duplications in direct orientation, is typical of NAHR. NAHR events recur with the same breakpoints in unrelated individuals and produce reciprocal duplications.
- Within the long repeats, the crossover point can only be placed in the stretch where the two copies differ; short reads cannot map it at all, and even long reads must span the repeat.
- The second deletion is non-recurrent. Microhomology alone suggests NHEJ or microhomology-mediated repair; a templated insertion from nearby suggests a replication-based mechanism (FoSTeS/MMBIR).
- Both deletions remove a common region; a dosage-sensitive (haploinsufficient) gene in the overlap is the likely cause. Check constraint and dosage annotations for the genes in the region.
- For a new deletion, compare with population SV catalogues (gnomAD-SV), dosage-sensitivity databases and segregation in the family, and confirm the breakpoints.

Common errors:

- Assuming that all recurrent deletions are caused by NHEJ.
- Treating the deletion size as evidence of the mechanism.
- Assuming that every gene in a deleted region contributes to the phenotype.

Connections: Section 6.7; SV detection in Section 5.4; dosage balance in Section 3.4.

7 Expression analysis

> **From the exam description**
>
> Expression analysis of genes and proteins: methods, algorithms, statistics.

7.1 Overview

Measuring which genes are expressed, and how much, links the genome to the phenotype. Expression analysis was the first area of genomics that produced large, quantitative data sets about many genes in many samples, and it forced biologists to confront statistical problems that are now everywhere: normalisation, multiple testing, batch effects and the exploration of high-dimensional data. This chapter follows the development from microarrays to single-cell and spatial methods:

- microarrays, their preprocessing and what they taught us (Section 7.2);
- RNA-seq: library preparation and experimental design, spliced alignment, transcript assembly, quantification and normalisation (Section 7.3);
- statistics: differential expression with count models, multiple testing, clustering and its validation, classification with many genes and few samples, and dimensionality reduction (Section 7.4);
- interpretation: gene set analysis, co-expression and eQTLs, and the relation between mRNA and protein levels (Section 7.5);
- single-cell genomics: technologies, analysis, multimodal data, spatial transcriptomics, foundation models and cell types (Section 7.6);
- single-cell sequencing of cancer and tumour evolution (Section 7.7).

The databases that archive expression data are described in Section 2.8, and the measurement of proteins in Chapter 8.

7.2 The first genome-wide methods: microarrays

Measuring which genes are expressed, and how much, links the genome to the phenotype. Before the 1990s, expression was measured one gene at a time, for example with Northern blots. Two approaches made it possible to measure all genes at once: counting short sequence tags, as in *serial analysis of gene expression* (SAGE) (Velculescu et al. 1995), and hybridisation to DNA microarrays. Microarrays dominated for about fifteen years, and they introduced most of the ideas that are still used to analyse expression data.

7.2.1 Principle

A **DNA microarray** is a solid surface with thousands to millions of spots (*features*), each containing many copies of a DNA probe for one transcript. RNA from a sample is converted to labelled cDNA or cRNA and hybridised to the array. Each labelled molecule binds to the probe with the complementary

sequence, and the fluorescence intensity of each spot is a measure of how abundant that transcript was in the sample. The relation is monotonic but not simply proportional: background dominates at low abundance, the signal saturates at high abundance, and each probe has its own binding affinity. Intensities are therefore relative measures, best compared for the same probe between samples. Three main technologies were used:

- **Spotted cDNA arrays**, developed in Patrick Brown's laboratory at Stanford, were made by robotically printing PCR products onto glass slides (Schena et al. 1995). They were usually used in *two-colour* experiments: two samples, labelled with different dyes (Cy3 and Cy5), were hybridised to the same array, and the result was the ratio between them. Because they could be built in academic laboratories, they spread rapidly.
- **Affymetrix GeneChips** were made by synthesising short (25-nucleotide) oligonucleotides directly on the chip with photolithography, the technique used to make computer chips (Fodor et al. 1991; Lockhart et al. 1996). Each gene was measured with a *probe set* of about 11–20 different probes, each with a *mismatch* control probe that differed in the central base. These were *one-colour* arrays, each measuring one sample, and the high reproducibility of the industrial process made them the most widely used platform.
- **Illumina BeadArrays** use a different principle. Probes are attached to microscopic beads, which are randomly distributed in wells etched in a fibre-optic bundle or a glass slide. Since the position of each bead is random, the array is decoded after manufacture by a series of hybridisations that identify which probe each bead carries (Gunderson et al. 2004). Each probe is present on many beads, which gives built-in replication. BeadArrays were used for expression profiling (Kuhn et al. 2004), and, above all, for **SNP genotyping**: the genotyping chips used in most genome-wide association studies, measuring up to millions of SNPs per sample, are Illumina bead arrays.

7.2.2 Preprocessing and normalisation

The raw data from an array are images, and many steps are needed before intensities can be compared between genes and samples (Quackenbush 2001):

1. **Image analysis**: locating the spots and estimating their intensity and the local background.
2. **Background correction**: removing the signal from non-specific hybridisation and the optical background.
3. **Transformation**: working on the logarithmic scale, usually $\log_2$, because intensities span several orders of magnitude, errors are roughly multiplicative, and fold changes become differences.
4. **Normalisation**: removing systematic differences between arrays or dyes, caused by differences in the amount of RNA, labelling efficiency or scanner settings. For two-colour arrays, the log-ratio $M = \log_2(R/G)$ is plotted against the average log intensity A (an *MA plot*), and a curve fitted with local regression (loess) is subtracted, so that most genes have M close to zero. For one-colour arrays, **quantile normalisation** forces all arrays to have the same distribution of intensities (Bolstad et al. 2003).
5. **Summarisation**: for Affymetrix arrays, combining the probes of a probe set into one expression value. The *robust multi-array average* (RMA) fits a model across arrays that accounts for probe-specific affinities, and ignores the mismatch probes, which turned out to measure specific signal as well as background (Irizarry 2003).

These steps are not just technicalities. Normalisation methods assume that most genes do not change between samples, an assumption that fails in some experiments, and the choice of method can change the results.

7.2.3 What microarrays showed, and their limitations

Microarrays made it possible to ask questions about whole transcriptomes. Clustering genes by their expression profiles showed that genes with related functions are co-expressed (Eisen et al. 1998). Expression profiles could classify cancers: acute leukaemias could be told apart by expression alone (Golub et al. 1999), breast tumours fell into molecular subtypes with different prognoses (Perou et al. 2000), and a 70-gene signature predicted the outcome of breast cancer (Veer et al. 2002) and became a clinical test. Atlases of expression across tissues showed which genes are ubiquitous and which are tissue specific (Su et al. 2004). The analysis of these experiments raised the statistical problems that are discussed in Section 7.4: how to test thousands of genes with few replicates, for which empirical Bayes methods such as *limma* were developed (Smyth 2004), and how to control false discoveries.

The early years also showed how easily such experiments go wrong. Results were hard to reproduce between laboratories and platforms until standards for reporting experiments, MIAME (Brazma et al. 2001), and large comparison studies (MAQC Consortium 2006) were established. Microarrays have several built-in limitations:

- they can only measure transcripts whose sequences are known and represented on the array;
- signals are affected by *cross-hybridisation* of similar sequences and by probe-specific affinities, so intensities of different genes cannot be compared directly;
- the dynamic range is limited by background at the low end and saturation at the high end;
- they cannot easily distinguish isoforms, detect new transcripts or measure allele-specific expression.

RNA-seq (Section 7.3) removed most of these limitations, and replaced microarrays for expression profiling from about 2010. Arrays remain in use for genotyping and DNA methylation profiling, where they are cheap and robust.

7.3 RNA sequencing

RNA-seq measures expression by sequencing cDNA made from the RNA in a sample and counting the reads that come from each gene or transcript. It was introduced in 2008 (Mortazavi et al. 2008; Nagalakshmi et al. 2008), shown to agree well with microarrays while being more reproducible and sensitive (Marioni et al. 2008), and quickly became the standard (Wang et al. 2009; Stark et al. 2019). Because it does not depend on predefined probes, RNA-seq can discover new genes and transcripts, measure isoforms, detect allele-specific expression, fusion genes and RNA editing, and be used in any organism, with or without a reference genome. Its dynamic range is limited only by the sequencing depth.

7.3.1 Library preparation and experimental design

Most of the RNA in a cell is ribosomal. To sequence mRNA, either polyadenylated RNA is selected with oligo(dT), or rRNA is depleted, which also keeps non-polyadenylated RNAs. The RNA is fragmented,

reverse transcribed into cDNA, ligated to adapters and amplified. *Strand-specific* protocols record which strand the transcript came from, which matters where genes overlap on opposite strands. Typical experiments use 20–50 million short reads per sample for gene-level analysis. Long-read sequencing (Section 5.2) reads entire transcripts and is increasingly used to define isoforms (see below).

The most important design decision is the number of **biological replicates**. The key concept is the **experimental unit**: the smallest unit that is independently assigned to (or sampled from) a condition, such as an animal, a patient or an independently grown culture. *Biological replicates* are different experimental units in the same condition, and they capture the natural variation between individuals. *Technical replicates* are repeated measurements of the same unit, for example the same RNA sequenced in two libraries or two lanes; they measure only the noise of the protocol. Technical replicates show little variation, while biological replicates vary much more, and differential expression can only be assessed relative to biological variation. Treating technical replicates, or several samples from the same individual, as independent biological replicates is called *pseudoreplication* and gives far too many significant results. Studies have shown that with three biological replicates many true changes are missed, and that six or more are needed for good sensitivity (Schurch et al. 2016).

Good design also controls **confounding**. Technical *batch effects* (different days, operators, reagent lots or sequencing runs) can be larger than the biological differences of interest (Leek et al. 2010). If all control samples are processed in one batch and all treated samples in another, batch and condition are confounded, and no statistical method can separate them. The remedies are classical: **randomise** the assignment of samples to conditions and to processing order; **block**, by processing equal numbers of samples from each condition in every batch, so that batch can be included as a covariate in the model (Section 7.4); and use **paired designs** where possible, for example tumour and normal tissue from the same patient, or before and after treatment in the same individual, so that the comparison is made within each individual and differences between individuals cancel out. Such design decisions must be made before the experiment; they cannot be repaired in the analysis.

7.3.2 The analysis workflow

A standard analysis has the following steps (Conesa et al. 2016):

1. **Quality control** of the reads: base qualities, adapter content, duplication and rRNA contamination.
2. **Alignment or quantification**, described below.
3. **Counting** reads per gene, or estimating abundances per transcript.
4. **Normalisation** for sequencing depth and composition.
5. **Exploratory analysis**, such as PCA and clustering, to detect outliers and batch effects (Section 7.4).
6. **Statistical testing** for differential expression, and interpretation with gene sets and pathways (Section 7.5).

Each step rests on assumptions, and an observed difference can have several explanations besides regulation within cells: a change in cell composition, poor RNA quality, protocol bias, errors in the annotation or a batch effect (Figure 7.1). A longer gene list does not repair a flawed design.

7.3.2.1 Quality control

Quality control is a diagnosis of how the data were generated, not an automatic filter. Before alignment, base qualities, adapter content, over-represented sequences and per-cycle base composition are checked (Section 5.4). After alignment, the useful statistics are specific to RNA: the fraction of uniquely mapped reads, the fractions of ribosomal and mitochondrial reads, strand specificity, splice-junction support and the coverage along gene bodies. Degraded RNA gives a characteristic **3′ bias**, since fragments

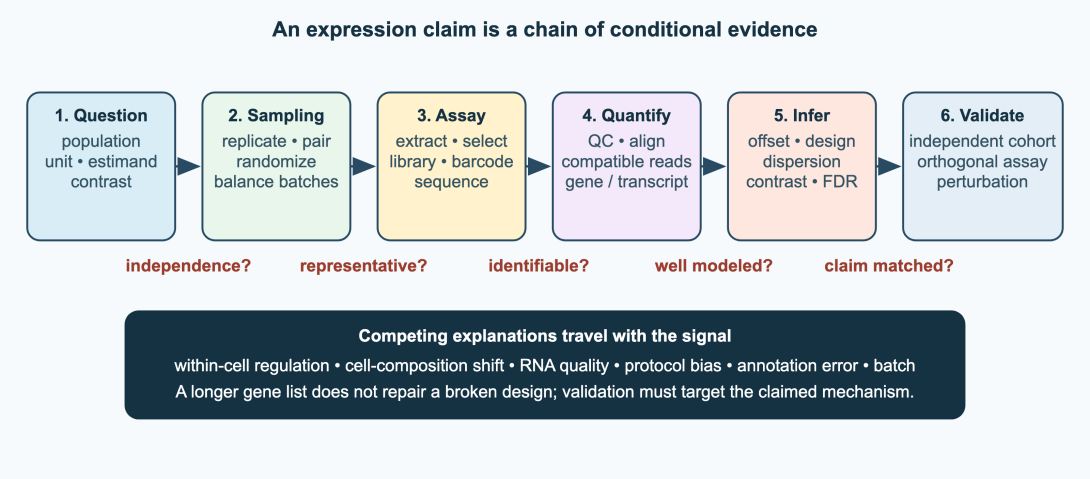

Figure 7.1: An expression result as a chain of evidence, from the biological question to validation. Each step has its own question that must be answered before the next can be trusted. Figure: Matteo Tadiello, *Modern Bioinformatics: From Foundations to Frontiers* (CC BY 4.0).

near the poly(A) tail survive best. At the level of samples, PCA, sample correlations and clustering show whether samples group by condition or by processing batch, and genotypes called from the reads can confirm that each sample comes from the expected individual. An outlying sample is a reason to investigate, not to exclude: exclusion rules should be decided before the results are known, and conclusions checked with and without doubtful samples. The SEQC/MAQC-III consortium sequenced reference RNA mixtures at many sites and showed that platform, site, expression level and analysis pipeline all affect the results, while relative expression measures were reproducible across sites ("A Comprehensive Assessment of RNA-Seq Accuracy, Reproducibility and Information Content by the Sequencing Quality Control Consortium" 2014).

7.3.2.2 Spliced alignment

RNA-seq reads come from spliced transcripts, so a read that spans an exon–exon junction aligns to the genome in two parts separated by an intron, which may be tens of kilobases long. Ordinary DNA read mappers (Section 5.4) cannot handle this. **TopHat** first mapped reads that align without gaps, predicted junctions from them and then aligned the remaining reads across those junctions (Trapnell et al. 2009). **STAR** searches for the longest prefix of the read that matches the genome exactly (the *maximal mappable prefix*) using an uncompressed suffix array, then repeats the search for the rest of the read, and stitches the pieces together (Dobin et al. 2012). It is very fast but needs about 30 GB of memory for the human genome. **HISAT2** uses a hierarchical graph FM-index with much smaller memory requirements (Kim et al. 2019).

7.3.2.3 Transcript assembly

Alignments can be used to reconstruct the transcripts themselves. **Reference-guided assembly**, with Cufflinks (Trapnell et al. 2010) or StringTie (Pertea et al. 2015), builds a graph of overlapping alignments for each gene and finds a small set of transcripts that explain the reads, which can reveal new isoforms. Cufflinks used a minimum path cover of the overlap graph, the most parsimonious set of transcripts. In organisms without a reference genome, transcripts are assembled **de novo** with de Bruijn graph methods such as Trinity (Grabherr et al. 2011) (Section 5.3).

7.3.2.4 Quantification and pseudo-alignment

The simplest quantification counts the reads that overlap each gene. Estimating the abundance of individual **transcripts** is harder, because isoforms of the same gene share most of their exons, so many reads are compatible with several transcripts. RSEM solves this with the **expectation–maximisation** (EM) algorithm: it alternates between assigning each read fractionally to transcripts in proportion to their current abundance estimates, and re-estimating the abundances from these assignments (Li and Dewey 2011).

Aligning every read base by base is not necessary for quantification. It is enough to know *which* transcripts a read is compatible with. **kallisto** introduced **pseudo-alignment**: it builds a de Bruijn graph of the transcriptome, looks up the k-mers of each read, and intersects the sets of transcripts that contain them (N. L. Bray et al. 2016). Reads with the same set of compatible transcripts form an *equivalence class*, and the EM algorithm then runs on the counts of these classes. **Salmon** uses a similar *selective alignment* and models sequence-specific, fragment-GC and positional biases (Patro et al. 2017). These methods are one to two orders of magnitude faster than alignment and similarly accurate for known transcripts, but they cannot discover new ones.

7.3.2.5 Long-read RNA-seq

Short reads cover only a small part of a transcript, so the full isoform must be inferred by assembly or by EM, and different combinations of exons far apart in the same gene are hard to resolve. Long-read platforms (PacBio and Oxford Nanopore; Section 5.2) can sequence complete cDNA molecules, and nanopore sequencing can also read native RNA directly. Each read then shows one **full-length isoform**, with its exact combination of exons, its start and end sites and its poly(A) tail, so no assembly is needed. Reads are aligned to the genome with spliced aligners such as minimap2 (Li 2018), and grouped into known and new transcripts. This has made long reads the method of choice for **transcript discovery** and for building isoform catalogues, and has shown that many genes have more isoforms than annotated (Pardo-Palacios et al. 2024). The drawbacks are fewer reads per sample, higher error rates on some platforms (notably direct RNA sequencing), which make exact splice sites harder to call, truncated reads from degraded RNA, and a bias towards shorter molecules. Short reads are therefore still often used for quantification, sometimes in combination with long reads.

7.3.3 Normalisation

Raw counts are not comparable between genes or samples. Longer transcripts produce more fragments, and samples sequenced more deeply produce more reads. A gene with twice as many reads as another is therefore not necessarily twice as highly expressed. Several units correct for these effects:

- **CPM** (counts per million) divides by the library size and corrects for depth only.
- **RPKM/FPKM** (reads or fragments per kilobase of transcript per million mapped reads) also divides by the transcript length (Mortazavi et al. 2008).
- **TPM** (transcripts per million) first divides each count by the transcript length, and then scales so that the values in each sample sum to one million:

$$\mathrm{TPM}_i = \frac{c_i/\ell_i}{\sum_j c_j/\ell_j} \times 10^6,$$

  where c_i is the count and ℓ_i the effective length of transcript i. TPM estimates the relative molar concentration of each transcript and, unlike RPKM, sums to the same total in every sample (Wagner et al. 2012).

These units do not handle **composition bias**. RNA-seq data are *compositional*: a library contains a fixed number of reads sampled from the RNA in it, so the counts measure each gene's share of the library, not its absolute amount. If a few genes are very highly expressed in one sample, they take up a large share of the reads, and all other genes appear lower even if their true expression is unchanged. Methods for differential expression therefore estimate normalisation factors under the assumption that most genes are not differentially expressed:

- **TMM** (trimmed mean of M-values), used by edgeR, computes the weighted mean of log-ratios between a sample and a reference sample after trimming the most extreme genes (Robinson and Oshlack 2010).
- The **median-of-ratios** method of DESeq computes, for each gene, the ratio of its count to the geometric mean of its counts across all samples. The median of these ratios in a sample is its *size factor* (Anders and Huber 2010; Love et al. 2014).

This assumption can fail. If the total amount of mRNA per cell changes, for example when a transcription factor such as MYC raises the expression of most genes, every gene's share of the library stays about the same, and all of these normalisations wrongly conclude that little has changed (Lovén et al. 2012). Detecting such global shifts requires an external reference, such as synthetic *spike-in* RNAs added in proportion to the number of cells.

TPM values are useful for comparing the relative abundance of transcripts within a sample. Because TPMs sum to the same total in every sample, they are still proportions, and they do not remove composition effects between samples; they are suitable for descriptive comparisons but are not a general normalisation. For differential expression, tools such as DESeq2 and edgeR take the raw (unnormalised) integer counts as input, not TPM or CPM values, and include the normalisation factors as offsets in the statistical model (Section 7.4).

7.4 Testing and statistics

Expression studies measure tens of thousands of genes in a handful of samples. This raises three statistical problems that appear throughout genomics: modelling the variability of the measurements with few replicates, testing thousands of hypotheses at once, and exploring high-dimensional data. The section starts with the general statistical background that is expected of every student, whatever their topic.

7.4.1 Statistical background

Most bioinformatics results end with a statistical statement: an E-value, a p-value for differential expression, a confidence in a phylogenetic split, an accuracy on a test set. You should be comfortable with the basic concepts and know their common pitfalls. The Nature Methods *Points of Significance* series (Statistics for Biologists) covers all of this in two-page articles and is the recommended starting point (Krzywinski and Altman 2013).

7.4.1.1 Probability and distributions

You should be able to explain conditional probability and **Bayes' theorem**,

$$P(H \mid D) = \frac{P(D \mid H)\,P(H)}{P(D)},$$

and use it on a simple example. A classic one: a test that detects a rare condition (1 in 1,000) with 99% sensitivity and 99% specificity still gives mostly false positives, because the few true cases are outnumbered by the 1% false positives among the many healthy people. The same base-rate argument explains why E-values must account for database size (Section 1.4) and why most predicted interactions or binding sites in a genome-wide screen are false.

Know the common distributions and when they arise: the **binomial** (number of successes in n trials), the **Poisson** (rare events, read counts at low coverage), the **normal** (sums of many small effects), the **negative binomial** (overdispersed counts, as in RNA-seq; Chapter 7) and the **extreme value** distribution (maxima, as in alignment scores; Section 1.4). Understand **likelihood**, the probability of the data given a model, and maximum-likelihood estimation. It underlies phylogenetics (Chapter 4), HMM training (Section 1.6) and much of machine learning.

7.4.1.2 Hypothesis tests and p-values

A statistical test compares the data with a **null hypothesis**. The **p-value** is the probability, *assuming the null hypothesis is true*, of observing data at least as extreme as those seen. It is not the probability that the null hypothesis is true, and a large p-value does not show that the null is true. A small p-value says nothing about how large or important an effect is: with enough data, a trivial difference becomes "significant". Report **effect sizes** with **confidence intervals**, not only p-values (Krzywinski and Altman 2013; Nuzzo 2014; Wasserstein and Lazar 2016).

You should know the most common tests and their assumptions:

- the **t-test** compares means. The one-sample test compares a mean with a fixed value, the two-sample test compares two groups, and the paired test compares two measurements on the same units. It assumes approximately normal data (or large samples) and, in its classic form, equal variances; **Welch's t-test** drops the equal-variance assumption and is usually the better default. The test statistic is the difference in means divided by its standard error;
- **non-parametric** alternatives, such as the Mann–Whitney (Wilcoxon rank-sum) and Wilcoxon signed-rank tests, use ranks and make fewer assumptions, at some cost in power;
- **χ^2 and Fisher's exact tests** for counts in contingency tables, for example enrichment of a GO term in a gene list (Chapter 10);
- **correlation** (Pearson for linear relationships, Spearman for monotonic ones), and why correlation does not imply causation;
- **permutation tests**, which build the null distribution by shuffling labels, and are useful when no standard test fits.

Know also the difference between **type I** errors (false positives, controlled by the significance level α) and **type II** errors (false negatives), and what determines **statistical power**: effect size, variability and sample size. Too few replicates is the most common reason for unreliable conclusions in genomics experiments.

7.4.2 Differential expression

The basic question is which genes change in expression between conditions. A t-test for each gene works poorly. With three replicates per group, the variance of each gene is estimated very imprecisely, and genes that happen to have a small sample variance get spuriously large t-statistics.

Moderated statistics. The solution, developed for microarrays, is to borrow information across genes. In the *limma* framework (Smyth 2004), an empirical Bayes model treats the true variances of all genes as drawn from a common prior distribution, estimated from all genes together. Each gene's variance is then *shrunk* towards the common value. The resulting moderated t-statistic is much more stable, and limma remains in use, also for RNA-seq data after a transformation that estimates the mean–variance relationship (voom) (Law et al. 2014).

Count models. RNA-seq produces counts. If the same library were sequenced repeatedly, the count of a gene would follow a Poisson distribution, with variance equal to the mean (Marioni et al. 2008). Between biological replicates, the variance is larger (*overdispersion*). The standard model is the **negative binomial** distribution, with variance

$$\mathrm{Var}(K) = \mu + \alpha\mu^2,$$

where μ is the mean and α the gene-specific *dispersion*. For highly expressed genes, the second term dominates, and $\sqrt{\alpha}$ is the biological coefficient of variation. edgeR (Robinson et al. 2009) and DESeq2 (Love et al. 2014) fit a **generalised linear model** for each gene, with a log link,

$$\log \mu_{ij} = \log s_j + \sum_r x_{jr}\beta_{ir},$$

where s_j is the normalisation factor of sample j (Section 7.3), x_{jr} the design matrix describing the samples (condition, batch, paired individuals) and β_{ir} the coefficients, such as the log fold change between conditions. As in limma, the dispersion of each gene is estimated with shrinkage towards a trend fitted across all genes. DESeq2 also shrinks the *fold changes*, so that large fold changes of low-count, noisy genes are not over-interpreted. Significance is assessed with Wald or likelihood-ratio tests. Including known batches and other covariates in the design matrix is the main way to deal with batch effects (Leek et al. 2010).

The tests answer slightly different questions. A **Wald test** divides an estimated coefficient, or a combination of coefficients, by its standard error. A **likelihood-ratio test** compares a full model with a reduced model without the terms of interest, and is the natural choice when the question involves several coefficients at once, such as any difference between several time points. The **quasi-likelihood F-test** of edgeR also takes into account the uncertainty in the estimated dispersion, and gives better control of false positives when there are few replicates (Lund et al. 2012). The test should follow from the question, not be chosen because it gives the most significant genes.

7.4.3 Design matrices, contrasts and interactions

The **design matrix** has one row per sample and one column per coefficient, and it states which comparisons the model can make. In a **paired design**, such as treated and untreated samples from the same donors, the model `~ donor + treatment` includes one coefficient per donor, so that the treatment effect is estimated *within* donors, and stable differences between donors are removed. A known batch is added in the same way, as long as it is not confounded with the condition. If two columns of the design matrix are identical, for example when all treated samples were processed in one batch,

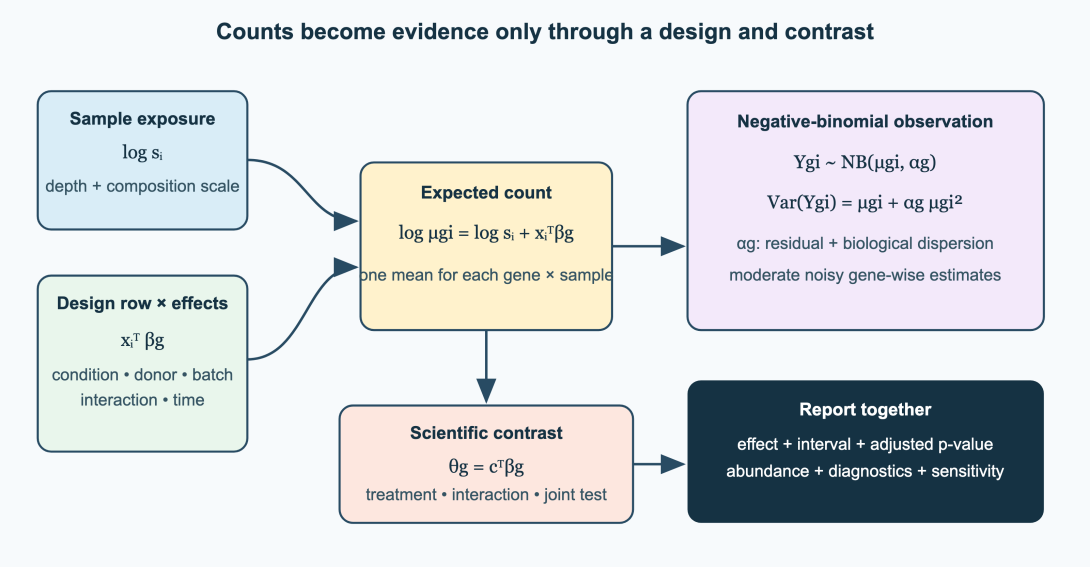

Figure 7.2: The negative binomial model of RNA-seq counts. The expected count of each gene in each sample combines a sample-specific offset for depth and composition with the design matrix and coefficients; the observed count varies around it with a gene-specific dispersion; a contrast of the coefficients answers the biological question. Figure: Matteo Tadiello, *Modern Bioinformatics: From Foundations to Frontiers* (CC BY 4.0).

the matrix is not of full rank and the two effects cannot be separated. Software that refuses to fit such a model is doing the right thing.

A **contrast** is a linear combination of coefficients, $c^T\beta$, that answers one question. In an experiment with two genotypes, A and B, each with and without treatment, the model `~ genotype + treatment + genotype:treatment` includes an **interaction** term. The interaction is a difference of differences:

$$(\mathrm{B}_{\mathrm{treated}} - \mathrm{B}_{\mathrm{control}}) - (\mathrm{A}_{\mathrm{treated}} - \mathrm{A}_{\mathrm{control}}),$$

and asks whether the response to treatment depends on the genotype. It is not the treatment effect in either genotype. A common error is to test the treatment in each genotype separately and conclude that the genotypes respond differently because the effect is significant in one and not in the other. The difference between "significant" and "not significant" is not itself significant (Gelman and Stern 2006); a non-significant result may simply reflect low power. Such errors were found in about half of the neuroscience papers that compared two effects in this way (Nieuwenhuis et al. 2011). The correct analysis tests the interaction directly. Contrasts should be written down, in words and as coefficients, before the analysis.

7.4.4 Differential transcript usage

Differential expression of a gene is not the only kind of change. A gene can switch between isoforms without changing its total expression: **differential transcript usage** (or exon usage) asks whether the *proportions* of the isoforms differ between conditions. This requires transcript-level quantification (Section 7.3), whose estimates are uncertain when isoforms share most of their sequence. Quantifiers such as Salmon and kallisto estimate this uncertainty by bootstrapping or Gibbs sampling, and transcript-level estimates can be summarised to genes for gene-level tests, which also improves those tests when isoform usage changes (Soneson et al. 2016). A claim about isoforms should only be made when the reads, for example unique exons or junctions, can actually distinguish them.

7.4.5 Multiple testing

If 20,000 genes are tested at a significance level of 0.05, about 1,000 will be called significant even if nothing changes. Two kinds of error rates are controlled:

- The **family-wise error rate** (FWER) is the probability of at least one false positive. The **Bonferroni correction** controls it by testing each of m hypotheses at level α/m. Holm's step-down method (Holm 1979) is uniformly more powerful and equally valid. FWER control is appropriate when any false positive is costly, but it is very conservative for genome-scale data (Noble 2009).
- The **false discovery rate** (FDR) is the expected proportion of false positives among the genes called significant (Benjamini and Hochberg 1995). It is the natural quantity when the result is a list of candidates for follow-up. The **Benjamini–Hochberg** procedure sorts the m p-values, $p_{(1)} \le \dots \le p_{(m)}$, finds the largest k for which $p_{(k)} \le \frac{k}{m}\alpha$, and rejects the hypotheses $1, \dots, k$. This controls the FDR at level α when the tests are independent or positively correlated.

The FDR is a property of the whole list, and an *expected* value over repeated experiments, not a statement about individual genes. A list called at FDR 5% is expected to contain about 5% false discoveries, but it does not mean that each gene in it has a 5% chance of being a false positive: genes near the cutoff are much more likely to be false than those with very small p-values.

Storey's **q-value** is the smallest FDR at which a gene would be called significant (Storey and Tibshirani 2003). It also estimates the proportion of true null hypotheses, π_0, from the flat part of the p-value histogram, which gives more power when many genes change. Efron's empirical Bayes approach estimates the **local false discovery rate**, the probability that a particular gene is null given its test statistic (Efron and Tibshirani 2002). The histogram of p-values is a useful diagnostic: under the null hypothesis p-values are uniformly distributed, so a peak near zero indicates true signal, while other shapes indicate problems with the model.

Statistical significance is not biological importance. The p-value depends on the effect size, the variability and the number of replicates, so a large fold change in a noisy, lowly expressed gene may not be significant, while with enough replicates very small fold changes become significant. A **volcano plot**, the $-\log_{10}$ p-value against the log fold change, shows both at once. Results are often filtered by both FDR and fold change, but there is no universal cutoff (such as a two-fold change): what matters depends on the gene and the biological question. Filtering on the estimated fold change after testing also undermines the FDR guarantee; it is better to test directly against a minimal relevant fold change, which both limma and DESeq2 allow (McCarthy and Smyth 2009; Love et al. 2014).

Removing genes before testing can increase power, because fewer tests are corrected for. **Independent filtering** removes genes with too few reads to give a significant result, using a statistic, such as the mean count over all samples, that is independent of the test statistic when the null hypothesis is true (Bourgon et al. 2010). DESeq2 does this automatically. A filter that uses the condition labels, such as keeping only genes that look different between the groups, is not independent and invalidates the FDR.

E-values in sequence searching (Section 1.4) are a built-in multiple-testing correction: they count the expected number of chance hits in the whole database. Be aware also of the *hidden* forms of multiple testing: trying several analyses and reporting the one that "worked", testing many subgroups, or choosing thresholds after seeing the data. These practices are a major reason why many published findings fail to replicate (Ioannidis 2005).

7.4.6 Clustering and dimensionality reduction

Expression data are high-dimensional: each sample is a point in a space with one dimension per gene, and each gene a point in a space with one dimension per sample. **Unsupervised** methods find structure

in these data without using the sample labels.

Clustering groups genes or samples with similar profiles. It requires a distance measure, such as Euclidean distance or one minus the correlation, which groups genes that go up and down together regardless of their absolute level.

- **Hierarchical clustering** repeatedly joins the two closest clusters, as in UPGMA (Section 4.3), and produces a tree (dendrogram). The distance between clusters is defined by the *linkage*: single (closest members), complete (most distant members) or average. Eisen's heat maps of hierarchically clustered genes and samples became the iconic display of expression data (Eisen et al. 1998).
- ***k*-means** partitions the data into k clusters by alternating between assigning each point to the nearest cluster centre and recomputing the centres. The number of clusters must be chosen, and the result depends on the starting point.
- Networks of co-expressed genes, built by thresholding correlations, are an alternative to clusters, and modules of co-expressed genes can be related to traits (Langfelder and Horvath 2008).

Principal component analysis (PCA) finds the orthogonal directions of largest variance in the data, computed from the singular value decomposition of the centred data matrix (Lever et al. 2017). Plotting samples on the first two or three components shows the main sources of variation. If samples group by processing date rather than by condition, there is a batch effect. PCA is linear, so the first components keep the large-scale structure of the data, and the fraction of variance explained by each component tells how much of the data the plot shows.

t-SNE (Maaten and Hinton 2008) and **UMAP** (McInnes et al. 2018; Becht et al. 2018) are non-linear methods that place similar points close together in two dimensions. They preserve local neighbourhoods and reveal clusters, which has made them the standard way to visualise single-cell data (Section 7.6). However, distances between clusters, cluster sizes and densities in such plots are not meaningful, and the layout depends on parameters and random initialisation. Two clusters that lie close together, or are joined by a bridge of cells, are not necessarily related by lineage or development, and well-separated islands can be artefacts of the method. They are tools for visualisation, not for quantitative analysis; clustering and trajectory inference should be done on the underlying data, such as the PCA space, not on the two-dimensional embedding (Chari and Pachter 2023).

7.4.7 Choosing and validating a clustering

Clustering always finds clusters. Hierarchical clustering returns a tree and k-means returns k groups even for random noise. The result depends on choices made before any algorithm runs, so a clustering is a hypothesis to be checked, not a finding in itself (D'haeseleer 2005).

Distance measure. The distance decides what "similar" means. *Euclidean distance* between two gene profiles is dominated by the absolute level: two highly expressed genes are close even if one rises when the other falls. *Correlation distance*, $d = 1 - r$, compares the shape of the profiles: genes that go up and down together are close, whatever their level. With $1 - |r|$, anticorrelated genes are also grouped together, which may be wanted for a repressor and its targets but mixes opposite responses. Spearman correlation is less sensitive to outliers. The two families are related: for profiles over n samples that are centred and scaled to unit variance, the squared Euclidean distance is $2(n-1)(1-r)$.

Scaling. Clustering is done on log-transformed or variance-stabilised values, so that a few very highly expressed genes do not dominate. When genes are clustered by the shape of their response, each gene is standardised (centred and divided by its standard deviation). When samples are clustered, the genes with the largest variance dominate the distance, which is why the analysis is usually restricted to the

most variable genes; standardising every gene instead gives the noise of flat, unexpressed genes the same weight as real signal. Strong batch effects become clusters of their own.

Linkage. In hierarchical clustering, *single* linkage tends to chain points into long, straggling clusters and is sensitive to noise; *complete* linkage gives compact clusters of similar diameter; *average* linkage (UPGMA) lies between them and is common for expression data; *Ward's* method joins the pair of clusters that least increases the within-cluster variance and, like k-means, favours compact, spherical clusters. A dendrogram becomes clusters only when it is cut at some height, and the left–right order of its leaves is partly arbitrary, because each node can be flipped. Neighbouring rows in a clustered heat map are therefore not necessarily similar.

How many clusters? There is rarely one correct number. Internal criteria compare the tightness of clusters with their separation. The *elbow* in the within-cluster sum of squares as a function of k is often unclear. The *gap statistic* compares this sum with that of reference data without cluster structure (Tibshirani et al. 2001). The *silhouette* of a point is $s = (b - a)/\max(a, b)$, where a is its mean distance to the other members of its own cluster and b its mean distance to the members of the nearest other cluster; s lies between -1 and 1, and an average close to zero means that the data have little cluster structure (Rousseeuw 1987). Model-based clustering with Gaussian mixtures can choose k with a criterion such as BIC.

Validation. *Stability* is tested by resampling: the samples or genes are subsampled or bootstrapped, the data re-clustered, and pairs of items that are grouped together consistently indicate robust clusters. Consensus clustering summarises this as a matrix of co-clustering frequencies (Monti et al. 2003). Stable clusters can still be artefacts, for example of batch. *External* validation asks whether the clusters mean something biologically: whether gene clusters are enriched in functional annotation such as GO terms (Gibbons and Roth 2002) (but see the caveats in Section 7.5), or whether sample clusters agree with known labels, measured for example with the adjusted Rand index. The strongest test is that the same clusters appear in an independent data set.

Biclustering. Ordinary clustering groups genes by their behaviour across *all* samples, but many genes are co-regulated only under some conditions or in some tumours. **Biclustering** searches for submatrices: subsets of genes with a coherent pattern over subsets of samples. It was introduced to expression data by Cheng and Church in 2000, and many algorithms followed (Madeira and Oliveira 2004). Matrix factorisations, such as non-negative matrix factorisation, address the same problem by letting a gene contribute to several overlapping programs.

7.4.8 Classification with many genes and few samples

Clustering is *class discovery*; predicting a known class, such as tumour type, response to a drug or survival, is *class prediction*, a supervised learning problem (4). The early leukaemia study did both (Golub et al. 1999). Expression data are extreme for supervised learning: the number of features p (about 20,000 genes) is far larger than the number of samples n (often tens to a few hundred), the $p \gg n$ **problem**. This has several consequences:

- With more genes than samples, a linear classifier can separate *any* labelling of the training samples perfectly, including random labels. Accuracy on the training data means nothing.
- Among thousands of genes, many correlate with the outcome by chance.
- Many different gene sets predict equally well, so a signature is not unique. Most random sets of genes are significantly associated with breast cancer outcome, because so many genes correlate with proliferation (Venet et al. 2011).

Models for this situation are simple and **regularised**: nearest shrunken centroids shrinks each class mean towards the overall mean, and genes for which every class mean is shrunk all the way to it drop out

of the classifier (Tibshirani et al. 2002); penalised regression (lasso, elastic net) and linear discriminant analysis with a diagonal covariance matrix are also common. How the penalties work is described in 4.

The most common error is **selection bias**. If the genes that best separate the classes are chosen using all samples, and a classifier on those genes is then cross-validated, the test samples have already influenced the model, and the estimated error can be close to zero even for random labels (Ambroise and McLachlan 2002; Simon et al. 2003). Gene selection, and the tuning of any penalty, are part of the model and must be repeated inside each cross-validation fold (nested cross-validation). Even a correctly cross-validated estimate comes from the same cohort, laboratory and platform. A clinical signature needs validation in an independent cohort, and must improve on the established clinical predictors, such as tumour grade and size, not only on chance.

7.5 From gene lists to biology

A differential expression analysis typically ends with a list of hundreds or thousands of genes. Interpreting such a list gene by gene is impossible, and individual genes are often not significant even when a whole pathway changes modestly. This section describes how gene lists are interpreted with prior knowledge, and how mRNA levels relate to protein levels.

7.5.1 What a change in expression means

A difference in the measured amount of a transcript does not by itself show that its transcription has changed. The amount of an RNA, M, is a balance between synthesis and degradation,

$$\frac{dM}{dt} = k_{\text{syn}} - k_{\text{deg}} M,$$

so that at steady state $M = k_{\text{syn}}/k_{\text{deg}}$. A higher level can result from faster transcription, from changes in processing or export, or from slower degradation, and an ordinary RNA-seq experiment cannot tell these apart. Methods that label newly made RNA, or that compare unspliced and spliced reads (as RNA velocity does; Section 7.6), are needed for that.

A bulk sample is also a **mixture of cell types**. The measured expression of gene g is approximately

$$A_g = \sum_c \pi_c \, a_{gc},$$

where π_c is the contribution of cell type c and a_{gc} the expression of the gene in that cell type. A_g can change because the expression within a cell type changes, or because the proportions of the cell types change, for example when a disease leads to an influx of immune cells into a tissue. These are different biological conclusions. Bulk data can be **deconvolved** into estimated proportions of cell types, using reference expression profiles of purified cells or single-cell data; CIBERSORT, for example, estimates the proportions of immune cell types from tissue expression profiles with support vector regression (Newman et al. 2015). Deconvolution depends on the reference being appropriate for the tissue. Single-cell data separate the two kinds of change directly (Section 7.6).

Finally, an expression study is usually exploratory, and its key results should be **validated** with independent samples or with a different method, such as quantitative PCR, in situ hybridisation, protein measurements or perturbation experiments. Gene set analysis summarises the same data in another way and is not an independent confirmation. Agreement between RNA and protein strengthens an association, but neither shows that the gene causes the phenotype.

7.5.2 Gene set analysis

Gene sets are groups of genes that share a function, a location or a regulatory mechanism: Gene Ontology terms (Section 2.6), pathways from KEGG or Reactome, targets of a transcription factor or microRNA, or signatures from earlier experiments. The Molecular Signatures Database (MSigDB) collects many such sets, including a small curated "hallmark" collection (Liberzon et al. 2015).

Over-representation analysis (ORA) asks whether a gene set is over-represented among the significant genes. With N genes in total, K of which belong to the set, and n significant genes, of which k are in the set, the probability of seeing k or more by chance is given by the **hypergeometric distribution** (equivalent to a one-sided Fisher's exact test):

$$P(X \geq k) = \sum_{i \geq k} \frac{\binom{K}{i}\binom{N-K}{n-i}}{\binom{N}{n}}.$$

Tools such as DAVID made this routine for many annotation types (Huang et al. 2008). ORA is simple, but it ignores the size of the changes and assumes that genes are independent. Two choices are part of the null hypothesis itself, not technical details. The first is the **background** (the universe of N genes): it should be the genes that were actually measured and could have been detected, not the whole genome. With the whole genome as background, any set of genes expressed in the tissue studied looks enriched, simply because unexpressed genes could never have been selected. The second is the **threshold** that defines the gene list: changing the FDR or fold-change cutoff changes n and k, and can change which sets are significant. Results that hold only for one background or one threshold should be treated with caution. Since thousands of gene sets are tested, multiple-testing correction is needed (Section 7.4), and because gene sets overlap heavily, the significant sets are often redundant.

Gene set enrichment analysis (GSEA) avoids the cutoff (Subramanian et al. 2005). All genes are ranked by a statistic of differential expression. For each gene set, a running-sum statistic walks down the ranked list, increasing when it meets a gene in the set and decreasing otherwise. The maximum deviation from zero, the *enrichment score*, is large when the members of the set are concentrated at the top or bottom of the list, similar to a Kolmogorov–Smirnov statistic. Significance is assessed by permuting the sample labels, which keeps the correlation between genes, or the gene labels, which is faster but ignores it. GSEA can detect pathways in which many genes change modestly, the typical situation in biology.

Methods differ in the null hypothesis they test. *Competitive* tests ask whether the genes in a set are more differentially expressed than other genes. *Self-contained* tests ask whether any of the genes in the

set are differentially expressed at all. Pathway methods that also use the topology of the network, and network-based approaches, are discussed in Chapter 11.

7.5.3 Co-expression and regulatory variation

Expression data also reveal relationships between genes. Genes with correlated expression across many conditions often share functions, which is used to predict function (Chapter 10) and to define modules (Langfelder and Horvath 2008). Combined with genotypes, expression becomes a quantitative trait: **expression quantitative trait loci** (eQTLs) are genetic variants associated with the expression of a gene. The GTEx project mapped eQTLs in about 50 tissues from nearly a thousand donors and found that almost all genes have genetic variants that affect their expression (The GTEx Consortium 2020). eQTLs are an important tool for interpreting the non-coding variants found in genome-wide association studies.

7.5.4 Protein-level expression

What matters for most cellular functions is the amount of protein, not mRNA. How well do mRNA levels predict protein levels? Early studies found correlations that were surprisingly low. A large study in mouse cells measured mRNA and protein levels and turnover for thousands of genes, and concluded that protein levels are determined mainly by translation rates (Schwanhäusser et al. 2011). A later reanalysis argued that much of the apparent discrepancy is due to measurement noise, and that across genes in steady state, mRNA levels explain most of the variation in protein levels, while during dynamic changes, and for comparisons of the same gene between conditions, post-transcriptional regulation is more important (Liu et al. 2016).

The **Human Protein Atlas** (HPA), a Swedish project started in 2003, combines RNA-seq of human tissues and cell lines with antibody-based imaging of the corresponding proteins, and classifies each gene by where it is expressed, from ubiquitous *housekeeping* genes to genes enriched in a single tissue (Uhlén et al. 2015). Mass-spectrometry and antibody-based measurement of proteins are described in Chapter 8, and the HPA in Section 2.8.

7.6 Single-cell genomics

Bulk RNA-seq measures the average expression of millions of cells. A tissue is a mixture of cell types, and even cells of the same type differ, so the average can hide the most interesting biology. **Single-cell RNA-seq** (scRNA-seq) measures the transcriptome of each cell separately. It has become one of the fastest-developing areas of genomics, with its own experimental methods, statistical models and analysis workflows (Luecken and Theis 2019; Heumos et al. 2023).

7.6.1 Technologies

The first single-cell transcriptome was published in 2009 (Tang et al. 2009). The number of cells that can be profiled in one experiment has since grown exponentially, from a handful to millions (Svensson et al. 2018):

- **Plate-based methods**, such as Smart-seq2 (Picelli et al. 2013), sort single cells into wells and produce full-length cDNA. They give high sensitivity and full transcript coverage for hundreds to thousands of cells.
- **Droplet-based methods**, such as Drop-seq (Macosko et al. 2015), inDrop (Klein et al. 2015) and the commercial 10x Genomics Chromium platform (Zheng et al. 2017), encapsulate single cells in nanolitre droplets together with beads carrying barcoded primers. Every transcript from the same cell gets the same **cell barcode**, so tens of thousands of cells can be sequenced together and separated computationally.
- **Combinatorial indexing** methods label cells in several rounds of split-pool barcoding without physically isolating them, and reach millions of cells.

Most high-throughput methods sequence only the 3' or 5' end of each transcript, and tag each original molecule with a **unique molecular identifier** (UMI), a random sequence added before amplification (Islam et al. 2013). Reads with the same UMI come from the same molecule, so counting UMIs instead of reads removes amplification bias.

7.6.2 Properties of the data

A typical cell contains a few hundred thousand mRNA molecules, of which only a few thousand to tens of thousands are captured. The data are therefore a very **sparse** matrix of counts, with most entries zero. Many zeros were first thought to be technical *dropouts* requiring special zero-inflated models, but for UMI data the number of zeros is largely what is expected from sampling a small number of molecules at the given sequencing depth, and negative binomial or Poisson models fit well (Svensson 2020). Whether extra zeros need to be modelled therefore depends on the protocol and the model; it may matter more for read counts from full-length, non-UMI protocols. Many observed zeros also reflect real biological differences between cell types. Other technical problems are specific to single cells: empty droplets, *doublets* (two cells with the same barcode), ambient RNA from lysed cells, and dying cells with high fractions of mitochondrial reads.

7.6.3 The analysis workflow

The standard workflow, implemented in the R package **Seurat** (Hao et al. 2021) and the Python package **Scanpy** (Wolf et al. 2018), consists of (Luecken and Theis 2019; Heumos et al. 2023):

1. **Quality control**: removing barcodes with too few genes, too many counts (possible doublets) or a high mitochondrial fraction.
2. **Normalisation** for the number of molecules captured per cell, for example by scaling and log-transforming, by pooling cells to estimate size factors (Lun et al. 2016), or with regularised negative binomial regression (Hafemeister and Satija 2019).
3. **Feature selection**: keeping the most variable genes.
4. **Dimensionality reduction** with PCA (Section 7.4).
5. Building a ***k*-nearest-neighbour graph** of cells in PCA space and **clustering** it with community-detection algorithms such as Louvain or Leiden (Traag et al. 2019).
6. **Visualisation** with UMAP or t-SNE.

7. Finding **marker genes** for each cluster and **annotating** the clusters as cell types, by comparison with known markers or by transferring labels from annotated reference atlases.

A cluster is a computational result, not automatically a cell type. The number of clusters depends on the resolution parameter, on the choice of genes and on batch correction; a continuous process such as differentiation can be cut into several arbitrary clusters; and residual batch effects, doublets or stressed cells can form clusters of their own. Annotation is therefore an inference that should be supported by several known markers, by biological context and, where possible, by independent validation, for example with imaging or protein markers.

Further analyses depend on the question:

- **Data integration.** Samples processed separately differ by batch effects, which must be removed before cells from different samples, individuals or technologies can be compared, without removing real biological differences. Harmony iteratively corrects the PCA embedding (Korsunsky et al. 2019). scVI uses a variational autoencoder, a deep generative model of the counts with batch as a covariate (Lopez et al. 2018). Integration is a trade-off between mixing the batches and keeping the biological variation, and a large benchmark found that the balance depends on the method and the preprocessing, in particular when biology and batch overlap (Luecken et al. 2021). If a disease state is present in only one batch, forcing the batches to mix can remove the disease signal. An integrated embedding is useful for clustering, visualisation and transfer of labels, but tests between conditions should go back to the uncorrected counts and a design that respects donors (Figure 7.3).
- **Trajectory inference.** Cells in development or differentiation form continua rather than discrete clusters. *Pseudotime* methods order cells along a path through expression space (Trapnell et al. 2014). **RNA velocity** uses the ratio of unspliced to spliced reads to estimate whether each gene is being switched on or off, and so predicts the future state of each cell (La Manno et al. 2018).
- **Differential expression** between conditions should be tested between *samples*, not between individual cells. Cells from the same individual share its genotype, environment and sample processing, so they are not independent biological replicates; the experimental unit is the individual (Section 7.3). Treating thousands of cells as replicates is pseudoreplication and gives very many false positives (Squair et al. 2021; Zimmerman et al. 2021). In **pseudobulk** analysis, the counts of all cells of one cell type are summed for each sample, and the resulting sample-level counts are analysed with bulk methods such as edgeR, DESeq2 or limma. Mixed models with the individual as a random effect are an alternative; a comparison of the two strategies found that pseudobulk methods performed well (Crowell et al. 2020). More cells improve the description of each individual, but only more individuals support conclusions about a population.
- **Differential abundance** asks a different question: whether the *proportions* of cell types or states differ between conditions, for example an expansion of a T-cell population in disease, rather than whether genes change within a cell type. Proportions are compositional, since an increase in one cell type must lower the share of the others, and they must also be compared between samples, not between cells. Methods test either the cluster proportions or local neighbourhoods in the kNN graph, which avoids depending on a fixed clustering (Dann et al. 2021).

7.6.4 Multimodal single-cell data

RNA is only one layer of a cell's state. **Multimodal** (*multiome*) methods measure more than one layer in the same cell, using the shared cell barcode to link them. CITE-seq adds oligonucleotide-tagged antibodies, so that surface proteins are counted together with the transcriptome (Stoeckius et al. 2017). Joint RNA and ATAC methods, such as the 10x Multiome kit, measure gene expression and chromatin accessibility (Section 6.9) in the same nucleus, which links candidate regulatory regions to the genes whose expression they correlate with. Because each modality has its own noise and sparsity, they

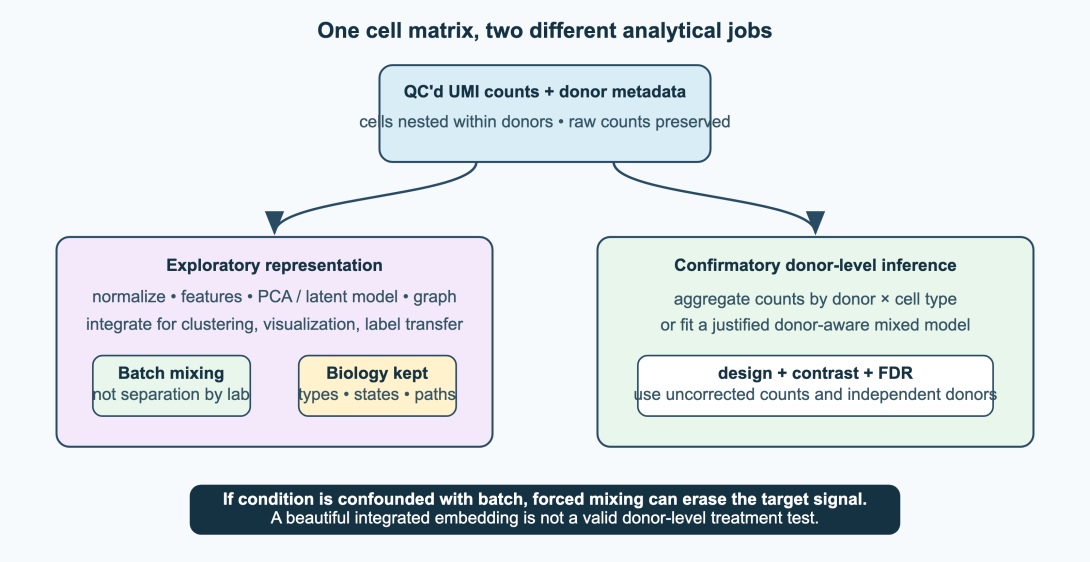

Figure 7.3: One single-cell count matrix supports two different analyses. Exploratory analyses of an integrated representation are used for clustering, visualisation and label transfer; tests between conditions aggregate the uncorrected counts by donor and cell type, or use mixed models with the donor as a random effect. Figure: Matteo Tadiello, *Modern Bioinformatics: From Foundations to Frontiers* (CC BY 4.0).

are first analysed separately and then combined, for example with Seurat's *weighted nearest neighbour* method, which learns for each cell how much to trust each modality (Hao et al. 2021). When modalities are measured in different cells, they can still be integrated by mapping both into a common space, but the link between them is then inferred rather than observed.

7.6.5 Spatial transcriptomics

Dissociating a tissue into single cells loses the information about where each cell was. **Spatial transcriptomics** measures expression while keeping its position, and was named Method of the Year 2020 by *Nature Methods* (Marx 2021). There are two families of methods:

- **Sequencing-based methods** capture RNA from a tissue section on an array of spatially barcoded spots. The method was developed in Stockholm by Patrik Ståhl, Joakim Lundeberg and colleagues (Ståhl et al. 2016) and commercialised as 10x Visium. Early spots were 100 µm across and contained several cells. Later methods, such as Slide-seq, reach near-cellular resolution (Rodriques et al. 2019).
- **Imaging-based methods**, such as MERFISH, detect individual RNA molecules in place with multiple rounds of fluorescent hybridisation, and measure hundreds to thousands of chosen genes at subcellular resolution (Chen et al. 2015).

Analysis tasks include identifying spatially variable genes and tissue domains, *deconvolution* of spots into mixtures of cell types using single-cell references, and the study of cell–cell communication between neighbouring cells. Spatial data bring their own statistical problems. Neighbouring spots are correlated (*spatial autocorrelation*), so methods that treat locations as independent overstate the evidence; tissue edges, histology and local cell density can mimic spatial patterns; and a single section is one sample, so conclusions about a tissue need replicate sections, ideally from several individuals. Platforms also differ in sensitivity as well as resolution, and the nominal spot size alone is not a sufficient basis for choosing between them (You et al. 2024). Spatial and multimodal methods are converging: spatial measurements of proteins and chromatin accessibility are being added to spatial RNA, and dissociated

single-cell multiome data are mapped onto tissue sections, so that each cell's type, regulatory state and position can be studied together.

7.6.6 Foundation models for single-cell data

Following the success of language models for proteins (Section 1.10), **foundation models** have been trained on tens of millions of single-cell transcriptomes. Geneformer represents each cell as a list of its genes ranked by expression, and learns with masked-gene prediction (Theodoris et al. 2023). scGPT uses a generative transformer (Cui et al. 2024). The models produce embeddings of genes and cells that can be fine-tuned for cell-type annotation, batch integration or the prediction of the effects of perturbations. Their value is still debated: independent evaluations found that, without fine-tuning, their embeddings often do not outperform simple baselines such as highly variable genes and PCA (Kedzierska et al. 2025), and that for predicting the effects of genetic perturbations they do not yet beat simple linear models (Ahlmann-Eltze et al. 2025). This is an area where students should expect rapid change, and where critical evaluation against simple baselines is essential (Chapter 12).

7.6.7 Cell types and cell atlases

Single-cell data have revived an old question: **what is a cell type?** Classically, cell types were defined by morphology, location, function or a few marker proteins. Single-cell transcriptomics proposes them as clusters in expression space, which raises new questions: at which resolution should clusters be cut, how do discrete types relate to continuous states, and how should types defined by expression be matched to those defined by other properties (Zeng 2022)? The **Human Cell Atlas** aims to map all cell types in the human body (Regev et al. 2017), and atlases of whole organisms, such as Tabula Muris (The Tabula Muris Consortium 2018) and Tabula Sapiens (The Tabula Sapiens Consortium 2022), provide references across organs. Such references, together with ontologies of cell types, make it possible to annotate new data sets automatically. The atlases, and the efforts to build models of cells from them, are discussed further in Section 13.7.

7.7 Single-cell sequencing and cancer evolution

Cancer is an evolutionary process within the body. Single-cell methods have made it possible to follow this process cell by cell, and to apply to tumours the phylogenetic methods developed for species (Chapter 4).

7.7.1 Cancer as clonal evolution

In 1976 Peter Nowell proposed that tumours evolve like populations of organisms: they start from a single cell, and successive mutations followed by selection of the fittest subclones lead to increasingly malignant cell populations (Nowell 1976). The concepts of Chapter 3 apply directly: mutation, selection, drift and population size all shape a tumour, and the result is **intratumour heterogeneity**, genetically different subclones within the same tumour. This heterogeneity matters clinically, because a treatment that kills the dominant clone selects for resistant subclones, which then cause relapse.

Bulk sequencing of tumours measures the frequency of each mutation in a mixture of normal and tumour cells. *Clonal* mutations, present in all tumour cells, occurred early, while *subclonal* mutations, present in only some, occurred later. Sequencing several regions of the same tumour showed that a biopsy from one region misses many of the mutations, and that tumours evolve in a **branched** rather than a linear way (Gerlinger et al. 2012; McGranahan and Swanton 2017). Reconstructing the subclones and their phylogeny from bulk data is a deconvolution problem with many possible solutions (Schwartz and Schäffer 2017).

7.7.2 Single-cell DNA sequencing

Single-cell sequencing removes the need for deconvolution. A cell contains only two copies of its genome, about 6 pg of DNA, which must be amplified before sequencing, and whole-genome amplification introduces errors, uneven coverage and the loss of one allele (*allelic dropout*) (Gawad et al. 2016). Copy-number changes, which affect large regions, can nevertheless be measured robustly even with very shallow sequencing of each cell. Navin and colleagues used single-nucleus sequencing of breast tumours to show that copy-number profiles grouped cells into a few major clones, and that a tumour can arise through a short burst of large genomic changes followed by stable clonal expansion (*punctuated* evolution) (Navin et al. 2011). High-throughput single-cell DNA sequencing of thousands of cells later showed that breast tumours maintain a reservoir of subclonal diversity during their growth (Minussi et al. 2021).

Trees of single cells are built with methods adapted from phylogenetics (Section 4.3), with models that account for the specific errors of single-cell data, such as allelic dropout and false-positive mutations, and for the fact that copy-number changes are not independent events at single sites (Schwartz and Schäffer 2017). Many mutation-tree methods rest on the **infinite-sites assumption**: each site mutates at most once in the history of the tumour, and a mutation, once gained, is never lost. Cancer genomes violate this. A deletion or a loss of heterozygosity can remove a mutation from a subclone, and copy-number changes alter the number of copies of a mutated allele, which also distorts the variant allele frequencies used in bulk deconvolution. In addition, a single biopsy or a small sample of cells may miss subclones altogether. Trees inferred under the infinite-sites model should therefore be read as hypotheses, and newer methods relax the assumption, for example by allowing mutation losses or by modelling single-nucleotide and copy-number changes jointly.

7.7.3 Single-cell transcriptomics of tumours

Single-cell RNA-seq of tumours measures both the cancer cells and the **tumour microenvironment**: immune cells, fibroblasts and blood vessels (Lawson et al. 2018). In glioblastoma, cells from the same tumour expressed programmes characteristic of different molecular subtypes, which had been defined from bulk data as properties of whole tumours (Patel et al. 2014). In metastatic melanoma, scRNA-seq separated malignant from non-malignant cells, identified cancer cell states associated with drug resistance and characterised the state of the infiltrating T cells (Tirosh et al. 2016).

Cancer cells are usually identified in scRNA-seq data by inferring large **copy-number changes** from the expression of neighbouring genes along each chromosome, since an amplified region raises the average expression of all its genes (Patel et al. 2014; Gao et al. 2021). This also makes it possible to group cancer cells into genetic subclones and link genotype to transcriptional state.

Single-cell studies have shown that not all heterogeneity is genetic. Cancer cells with the same genome can occupy different transcriptional or epigenetic states, and switch between them. Some of these states, such as slowly dividing *persister* cells, survive treatment without any resistance mutation. Integrating genetic and non-genetic heterogeneity, using multi-omic methods that measure DNA, RNA and chromatin in the same cell, and lineage tracing, is a major current goal (Nam et al. 2020).

7.8 Key concepts

A checklist for revision.

- **Before microarrays:** Northern blots, ESTs and SAGE
- **Microarrays:** spotted cDNA (two-colour) vs. Affymetrix oligonucleotide (one-colour) arrays; Illumina BeadArrays and SNP genotyping arrays; background correction, log transformation, MA plots and loess, quantile normalisation, RMA; MIAME and reproducibility; limitations (known sequences, cross-hybridisation, non-linear intensity response and dynamic range)
- **Landmark microarray studies:** co-expression clusters; cancer classification and breast cancer subtypes; expression signatures in the clinic; tissue atlases
- **RNA-seq experiments:** poly(A) selection vs. rRNA depletion; strand-specific libraries; sequencing depth; the experimental unit; biological vs. technical replicates, pseudoreplication and how many replicates are needed; batch effects and confounding; randomisation, blocking and paired designs
- **RNA-seq quality control:** RNA-specific statistics (unique mapping, rRNA and mitochondrial fractions, strandedness, gene-body coverage and 3′ bias); sample-level PCA and identity checks; outliers as a reason to investigate; the SEQC/MAQC-III reproducibility study
- **RNA-seq analysis:** spliced alignment (TopHat, STAR, HISAT2); reference-guided and de novo transcript assembly (Cufflinks, StringTie, Trinity); quantification with EM (RSEM); pseudo-alignment and equivalence classes (kallisto, Salmon); long-read RNA-seq for full-length isoforms and transcript discovery
- **Normalisation:** CPM, RPKM/FPKM, TPM and what TPM does not correct; compositional data and composition bias; TMM and median-of-ratios size factors; global shifts and spike-ins; raw counts as input to DE tools
- **Differential expression:** why a plain t-test fails; empirical Bayes and moderated statistics (limma, voom); Poisson vs. negative binomial models; dispersion and its shrinkage; GLMs and design matrices; fold-change shrinkage (DESeq2, edgeR); Wald, likelihood-ratio and quasi-likelihood F-tests
- **Statistical background:** Bayes' theorem and base rates; binomial, Poisson, normal, negative binomial and extreme value distributions; likelihood; p-values and what they are not; effect sizes and confidence intervals; t-tests, non-parametric, χ^2/Fisher and permutation tests; correlation; type I/II errors and power

- **Design and contrasts:** design matrices and full rank; paired designs (`~ donor + treatment`); contrasts; interactions as a difference of differences; why "significant in one group but not the other" is not a test of a difference
- **Differential transcript usage:** isoform proportions vs. total gene expression; uncertainty of transcript estimates; summarising transcripts to genes
- **Multiple testing:** FWER and Bonferroni; FDR and the Benjamini–Hochberg procedure; q-values and π_0; local FDR; why FDR is not a per-gene probability; p-value histograms; significance vs. effect size; volcano plots and fold-change thresholds; independent filtering
- **Clustering and dimensionality reduction:** distance measures; hierarchical clustering and linkage; k-means; co-expression networks; PCA; t-SNE and UMAP and their pitfalls (distances and proximity are not lineage)
- **Choosing and validating clusters:** clustering always finds clusters; Euclidean vs. correlation distance and what each groups together; log transformation, standardising genes and selecting variable genes; single, complete, average and Ward linkage; cutting a dendrogram; choosing k (elbow, gap statistic, silhouette, BIC); stability by resampling and consensus clustering; external validation with annotation and independent data; biclustering
- **Classification from expression data:** class discovery vs. class prediction; the $p \gg n$ problem and perfect separation of random labels; unstable signatures and random signatures; nearest shrunken centroids and penalised regression; selection bias when genes are chosen outside cross-validation; independent validation cohorts and clinical baselines
- **What an expression change means:** synthesis and degradation at steady state; bulk samples as mixtures of cell types; changes in composition vs. changes within cells; deconvolution (CIBERSORT); validation with independent samples and orthogonal methods
- **Interpretation:** gene sets and MSigDB; over-representation analysis and the hypergeometric test; choice of background and threshold; GSEA; competitive vs. self-contained tests; eQTLs and GTEx
- **mRNA and protein:** how well mRNA predicts protein levels; the Human Protein Atlas
- **Single-cell RNA-seq:** plate-based vs. droplet methods; cell barcodes and UMIs; sparsity and whether zeros are inflated; doublets, ambient RNA and QC; normalisation, HVGs, PCA, kNN graphs, Leiden clustering, UMAP; marker genes and annotation, and why clusters are not automatically cell types; integration (Harmony, scVI) and the trade-off between batch mixing and conserved biology; pseudotime and RNA velocity; pseudobulk differential expression and why cells are not replicates; differential abundance of cell types; multimodal data (CITE-seq, joint RNA+ATAC, weighted nearest neighbours)
- **Spatial transcriptomics:** sequencing-based (spatial barcodes, Visium, Slide-seq) vs. imaging-based (MERFISH); deconvolution; spatial autocorrelation and replicate sections
- **Foundation models:** Geneformer and scGPT; evaluations against simple baselines
- **Cell types:** what is a cell type; the Human Cell Atlas, Tabula Muris and Tabula Sapiens
- **Cancer evolution:** Nowell's clonal evolution; intratumour heterogeneity; clonal vs. subclonal mutations; branched and punctuated evolution; single-cell DNA sequencing and its errors; the infinite-sites assumption and how copy-number changes and loss of heterozygosity violate it; inferring copy number from scRNA-seq; tumour microenvironment; non-genetic heterogeneity and persister cells

7.9 Recommended reading

These papers are recommended for reading in full:

- Wang et al. (2009) — RNA-seq, a revolutionary tool for transcriptomics; why sequencing replaced arrays.

- Conesa et al. (2016) — a survey of best practices for RNA-seq data analysis, from design to interpretation.
- Love et al. (2014) — DESeq2; negative binomial models, dispersion and fold-change shrinkage.
- Benjamini and Hochberg (1995) — the false discovery rate; the most important idea in genome-scale statistics.
- Luecken and Theis (2019) — best practices in single-cell RNA-seq analysis, step by step.
- Nam et al. (2020) — cancer evolution studied with single-cell multi-omics.

Titles, abstracts, links and the full texts are in Section A.7; a longer list of further papers is in Section B.7.

7.10 Background reading (open access)

- **DNA microarray (Wikipedia)** — A DNA microarray is a collection of microscopic DNA spots attached to a solid surface. Scientists use DNA microarrays to measure the expression levels of large numbers of genes simultaneously or to genotype multiple regions of a genome. Each DNA spot contains picomoles of a specific DNA sequence, known as probes.
  https://en.wikipedia.org/wiki/DNA_microarray
- **RNA-Seq (Wikipedia)** — RNA-Seq is a next-generation sequencing (NGS) technique used to quantify and identify RNA molecules in a biological sample, providing a snapshot of the transcriptome at a specific time. It enables transcriptome-wide analysis by sequencing cDNA derived from RNA.
  https://en.wikipedia.org/wiki/RNA-Seq
- **Transcriptomics technologies (Wikipedia)** — Transcriptomics technologies are the techniques used to study an organism's transcriptome, the sum of all of its RNA transcripts. The information content of an organism is recorded in the DNA of its genome and expressed through transcription.
  https://en.wikipedia.org/wiki/Transcriptomics_technologies
- **Multiple comparisons problem (Wikipedia)** — Multiple comparisons, multiplicity or multiple testing problem occurs when many statistical tests are performed on the same dataset. Each test has its own chance of a Type I error, so the overall probability of making at least one false positive increases as the number of tests grows.
  https://en.wikipedia.org/wiki/Multiple_comparisons_problem
- **Bonferroni correction (Wikipedia)** — Bonferroni correction is a method to counteract the multiple comparisons problem in statistics. It is named after the mathematician Carlo Emilio Bonferroni.
  https://en.wikipedia.org/wiki/Bonferroni_correction
- **False discovery rate (Wikipedia)** — In statistics, the false discovery rate (FDR) is a method of conceptualizing the rate of type I errors in null hypothesis testing when conducting multiple comparisons. FDR-controlling procedures are designed to control the FDR, which is the expected proportion of "discoveries" that are false.
  https://en.wikipedia.org/wiki/False_discovery_rate
- **Bayes' theorem (Wikipedia)** — In probability theory, Bayes' theorem, named after Thomas Bayes, gives a mathematical rule for inverting conditional probabilities, allowing the probability of a cause to be found given its effect.
  https://en.wikipedia.org/wiki/Bayes%27_theorem
- **Student's t-test (Wikipedia)** — Student's t-test is a statistical test used to test whether the difference between the response of two groups is statistically significant or not. It is any statistical hypothesis test in which the test statistic follows a Student's t-distribution under the null hypothesis.
  https://en.wikipedia.org/wiki/Student%27s_t-test

- **p-value (Wikipedia)** — In null-hypothesis significance testing, the p-value is the probability of obtaining test results at least as extreme as the result actually observed, under the assumption that the null hypothesis is correct.
  https://en.wikipedia.org/wiki/P-value
- **Statistics for Biologists** — Nature's collection of short articles for biologists, including the *Points of Significance* column from Nature Methods, explaining p-values, power, multiple testing, regression, PCA and other statistical concepts.
  https://www.nature.com/collections/qghhqm
- **Think Stats** — Allen Downey's free book introducing probability and statistics through Python programming and exploratory data analysis.
  https://greenteapress.com/wp/think-stats-3e/
- **Principal component analysis (Wikipedia)** — Principal component analysis (PCA) is a linear dimensionality reduction technique with applications in exploratory data analysis, visualization and data preprocessing.
  https://en.wikipedia.org/wiki/Principal_component_analysis
- **Gene set enrichment analysis (Wikipedia)** — Gene set enrichment analysis (GSEA) (also called functional enrichment analysis or pathway enrichment analysis) is a method to identify classes of genes or proteins that are over-represented in a large set of genes or proteins, and may have an association with different phenotypes (e.g. different organism growth patterns or diseases).
  https://en.wikipedia.org/wiki/Gene_set_enrichment_analysis
- **Single-cell transcriptomics (Wikipedia)** — Single-cell transcriptomics refers to the quantification and analysis of the transcriptomes of individual cells. Single-cell transcriptomics makes it possible to unravel heterogeneous cell populations, reconstruct cellular developmental pathways, and model transcriptional dynamics.
  https://en.wikipedia.org/wiki/Single-cell_transcriptomics
- **Spatial transcriptomics (Wikipedia)** — Spatial transcriptomics, or spatially resolved transcriptomics, is a method that captures positional context of transcriptional activity within intact tissue.
  https://en.wikipedia.org/wiki/Spatial_transcriptomics
- **Somatic evolution in cancer (Wikipedia)** — Somatic evolution is the accumulation of mutations and epimutations in somatic cells during a lifetime, and the effects of those mutations and epimutations on the fitness of those cells. This evolutionary process has first been shown by the studies of Bert Vogelstein in colon cancer.
  https://en.wikipedia.org/wiki/Somatic_evolution_in_cancer

7.11 Student recommendations

Recommended by students preparing for the exam: papers, reviews, online lectures, tutorials and short explanations. To suggest something, use the suggestion form (SU login).

No recommendations yet.

7.12 Review problems

These problems are adapted from Matteo Tadiello, *Modern Bioinformatics: From Foundations to Frontiers* (CC BY 4.0), used with permission. For a longer treatment of this topic, see the chapters "Gene-Expression Analysis" and "Statistics and Machine Learning for Bioinformatics" of that book. In the HTML version, click a box to show the extensions, solution outline and common errors.

7.12.1 Designing a bulk RNA-seq experiment

A study aims to identify genes affected by a drug in cultures derived from patients. Formulate an experimental and statistical design that supports a conclusion about the patient population.

Extensions, solution outline and common errors

Extensions:

- What is a biological replicate, and is a technical replicate useful?
- Would you prefer more samples or more sequencing depth?
- How do you handle paired control and treated cultures from each patient?
- What if all controls were prepared in one batch and all treated samples in another?

Solution outline:

1. Define what is to be estimated: the average change associated with the drug within patients, in the target population.
2. Treat patients, not wells or reads, as the independent experimental units; base the sample size on the expected effect, the variability and the number of tests.
3. Pair treatment within patients, randomise and balance the processing, and decide the exclusion rules and the primary contrast in advance.
4. Use a design such as `~ patient + treatment`; add nuisance covariates that can be estimated, and an interaction only if the question requires it.
5. Once the coverage is adequate, prefer more biological replicates to deeper sequencing; technical replicates describe the measurement, not the population.
6. State that perfect confounding of treatment and batch cannot be repaired computationally.

Common errors:

- Calling several wells from one culture independent biological replicates.
- Choosing the number of samples from "typical RNA-seq practice" without considering the effect size or the dispersion.
- Promising that batch correction will recover a perfectly confounded treatment effect.
- Letting a PCA plot decide the design after the results are visible.

Connections: experimental design and replication (Section 7.3); power and statistical background (Section 7.4.1); sequencing technologies (Section 5.2).

7.12.2 Alignment versus pseudo-alignment

Decide whether RNA-seq reads should be aligned to a genome or assigned to a transcriptome by pseudo-alignment or lightweight mapping, for a specified biological analysis.

Extensions, solution outline and common errors

Extensions:

- What does pseudo-alignment keep, and what does it discard?
- How are reads compatible with several isoforms assigned?
- When is genome alignment necessary?
- What happens if the annotation is incomplete?

Solution outline:

1. Start from the feature of interest: gene abundance, transcript abundance, new splice junctions, fusion genes, allele-specific expression or evidence to inspect in a genome browser.
2. Explain spliced genome alignment as placing reads on genomic coordinates across introns, followed by counting or transcript assembly.
3. Explain equivalence classes of compatible transcripts and the probabilistic assignment of reads with a mixture likelihood and the EM algorithm.
4. Prefer fast transcriptome quantification for the abundance of annotated transcripts, and genome alignment for new features or questions that depend on coordinates.
5. Record the versions of genome, transcriptome and annotation, the strandedness and the treatment of multi-mapping reads.
6. Validate isoforms that are hard to distinguish with junction-specific or targeted evidence, and take the uncertainty of the estimates into account.

Common errors:

- Saying that pseudo-alignment means "no mapping".
- Assuming that paired-end reads uniquely identify every isoform.
- Ignoring mismatches between the reference genome and the annotation.
- Treating transcript estimates from shared reads as direct observations.

Connections: spliced alignment and quantification (Section 7.3); differential transcript usage (Section 7.4); exact matching and indexes (Section 1.4); read mapping (Section 5.4); gene annotation (Section 5.6).

7.12.3 Normalisation and composition effects

Explain why raw counts cannot be compared directly between libraries, and why testing TPM values does not in general give valid differential expression results that take replicates into account.

Extensions, solution outline and common errors

Extensions:

- What do TMM and the median-of-ratios normalisation of DESeq2 estimate?
- What is the difference between correcting for library depth and for transcript length?
- What if nearly all genes truly increase in every cell?
- Are spike-ins a complete solution?

Solution outline:

1. Counts depend on sequencing depth, library composition, feature length and protocol bias, as well as on abundance.
2. Describe TMM and median-of-ratios scaling as robust estimates of the relative depth, under the assumption that most genes do not change.
3. Include the scaling factors in the count model as offsets, and use the raw counts for inference.
4. Describe TPM as a length-adjusted proportion within a sample, useful for describing abundance but not a model of the variance between replicates.
5. Explain that a global change per cell cannot be detected from standard relative libraries without an external reference.

6. Discuss spike-ins and cell counts as additional assumptions rather than complete solutions.

Common errors:

- Equating normalised counts with absolute numbers of molecules per cell.
- Saying that normalisation makes all samples biologically identical.
- Applying batch correction or quantile normalisation before asking what signal it removes.
- Comparing RPKM or TPM values with a t-test, ignoring the dependence of the variance on the mean.

Connections: normalisation (Section 7.3); microarray normalisation (Section 7.2); relative and absolute quantification in proteomics (Section 8.4).

7.12.4 Negative binomial differential expression

Derive and interpret the negative binomial generalised linear model used by DESeq2 or edgeR for differential expression with replicates.

Extensions, solution outline and common errors

Extensions:

- Why not use a Poisson model?
- What is dispersion, and why is it shrunk?
- How do Wald, likelihood-ratio and quasi-likelihood tests differ?
- How should fold changes and the FDR be reported?

Solution outline:

1. Write $Y_{gi} \sim \mathrm{NB}(\mu_{gi}, \alpha_g)$ and $\mathrm{Var}(Y) = \mu + \alpha\mu^2$.
2. Write $\log \mu_{gi} = \log s_i + x_i^T \beta_g$, and define the offset, the row of the design matrix, the coefficients and the contrast.
3. Explain that the Poisson variance equals the mean and misses the overdispersion between biological replicates.
4. Explain how noisy dispersion estimates of individual genes are shrunk towards a trend fitted across all genes (empirical Bayes).
5. Use a Wald test for a single coefficient or contrast, a likelihood-ratio test for a question involving several coefficients, or a quasi-likelihood test to account for uncertainty in the dispersion.
6. Report the effect size, its uncertainty, the adjusted p-value and the abundance; shrinkage stabilises noisy estimates but does not create evidence.

Common errors:

- Calling dispersion only technical noise.
- Interpreting a shrunken log fold change as the observed change.
- Defining the FDR as the probability that a particular gene is a false positive.
- Choosing the test that gives the longest gene list.

Connections: differential expression and multiple testing (Section 7.4); linear models (4); peptide- and protein-level FDR (Section 8.4).

7.12.5 Contrasts, interactions and batch

A drug effect is statistically significant in wild type but not in a mutant. Does this show that the effect of the drug depends on the genotype? Formulate the appropriate test.

Extensions, solution outline and common errors

Extensions:

- Which contrast tests whether the effect differs?
- What if genotype and batch are correlated?
- What makes a design matrix rank-deficient?
- How would you analyse an experiment with several time points?

Solution outline:

1. Reject the comparison of two significance labels; test a difference of differences.
2. Specify $(\text{mut}_{\text{drug}} - \text{mut}_{\text{control}}) - (\text{WT}_{\text{drug}} - \text{WT}_{\text{control}})$ in a model with main effects and an interaction.
3. Include batch when it can be estimated; inspect the design matrix, and explain that perfect confounding makes separate coefficients impossible.
4. For time courses, test the condition-by-time terms jointly, for example with a likelihood-ratio test.
5. Keep the independent experimental unit and any repeated measurements explicit.
6. Interpret an interaction as a context-dependent association, not automatically as a mechanism.

Common errors:

- "Significant here, not significant there" as a test of interaction.
- Removing a batch effect until the groups look mixed in a PCA plot.
- Including more coefficients than the design supports.
- Treating repeated time points from the same individual as independent.

Connections: design matrices, contrasts and interactions (Section 7.4); batch effects and confounding (Section 7.3); linear models (4).

7.12.6 Single-cell differential expression

A data set contains 10,000 cells from each of three treated and three control patients. What is the sample size for a conclusion about the effect of treatment in the patient population? Formulate a valid analysis of differential expression within a cell type.

Extensions, solution outline and common errors

Extensions:

- Why are cells not independent replicates?
- What is pseudobulk analysis?
- Are zeros "dropouts" that require a zero-inflated model?
- How do you separate differential abundance from differential expression within a cell type?

Solution outline:

1. The sample size is six patients; the cells are nested measurements within patients.
2. Sum the UMI counts per patient and cell type (pseudobulk) and use a bulk count model, or use a mixed model with the patient as a random effect.
3. Treat UMI zeros as non-detections; do not assume extra zero inflation without evidence.
4. Distinguish a change of expression within a cell population from a change in the frequency of that population.
5. Check that each patient contributes enough cells, and show the results per patient.
6. Distinguish exploratory marker genes from tests between conditions.

Common errors:

- Reporting a tiny p-value driven by thousands of correlated cells.
- Downsampling cells and claiming that this creates biological independence.
- Confusing more immune cells with activation within immune cells.

Connections: single-cell analysis, pseudobulk and differential abundance (Section 7.6); experimental units (Section 7.3); pitfalls in evaluation (4).

7.12.7 Clustering, annotation and integration

After integration of several single-cell RNA-seq batches, the cells appear well mixed in a low-dimensional embedding. Is this enough to show that the integration was successful?

Extensions, solution outline and common errors

Extensions:

- What should be preserved, as well as mixed?
- Is a cluster a cell type?
- Can the corrected matrix be used for differential expression?
- What if a disease state occurs in only one batch?

Solution outline:

1. Define the purpose of the integration: visualisation, clustering, mapping to a reference or label transfer.
2. Assess batch mixing and the conservation of known cell types, continuous states, rare populations and marker genes separately.
3. Explain that biology confounded with batch cannot be recovered; forced mixing may erase a disease signal.
4. Annotate clusters with several positive and negative markers, reference data and consistency across samples.
5. Keep the uncorrected counts and use models that take patients into account for tests between conditions.
6. Compare several methods and parameters; an attractive UMAP is not validation.

Common errors:

- Treating maximal batch mixing as the only goal.
- Naming a cluster after one marker gene.
- Reading distances between clusters or cluster sizes literally from a UMAP.

Connections: single-cell analysis and integration (Section 7.6); clustering and dimensionality reduction (Section 7.4); unsupervised learning (4).

7.12.8 Spatial transcriptomics and validation

Design an analysis to determine whether an immune-response programme is localised at the boundary of a tumour, and distinguish spatial association from evidence of signalling between cells.

Extensions, solution outline and common errors

Extensions:

- Would you choose sequencing-based spatial transcriptomics or an imaging-based method?
- What does deconvolution of spots infer?
- Why is ordinary differential expression between spots risky?
- How would you validate a proposed ligand–receptor interaction?

Solution outline:

1. Define the boundary, the target genes, the spatial scale, and whether the aim is transcriptome-wide discovery or targeted measurement.
2. Choose sequencing-based capture for broad discovery, or imaging for targeted measurement of single molecules, balancing field of view, sensitivity and resolution.
3. Align expression to histology, account for spots that contain several cells, segmentation errors and spatial autocorrelation.
4. Use replicate sections from several patients or animals; neighbouring spots are not independent individuals.
5. Describe deconvolution as inference of mixtures that depends on a reference, not as direct observation of single cells.
6. Validate expression with an independent imaging method, and signalling with protein localisation, perturbation or a functional response; co-expression alone is a hypothesis.

Common errors:

- Equating the nominal spot size with single-cell resolution.
- Treating an inferred cell type as observed ground truth.
- Inferring physical signalling from ligand and receptor transcripts alone.
- Generalising from one striking tissue section.

Connections: spatial transcriptomics (Section 7.6); what an expression change means (Section 7.5); protein interactions and networks (Section 11.3).

7.12.9 Statistical evidence and biological importance

A transcript has an estimated treatment log fold change of 0.35 and a nominal p-value of 0.003. Interpret these quantities without overstating the evidence.

Extensions, solution outline and common errors

Extensions:
Define the null model and tail event. Contrast a frequentist confidence interval with a Bayesian credible interval. Explain how low power, pseudoreplication, and selective reporting change the interpretation. State what additional evidence is required before describing the transcript as biologically important.
Solution outline:
The p-value is the probability, under the null model and its assumptions, of a test statistic at least as extreme as the observed statistic. It is neither the probability that the null is true nor the probability that the finding arose by chance. The coefficient estimates a conditional contrast on the model scale; its biological magnitude must be evaluated using an uncertainty interval, assay characteristics, covariate structure, and an appropriate multiplicity procedure. A 95% frequentist confidence procedure has 95% repeated-sampling coverage under the model, whereas a Bayesian credible interval has a posterior-probability interpretation conditional on the likelihood and prior. Independent replication and functional evidence are needed for a mechanistic claim.
Common errors:
Interpreting $p = 0.003$ as a 0.3% probability that the null is true; equating statistical significance with biological relevance; treating non-significance as proof of no effect; counting cells or technical replicates as independent organisms.

Connections: Section 7.4.1 (hypothesis tests and p-values); Section 7.4 (differential expression); Section 8.4 (error control in proteomics); Section 12.8 (prediction and causation).

7.12.10 Multiple testing and false-discovery control

A study tests 20,000 genes. Derive the Benjamini–Hochberg procedure and explain precisely what its false-discovery-rate guarantee does and does not mean.

Extensions, solution outline and common errors

Extensions:
Contrast FDR with family-wise error rate. Discuss independence, positive dependence, and arbitrary dependence. Explain adjusted p-values, q-values, independent filtering, and the need to define a hypothesis family before inspecting results.
Solution outline:
Let V be false rejections and R total rejections. FDR is $E[V/\max(R,1)]$, whereas FWER is $P(V \geq 1)$. Sort the m values so that $p_{(1)} \leq \cdots \leq p_{(m)}$, find the largest k satisfying $p_{(k)} \leq kq/m$, and reject through k. The original BH result assumes independent tests, with extensions to specified positive-dependence structures; Benjamini–Yekutieli provides a more conservative option under arbitrary dependence. The guarantee concerns a repeated-study expectation for a pre-specified family, not the probability that a particular reported gene is false.
Common errors:
Declaring that exactly 5% of reported genes are false; applying BH only after favourable tests have been selected; assuming correlated molecular features either invalidate every FDR method or remove the need for correction.

Connections: Section 7.4 (multiple testing); Section 8.4 (target–decoy FDR); Section 10.4 (function annotation).

7.12.11 Tumour subtypes and a prognostic signature

A group profiles 80 breast tumours by RNA-seq. Hierarchical clustering of the tumours gives three clear groups in a heat map. The group then selects the 50 genes most associated with survival, trains a classifier on them and reports a cross-validated accuracy of 95%. Evaluate both claims.

Extensions, solution outline and common errors

Extensions:

- Which distance measure, scaling and linkage would you choose, and how do they change the result?
- How would you decide whether there are three groups rather than two or five?
- How should the cross-validation have been done?
- What would convince you that the signature is clinically useful?

Solution outline:

1. Clustering always returns groups; the heat map alone is not evidence of subtypes.
2. State the choices: variance-stabilised data, the most variable genes, correlation or Euclidean distance on standardised genes, and the linkage; check that the groups survive other reasonable choices.
3. Assess the number of clusters with silhouettes or the gap statistic, and stability by resampling tumours and genes (consensus clustering).
4. Check that the groups do not follow batch, processing date or tumour purity, and validate them externally: known subtypes, enrichment of annotation, and replication in an independent cohort.
5. With $p \gg n$, selecting the 50 genes on all 80 tumours before cross-validation is selection bias; the selection must be repeated inside each fold, with nested cross-validation for any tuning.
6. Validate the final model on an independent cohort and show that it adds to clinical predictors such as grade, size and nodal status; compare with random gene sets of the same size.

Common errors:

- Treating a dendrogram as proof of discrete subtypes.
- Choosing k because the heat map "looks like" three groups.
- Reporting training or leaky cross-validated accuracy as performance on new patients.
- Interpreting the 50 selected genes as the causal drivers of outcome.

Connections: clustering and its validation, and classification with many genes (Section 7.4); landmark microarray studies (Section 7.2); regularisation, cross-validation and leakage (4).

8 Proteomics

> **From the exam description**
>
> Different proteomics methods. How are these used, algorithms.

8.1 Overview

Proteomics is the large-scale study of proteins: their identity, abundance, modifications, interactions, structures and locations. It is a broad field, built mainly on mass spectrometry, with its own instruments, algorithms and statistics, and with strong connections to the other chapters of this book. This chapter tries to cover as much of it as possible:

- mass spectrometry: history, instruments, bottom-up and top-down proteomics, fragmentation, acquisition strategies (DDA, DIA, targeted) and quantification (Section 8.2);
- algorithms for peptide identification: database search, spectral libraries, de novo sequencing with deep learning, and the prediction of spectra and retention times (Section 8.3);
- statistics: the target–decoy approach, Percolator, error control at different levels, the protein inference problem and quantitative statistics (Section 8.4);
- beyond abundance: post-translational modifications, interaction proteomics and hu.MAP, structural MS and spatial proteomics (Section 8.5);
- proteomics without MS: antibody-based proteomics and the Human Protein Atlas, affinity proteomics, multiplexed imaging and protein sequencing (Section 8.6);
- repositories, standards and the Human Proteome Project (Section 8.7).

8.2 Mass spectrometry methods

Proteomics studies the proteins themselves: which ones are present, how abundant they are, how they are modified, where they are and whom they interact with. mRNA levels predict protein levels only partly (Section 7.5), and many regulatory events, such as phosphorylation, cleavage and complex formation, happen only at the protein level. Proteomics is a broad field. Most of it is based on **mass spectrometry** (MS) (Aebersold and Mann 2003, 2016), and this section describes the instruments and experimental strategies. Methods that do not use MS are described in Section 8.6.

8.2.1 History

Mass spectrometry measures the mass-to-charge ratio (m/z) of ions. It was developed in the early twentieth century for atoms and small molecules, but proteins could not be analysed, because they could not be brought into the gas phase as intact ions. Proteomics before MS relied on **two-dimensional gel electrophoresis**, introduced by Patrick O'Farrell in 1975, which separates thousands of proteins by isoelectric point and size (O'Farrell 1975). Spots could be cut out and identified by Edman degradation, slowly, one protein at a time.

Two "soft" ionisation methods, published in 1988–1989, changed this:

- **Electrospray ionisation** (ESI): a solution is sprayed from a fine needle at high voltage, the droplets evaporate, and multiply charged ions of large molecules are released into the gas phase (Fenn et al. 1989). ESI works directly on the output of liquid chromatography.
- **Matrix-assisted laser desorption/ionisation** (MALDI): the sample is mixed with a matrix that absorbs laser light and releases mostly singly charged ions (Karas and Hillenkamp 1988; Tanaka et al. 1988).

John Fenn and Koichi Tanaka shared the 2002 Nobel Prize in Chemistry for these methods. In 1993 several groups showed that proteins could be identified by digesting them, measuring the masses of the peptides with MS (MALDI gives mostly singly charged ions, so the m/z gives the mass almost directly) and comparing these with the masses predicted from a sequence database, **peptide mass fingerprinting** (Henzel et al. 1993). Combined with the first complete genomes, which provided the databases, this started modern proteomics. The term *proteome* was coined in 1994.

8.2.2 Instruments

A mass spectrometer has an ion source, one or more **mass analysers**, which separate ions by m/z, and a detector. The main analysers differ in resolution, mass accuracy, speed and sensitivity:

- **Quadrupoles** filter ions with oscillating electric fields, letting only a chosen m/z through. They are robust and fast but have low resolution, and are used as filters and in targeted experiments.
- **Ion traps** store ions and eject them by m/z.
- **Time-of-flight** (TOF) analysers accelerate ions and measure how long they take to reach the detector; lighter ions arrive first. TOF is fast and has no upper mass limit. MALDI-TOF instruments are used for peptide mass fingerprinting and, in clinics, to identify bacteria.
- **Fourier-transform** analysers measure the frequency at which trapped ions oscillate, which depends on m/z. FT-ICR instruments use a strong magnet and give the highest resolution. The **Orbitrap**, invented by Alexander Makarov, traps ions in an electrostatic field around a central electrode and achieves very high resolution and mass accuracy (a few parts per million) without a magnet (Makarov 2000; Hu et al. 2005). Orbitrap instruments have dominated proteomics since the late 2000s.

Hybrid instruments combine analysers: a quadrupole selects precursor ions, which are fragmented in a collision cell and analysed in a TOF (**Q-TOF**) or an Orbitrap. Recent instruments add **ion mobility**, which separates ions by how fast they drift through a gas in an electric field. This depends on their charge and their size and shape (the *collisional cross section*), and adds a separation dimension between LC and m/z that can separate co-eluting peptides of similar m/z. In the timsTOF, ions are accumulated in a **trapped ion mobility spectrometry** (TIMS) device and released in order of mobility. The quadrupole is switched in step with this release, so that several precursors are selected for fragmentation within one mobility scan, which multiplies the rate of MS2 spectra (*parallel accumulation–serial fragmentation*, PASEF) (Meier et al. 2018). The same principle is used with DIA windows (dia-PASEF) (Meier et al. 2020).

The instrument never measures mass directly, only m/z. ESI produces peptide ions with several charges: a peptide of neutral mass M that has taken up z protons appears at $m/z = (M + z \cdot 1.007)/z$, where 1.007 Da is the mass of a proton. Each ion also appears as an *isotope envelope*, a series of peaks separated by $1/z$ caused by the natural abundance of ^{13}C. High resolution matters because resolving the envelope gives the charge state, and only then can the neutral monoisotopic mass be calculated from the measured m/z (*charge-state deconvolution*). This mass is what constrains the possible peptides. When this book speaks of the "mass" of a precursor or a peptide, it means the neutral mass inferred in this way.

8.2.3 Bottom-up and top-down proteomics

In **bottom-up** (shotgun) proteomics, proteins are digested into peptides, usually with trypsin, which cuts after lysine and arginine. The peptide mixture is separated by reversed-phase **liquid chromatography** (LC) coupled online to the mass spectrometer. As peptides elute, the instrument records a survey scan of intact peptide ions (**MS1**), selects precursor ions, fragments them and records the fragment spectra (**MS2**). This is **tandem mass spectrometry** (LC-MS/MS). Peptides are easier to separate, ionise and fragment than whole proteins, but the connection between a peptide and the protein it came from is lost, which leads to the protein inference problem (Section 8.4).

In **top-down** proteomics, intact proteins are measured and fragmented. This preserves the full *proteoform*, the exact combination of sequence variants, splice isoform and modifications of each molecule, but it is technically much harder, especially for large proteins (Toby et al. 2016). Large-scale top-down studies have shown that the products of one gene often appear as several distinct intact proteoforms (Tran et al. 2011). Top-down is not simply a better form of bottom-up proteomics. It trades depth and throughput for molecular resolution, and separation, charge-state deconvolution and fragmentation all become harder as the mass of the protein grows.

The difference matters for interpretation. Bottom-up depth came from digestion combined with multidimensional chromatography, as in the MudPIT analysis of the yeast proteome (Washburn et al. 2001), but digestion breaks the link between modifications on different peptides. Observing a phosphorylated peptide and an acetylated peptide from the same gene does not show that both modifications occur on the same molecule. **Middle-down** proteomics, which analyses longer peptides produced by less frequently cutting proteases, lies in between: it keeps more information on which modifications co-occur, for example on histone tails, while remaining easier than the analysis of intact proteins. A tryptic peptide can support a gene-level protein group, but it rarely establishes the intact proteoform.

8.2.4 Fragmentation and b- and y-ions

The most common fragmentation method, **collision-induced dissociation** (CID), and its beam-type variant HCD, collide peptide ions with gas molecules. The peptide breaks mainly at the amide bonds of the backbone. If the charge stays on the N-terminal fragment it is a **b-ion**; if it stays on the C-terminal fragment it is a **y-ion**. A complete series of b-ions (or y-ions) forms a ladder in which the mass difference between consecutive peaks equals the mass of one amino acid residue, so the sequence can in principle be read from the spectrum. In practice spectra are incomplete and noisy, and contain other ion types, neutral losses and peaks from co-fragmented peptides. Leucine and isoleucine have the same mass and cannot be distinguished. Electron-based fragmentation (ETD and ECD) cleaves a different backbone bond, producing c- and z-ions, and preserves labile modifications such as phosphorylation and glycosylation.

8.2.5 Acquisition strategies

How the instrument decides which ions to fragment determines what is measured:

- **Data-dependent acquisition** (DDA): after each MS1 scan, the instrument selects the most intense precursors (the *top N*) for fragmentation, and excludes them for a while so that other peptides get a chance. Each MS2 spectrum ideally comes from one peptide, which makes identification simple. But selection is semi-random, so different runs identify different peptides, and low-abundance peptides are missed, which causes many **missing values** across samples.

- **Data-independent acquisition** (DIA), introduced as **SWATH-MS** (Gillet et al. 2012; Ludwig et al. 2018), fragments *all* ions in a series of wide m/z windows that together cover the mass range, repeated throughout the LC run. Every peptide is fragmented in every run, which gives more complete and reproducible quantification. The price is that each MS2 spectrum is a mixture of fragments from many peptides, which requires dedicated algorithms (Section 8.3).
- **Targeted acquisition**: in **selected reaction monitoring** (SRM, also called MRM) on triple-quadrupole instruments, the instrument monitors only predefined pairs of precursor and fragment masses for a list of peptides (Lange et al. 2008). **Parallel reaction monitoring** (PRM) records full fragment spectra of selected precursors on high-resolution instruments (Peterson et al. 2012). Targeted methods are the most sensitive and accurate, and are used to validate biomarkers, but they measure only a few hundred peptides chosen in advance. A multi-laboratory study showed that targeted assays with isotope-labelled internal standards can be transferred between laboratories with good reproducibility, provided that sample preparation is standardised (Addona et al. 2009).

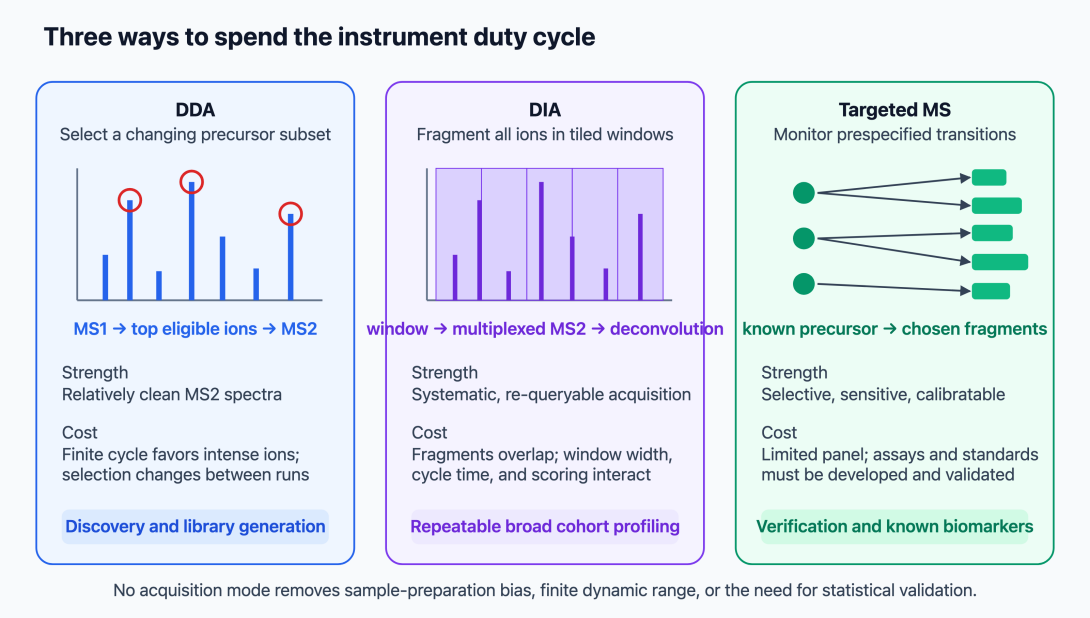

Figure 8.1: The three acquisition strategies. Data-dependent acquisition fragments a changing subset of the most intense precursors, data-independent acquisition fragments all ions in a series of m/z windows, and targeted acquisition monitors predefined precursor–fragment transitions. Figure: Matteo Tadiello, *Modern Bioinformatics: From Foundations to Frontiers* (CC BY 4.0).

All three strategies divide a limited **duty cycle** between scans. Chromatographic peaks last only seconds, and each peptide must be sampled several times across its peak for its area to be estimated. In DIA, the width of the isolation windows sets the trade-off: narrow windows mix fewer precursors and reduce interference, but more windows are needed to cover the mass range, which lengthens the cycle. Wide windows are fast but give more complex spectra. Variable-width windows, narrower where precursors are dense, are a common compromise. Offline fractionation before LC-MS reduces the complexity of each injection and increases depth, at the cost of instrument time and a more complicated pattern of missing values.

8.2.6 Quantification

Mass spectrometry is not inherently quantitative, since different peptides ionise with very different efficiency. Quantification therefore compares the *same* peptide between samples:

- **Label-free quantification** compares peptide intensities (the area of the MS1 peak over the elution time) or, more crudely, the number of spectra identified for each protein (*spectral counting*) between separate runs. It requires careful alignment of retention times and normalisation between runs. The MaxLFQ algorithm uses ratios of shared peptides between pairs of samples (Cox et al. 2014).
- **Metabolic labelling**: in **SILAC**, cells are grown with amino acids (usually arginine and lysine) containing heavy isotopes (Ong et al. 2002). Light and heavy samples are mixed before processing, and each peptide appears as a pair of peaks whose intensity ratio gives the relative abundance. Mixing early minimises technical variation.
- **Isobaric chemical tags**, **iTRAQ** (Ross et al. 2004) and **TMT** (Thompson et al. 2003), label peptides from up to 18 or more samples with tags of the same total mass, so that the same peptide from all samples appears as a single MS1 peak. On fragmentation, each tag releases a *reporter ion* of a different mass, whose intensities give the relative abundance in each sample. Multiplexing reduces missing values, but co-isolated peptides contribute reporter ions too, which compresses the measured ratios (*ratio compression*).
- **Absolute quantification** uses spiked-in heavy synthetic peptides of known amount (Gerber et al. 2003), or estimates absolute abundance from the sum of peptide intensities divided by the number of possible peptides (iBAQ) (Schwanhäusser et al. 2011).

None of these values is a count of molecules. Each method has its own biases. Label-free intensities depend on how well each peptide ionises, which is why only the same peptide can be compared between samples. Spectral counts are coarse, especially for proteins with few spectra, and favour long proteins, which give more peptides. Reporter-ion ratios are compressed by co-isolated peptides. Protein-level abundances are therefore relative measures between samples, unless they are calibrated with standards of known amount, as in AQUA. iBAQ values are approximations that are useful for ranking proteins within a sample, not exact copy numbers.

8.2.7 Experimental design and quality control

A proteomics result depends on a long chain of steps, from sampling and digestion to peptide identification, protein inference and statistics (Figure 8.2). Each step adds its own errors, and later computation cannot recover proteins that were lost or degraded before measurement.

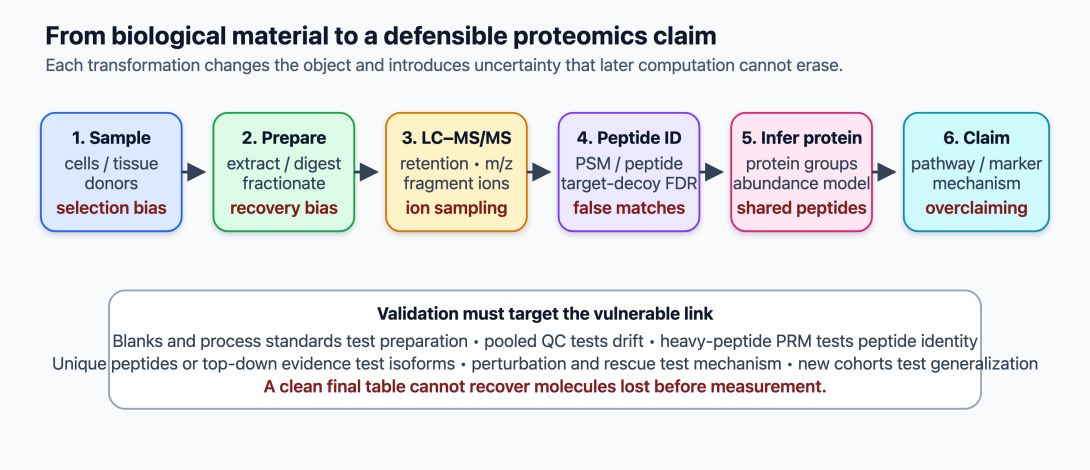

Figure 8.2: The chain of inference in a proteomics experiment. Each step, from sampling and preparation through LC-MS/MS, peptide identification and protein inference, introduces its own errors, and validation should target the weakest link. Figure: Matteo Tadiello, *Modern Bioinformatics: From Foundations to Frontiers* (CC BY 4.0).

The quantification strategies differ in how they handle the design:

- **SILAC** samples are mixed early, so later handling affects them equally. Incomplete labelling and the metabolic conversion of labelled arginine to proline can bias ratios, and a *label swap*, in which the heavy and light labels are exchanged between conditions in a replicate, reveals such bias. SILAC is limited to cells that can be grown in culture.
- **TMT** experiments with more samples than channels are split into several *plexes*. Comparisons within a plex are the most precise. A pooled reference sample included in every plex allows them to be put on a common scale (*bridging*), and conditions should be distributed evenly and randomly across plexes and channels. If a condition is confounded with a plex, no normalisation can separate the two. Ratio compression from co-isolated peptides can be reduced by narrower isolation windows or by a further round of fragmentation before reporter-ion measurement (MS3) (Ting et al. 2011).
- **Label-free** experiments measure every sample in a separate run, so drift of the LC and the instrument over time, and the order of the runs, must be monitored and randomised with respect to the conditions.

Quality control should be able to locate a failure, not only detect it. Common controls are blank injections, which reveal *carryover* from the previous sample; a pooled QC sample injected repeatedly during the run, which monitors drift; and standards added at different stages. A peptide standard added just before injection tests only the LC-MS system, whereas a protein standard added before digestion also tests digestion and recovery. Useful summaries include the rate of missed cleavages, mass errors, retention-time stability, the number of identifications per run and the coefficient of variation of the pooled QC samples. Finally, the unit of replication is the independent biological sample: repeated injections of the same digest, or several TMT channels made from one sample, are technical replicates.

8.3 Algorithms for peptide identification

A single LC-MS/MS run produces tens of thousands of fragment spectra. The central computational task is to work out which peptide produced each spectrum, a **peptide–spectrum match** (PSM). There are three approaches: comparing spectra with sequences in a database, comparing them with previously observed spectra, or reading the sequence directly from the spectrum (*de novo* sequencing). Since around 2019, deep learning has improved all three (Nesvizhskii 2010).

Terminology: from spectrum to protein group

- A **precursor** is the ion selected from the MS1 scan for fragmentation. It is a **peptide ion**: one peptide with a particular charge state (and particular modifications). The same peptide can give several precursors, for example with charge 2+ and 3+.

- A **peptide sequence** is the amino acid sequence itself, independent of charge. The same sequence with different modifications is sometimes called a different *peptidoform*.
- A **PSM** assigns one fragment spectrum to one peptide ion. Many PSMs can support the same peptide sequence.
- A **protein group** is the set of proteins that the observed peptides cannot distinguish (Section 8.4). It is usually what is reported, rather than a single protein or isoform.

Counts, error rates and quantities can refer to any of these levels, and a statement such as "5,000 identifications at 1% FDR" should say which.

8.3.1 Database search

Database search is the standard approach for organisms with a sequenced genome. For each experimental spectrum:

1. The protein database is digested *in silico* with the rules of the protease, and **candidate peptides** whose mass matches the precursor mass within a tolerance (a few ppm on modern instruments) are selected. The precursor mass is not measured directly: it is calculated from the measured m/z and the charge state inferred from the isotope envelope (Section 8.2).
2. For each candidate, a **theoretical spectrum** is generated, with the expected b- and y-ions.
3. A **score** measures the agreement between the experimental and theoretical spectra, and the best-scoring candidate is reported.

SEQUEST, from John Yates's laboratory, was the first such program (Eng et al. 1994). Its main score, *XCorr*, is the cross-correlation between the experimental spectrum and the theoretical one, minus the average correlation at shifted offsets, which corrects for random agreement. **Mascot** introduced a probability-based score, the probability that the observed number of matching peaks arises by chance (Perkins et al. 1999). Many others followed: X!Tandem (Craig and Beavis 2004), Andromeda, integrated in the widely used MaxQuant platform (Cox and Mann 2008; Cox et al. 2011), and MS-GF+, which computes exact score distributions with dynamic programming (Kim and Pevzner 2014).

A search score ranks the candidate peptides for one spectrum. A high score is not by itself a calibrated probability that the match is correct: score distributions differ between spectra, charge states and search spaces, and even a probability-based score such as Mascot's describes how unlikely the match is under a random-match model for that spectrum, not the error rate of a list of accepted PSMs. The FDR of a set of identifications must be estimated separately, with the target–decoy approach or another explicit error model (Section 8.4).

The size of the **search space** is a central issue. Allowing for variable post-translational modifications, non-specific cleavage, or sequence variants multiplies the number of candidates, which increases both search time and the chance that a random peptide scores well. *Open search* allows any mass difference between precursor and peptide, so that unexpected modifications can be discovered; MSFragger made this fast with an indexed fragment-ion database (Kong et al. 2017). In **proteogenomics**, the database is extended with peptides translated from genomic variants, new open reading frames or RNA-seq transcripts, which can reveal unannotated genes and improve gene annotation (Section 5.6). Such databases can be specific to the sample, for example built from the genome or RNA-seq data of the same tumour, so that peptides carrying the patient's own variants can be detected. Novel peptides need particularly strict error control: the extended database is larger, and a non-canonical peptide is a priori less likely to be correct than a canonical one, so its FDR should be estimated separately from that of the known peptides.

8.3.2 Spectral library search

Peptides that have been identified before have characteristic spectra, with reproducible relative intensities that the simple theoretical spectra of database search ignore. **Spectral library search** compares each spectrum with a library of previously identified, high-quality spectra, for example with a normalised dot product (Lam et al. 2007). It is faster and more sensitive than database search, but it can only identify peptides already in the library. Spectral libraries are also the basis of the analysis of DIA data.

8.3.3 De novo sequencing

De novo sequencing infers the peptide sequence from the spectrum alone, without a database. It is needed for organisms without a sequenced genome, for antibodies, whose sequences are generated by somatic recombination and mutation, for immunopeptidomics (peptides presented by MHC molecules, which are not tryptic), and for finding unexpected sequences.

The classical algorithms represent the spectrum as a **spectrum graph**: each peak is a node, interpreted as a possible b- or y-ion, and two nodes are connected by an edge if their mass difference equals the mass of one (or two) amino acids. The best path through the graph, found with dynamic programming, is the most likely sequence (Dančík et al. 1999). PEAKS combined this with careful scoring and became the standard commercial tool (Ma et al. 2003). The difficulty is that real spectra have missing fragment ions, noise peaks and ambiguous interpretations, so de novo methods were much less accurate than database search.

Deep learning has changed this. DeepNovo combined convolutional and recurrent neural networks to predict the sequence amino acid by amino acid (Tran et al. 2017). **Casanovo** treats de novo sequencing as a translation problem, from a "sentence" of peaks to a sequence of amino acids, using a transformer model, the architecture of large language models (Yilmaz et al. 2024). **InstaNovo** combines a transformer with a diffusion model that iteratively refines the predicted sequence, and was trained on tens of millions of spectra (Eloff et al. 2025). Such models, trained on very large collections of identified spectra from public repositories, are sometimes described as **foundation models** for peptide sequencing. They now identify many peptides with an accuracy approaching database search, and can find peptides that database search misses, although error control for de novo results is still less mature (Section 8.4).

8.3.4 Predicting spectra and retention times

The behaviour of a peptide in an LC-MS/MS experiment is largely determined by its sequence: its retention time on the chromatography column, the relative intensities of its fragment ions and, in ion-mobility instruments, its collisional cross section. Deep learning models now predict these properties accurately. **Prosit** predicts fragment intensities and retention times with a recurrent neural network trained on spectra of hundreds of thousands of synthetic peptides (Gessulat et al. 2019). **MS²PIP** predicts fragment intensities with gradient-boosted trees and deep learning (Gabriels et al. 2019). **AlphaPeptDeep** is a modular framework of neural network models, including transformers, for predicting spectra, retention times and collisional cross sections, which can easily be retrained for new modifications or instruments (Zeng et al. 2022).

Predicted properties are used in three ways:

- **Rescoring**: the agreement between the observed spectrum and the predicted one, which is much more specific than a simple theoretical spectrum, is added as a feature in rescoring (Section 8.4). This gives many more identifications at the same FDR, particularly for difficult cases such as non-tryptic immunopeptides.

- **Predicted spectral libraries**: libraries can be predicted for every peptide in a proteome, removing the need to build them experimentally.
- **DIA analysis**: DIA spectra mix fragments from many peptides, so they are analysed in a *peptide-centric* way. For each peptide in a (measured or predicted) library, the software extracts the chromatograms of its expected fragment ions at its expected retention time, and scores how well they co-elute and match the expected intensities, as in OpenSWATH (Röst et al. 2014). DIA-NN uses neural networks to separate true from false peptide signals and to correct for interference (Demichev et al. 2019). With predicted libraries, DIA can be analysed without any experimentally built library ("library-free" DIA).

8.4 Statistics and error control

Every spectrum gets a best-matching peptide, whether or not the correct peptide is in the database, and many spectra are noise or come from peptides that are not considered, so a large fraction of the top-scoring PSMs in a typical experiment are wrong. Error control is therefore the core statistical problem of proteomics, and it is addressed with ideas closely related to the false discovery rate in expression analysis (Section 7.4) (Nesvizhskii 2010).

8.4.1 The target–decoy approach

The **target–decoy** strategy estimates the number of false matches empirically (Elias and Gygi 2007). The spectra are searched against a database that contains the real (*target*) protein sequences and an equal number of *decoy* sequences that cannot be present in the sample, typically the target sequences reversed or shuffled. Decoys have the same size and amino acid composition as the targets, so a wrong match is equally likely to hit a target or a decoy. Above any score threshold, the number of decoy matches therefore estimates the number of false target matches, and

$$\widehat{\mathrm{FDR}} = \frac{\#\text{decoy matches above threshold}}{\#\text{target matches above threshold}}.$$

The threshold is chosen to give the desired FDR, usually 1% (here at the level of PSMs; see below for other levels), and, as in expression analysis, a **q-value** is computed for each PSM as the lowest FDR at which it would be accepted. The approach makes no assumptions about the score distribution and works with any search engine, which is why it became the standard. It assumes that decoys behave like random false matches, which can fail, for example if the decoy construction preserves too much of the target sequences or if the search space is very large.

In the usual *concatenated* search, targets and decoys compete for each spectrum, and only the best match is kept. Implementations differ in details, for example estimating the FDR as $(D+1)/T$ for D decoy and T target matches, which is slightly conservative, or rescaling when the decoy database is not the same size as the target database. With larger scores better, the q-value of a PSM with score s_i is

$$q_i = \min_{t \le s_i} \widehat{\mathrm{FDR}}(t),$$

the lowest estimated FDR of any threshold at which it is accepted. Two points are often misunderstood. First, an FDR is the expected proportion of errors in an accepted *list*: a PSM in a list at 1% FDR does not have a 1% chance of being wrong, since high-scoring PSMs are almost always right and those near the threshold much more often wrong. Second, a global FDR can hide much higher error rates in subgroups, such as modified peptides, unusual charge states, proteins identified by a single peptide or novel peptides (Section 8.3), which may need to be controlled separately.

Earlier, and complementary, approaches model the score distribution directly. **PeptideProphet** fits a mixture of two distributions, one for correct and one for incorrect PSMs, with the EM algorithm, and gives each PSM a **posterior error probability** (PEP), the probability that this particular match is wrong (Keller et al. 2002). The PEP is a local measure, like Efron's local FDR, while the q-value is a property of the whole list above a threshold.

8.4.2 Rescoring with machine learning: Percolator

A search engine score is only one of many features that distinguish correct from incorrect PSMs. Others include the mass error, the difference from the second-best score, the number of missed cleavages, the charge state, the retention time and, today, the similarity to a predicted spectrum (Section 8.3). **Percolator** combines them with a **semi-supervised** machine learning method (Käll et al. 2007). Decoy PSMs are known negatives. The best-scoring target PSMs are taken as provisional positives. A support vector machine is trained to separate the two sets, all PSMs are rescored, and the procedure is repeated with the new positives. Cross-validation prevents the classifier from overfitting. Percolator typically increases the number of PSMs or peptides accepted at 1% FDR by tens of percent, and the same principle is used in most current pipelines.

8.4.3 Levels of error control

Error rates can be controlled at several levels, and they are not the same:

- **PSM level**: each spectrum–peptide match.
- **Peptide level**: unique peptide sequences. Several spectra can match the same peptide, and correct peptides tend to be identified by more spectra than incorrect ones.
- **Protein level**: a protein (or protein group) is reported if at least one of its peptides is. Since false peptides are spread randomly over all proteins, while true peptides concentrate on a smaller number of proteins, a 1% FDR at the peptide level can correspond to a much higher FDR at the protein level, especially in large data sets. Protein-level FDR must therefore be estimated separately, for example with the *picked* target–decoy approach, which treats each target protein and its decoy as a pair (Savitski et al. 2015).

A "1% FDR" is therefore incomplete without its level: 1% of PSMs, of peptides or of protein groups are different statements, and an FDR controlled at one level does not control it at another. At the protein level, protein inference (below) adds a further ambiguity, because what is counted depends on how peptides are assigned to proteins and groups.

8.4.4 The protein inference problem

Bottom-up proteomics identifies peptides, but the biological questions are about proteins. This step is not a technical detail: every protein list, protein-level FDR and protein quantity in a proteomics paper depends on it. Many peptides are shared between several proteins: paralogues, isoforms produced by alternative splicing, and proteins with shared domains. Deciding which proteins are actually present is the **protein inference problem**. Observed peptides therefore rarely "identify the protein" directly. They are evidence for a set of candidate proteins, and the data often support only a group of them (Figure 8.3). The problem is most severe for splice isoforms, paralogues, immunoglobulins and other families of highly similar proteins (Nesvizhskii and Aebersold 2005).

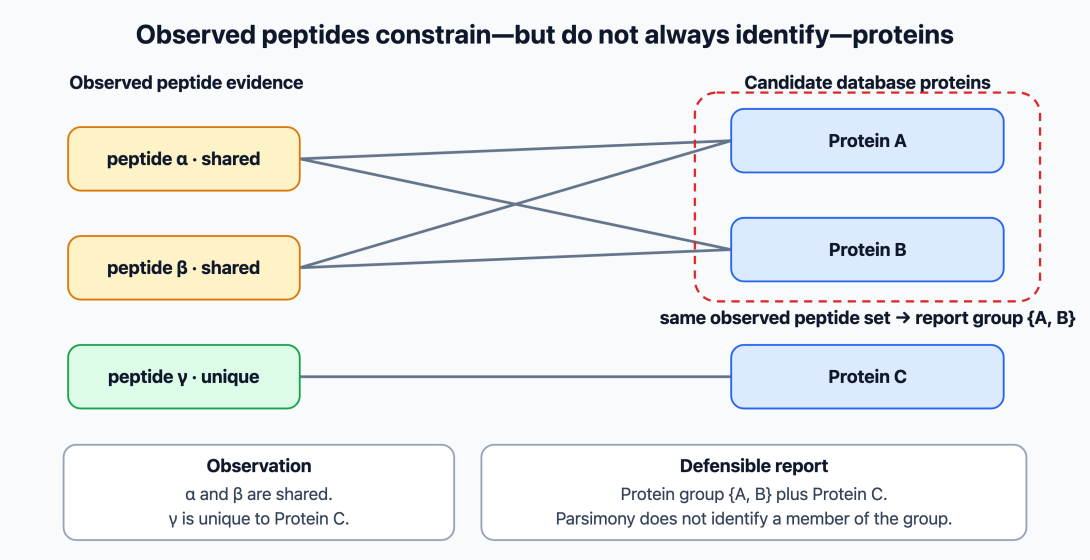

Figure 8.3: Protein inference. Peptides α and β are shared by proteins A and B, so they support only the group {A, B}, not either member alone, while peptide γ is unique to protein C. Figure: Matteo Tadiello, *Modern Bioinformatics: From Foundations to Frontiers* (CC BY 4.0).

The common solution follows the principle of **parsimony** (Occam's razor): report the smallest set of proteins that explains all observed peptides. Proteins that cannot be distinguished by the observed peptides are reported together as a **protein group**. ProteinProphet introduced a probabilistic version, which apportions shared peptides between proteins according to the evidence from their unique peptides (Nesvizhskii et al. 2003). Parsimony is a heuristic: a protein may be present even if all its peptides are shared with another, and conversely. Isoforms, in particular, can rarely be distinguished, because the peptides that would discriminate between them are often not observed. Software also differs in how shared peptides are used for quantification: some use only peptides unique to a group, others assign each shared peptide to the group with the most other evidence (the *razor* peptides of MaxQuant (Cox and Mann 2008)). The same peptide data can thus give different protein lists and quantities, depending on the rules used. Quantification makes this worse: if a shared peptide changes between conditions but the peptides unique to each isoform do not, the change cannot be assigned to one isoform. A transparent report separates unique, razor and shared peptides, and checks whether the conclusions change when shared or discordant peptides are excluded.

8.4.5 Statistics of quantification

Quantitative proteomics faces the same statistical problems as transcriptomics (normalisation, replicates, multiple testing, Section 7.4), with two additional complications. First, protein abundances are estimated from several peptides, which must be summarised robustly, since some peptides are shared or modified.

Second, **missing values** are frequent, often tens of percent of the peptide values in a label-free DDA data set, and they are not missing at random (Lazar et al. 2016). Some are *censored*: the peptide is present but below the detection limit, so it is more likely to be missing if it has low abundance. Others arise because the peptide was not selected for fragmentation or not identified in that run, which is closer to random. The two need different treatment. Simply ignoring missing values discards proteins that are present in one condition and absent from the other, which may be the largest changes, while replacing them with small values creates large fold changes that may be artefacts. Imputation with small values, models that treat low values as censored, or methods that transfer identifications between runs (*match between runs*) all affect the list of differentially abundant proteins considerably, and the chosen approach should be reported. Dedicated statistical packages, such as MSstats, fit linear mixed models at the peptide level and test proteins for differential abundance (Choi et al. 2014), and limma (Section 7.4) is also widely used.

8.4.6 Normalisation and differential abundance

A simple model of a label-free experiment helps to see what can and cannot be compared. The measured intensity of peptide p from protein i in sample s is approximately

$$I_{pis} \approx A_{is}\, R_{pi}\, E_{ps} + \varepsilon_{pis},$$

where A_{is} is the abundance of the protein, R_{pi} the response of the peptide (how well it is recovered and ionised), E_{ps} run-specific effects such as loading and interference, and ε_{pis} measurement error. Since R_{pi} varies enormously between peptides, intensities of different peptides cannot be compared directly, but the ratio for the same peptide between samples cancels it. Intensities are usually log-transformed, which makes these multiplicative effects additive.

Normalisation removes differences in E_{ps} that affect all peptides in a run, such as the amount loaded. Median or similar scaling assumes that most proteins do not change, and fails if most measured proteins really shift in one direction, or if the composition of the samples differs, for example between tissues. Normalising instead to internal standards, cell numbers or total protein answers a different question, and the choice should be stated. MaxLFQ postpones normalisation and estimates protein profiles from the ratios of peptides shared between pairs of samples (Cox et al. 2014).

For testing, the design (paired samples, batches, TMT plexes, repeated measurements) should be specified in the model before the results are examined. Moderated linear models and mixed models, as in limma and MSstats, borrow strength across proteins when replicates are few. Two different FDRs are involved in a typical study. The identification FDR decides which peptides and proteins enter the table; the FDR of the differential analysis decides which of them differ between conditions. Neither controls the other, and neither validates a subsequent pathway enrichment, which should use the measured proteins, not the whole proteome, as its background (Section 7.5).

8.5 Proteomics beyond protein abundance

Mass spectrometry measures much more than which proteins are present and how abundant they are. This section describes the analysis of post-translational modifications, interactions and complexes, protein structure, and the location of proteins in cells and tissues.

8.5.1 Post-translational modifications

Proteins are modified after translation by the addition of chemical groups (phosphate, acetyl, methyl, sugars), small proteins (ubiquitin, SUMO) or lipids, and by proteolytic cleavage. These **post-translational modifications** (PTMs) control activity, localisation, interactions and degradation, and they can only be measured at the protein level.

Phosphoproteomics is the most developed example. Phosphorylation of serine, threonine and tyrosine by kinases is the main mechanism of signalling in cells. Phosphopeptides are rare and their phosphorylation is often substoichiometric, so they are **enriched** before MS, typically with titanium dioxide or immobilised metal ions, or with antibodies against phosphotyrosine. Large-scale studies then measure tens of thousands of phosphorylation sites, and how they change over time after a stimulus (Olsen et al. 2006). Two computational problems are specific to PTMs:

- **Search space**: allowing each serine, threonine and tyrosine to be phosphorylated or not multiplies the number of candidate peptides.
- **Site localisation**: a peptide may contain several possible sites, and the spectrum must show which one carries the modification. Scores such as the Ascore compute the probability of each localisation from the site-determining fragment ions (Beausoleil et al. 2006). Identifying a phosphopeptide therefore does not by itself localise the phosphate to one residue: if the fragments that would distinguish neighbouring sites are missing, the site is ambiguous. Results are reported per site with a localisation probability (for example, Olsen et al. (2006) called sites with a probability of at least 0.75 "class I"), and the confidence in the site is separate from the FDR of the peptide identification.

Similar enrichment strategies exist for ubiquitination (antibodies against the di-glycine remnant left on lysines after trypsin digestion), acetylation and glycosylation. Interpreting PTM data, for example to infer which kinases are active, relies on databases of known sites and kinase substrate motifs.

8.5.2 Abundance and occupancy of modifications

A PTM data set answers up to four different questions, and the evidence for each is different:

1. Was a modified peptide identified? This rests on the database search and its FDR.
2. Which residue carries the modification? This is the localisation problem above, with its own error rate.
3. How abundant is the modified peptide? This is a relative quantity from the ion signal, like any other peptide.
4. What fraction of the molecules of the protein carry the modification (the *occupancy* or stoichiometry)? This requires the modified and the unmodified forms, and a correction for their different responses in the mass spectrometer.

Because modified peptides are enriched before measurement, an increase in a phosphopeptide can mean that the occupancy of the site rose, that the total amount of the protein rose, or that the enrichment recovered more material. Phosphoproteomics data are therefore usually interpreted together with a

measurement of the unenriched proteome, so that changes in sites can be separated from changes in protein abundance. Mechanistic claims about a single site are typically confirmed with synthetic modified peptides, targeted MS, or perturbation of the responsible kinase.

8.5.3 Interaction proteomics

Proteins act in complexes and pathways. Mass spectrometry is one of the two main experimental sources of protein interaction data, the other being the yeast two-hybrid system. The interaction networks built from these data are discussed in Chapter 11.

- **Affinity purification–mass spectrometry** (AP-MS): a tagged *bait* protein is purified from cells together with the proteins bound to it, the *preys*, which are identified by MS. The first proteome-scale studies mapped complexes in yeast (Gavin et al. 2002; Ho et al. 2002), and the BioPlex project has purified more than 10,000 human baits in two cell lines (Huttlin et al. 2021). AP-MS detects *co-complex* membership, not direct binding, and many identified preys are contaminants that bind to the beads or are simply abundant. Scoring methods, such as SAINT, compare the abundance of each prey with negative controls to compute the probability of a true interaction (Choi et al. 2010), and the CRAPome collects contaminants seen in control experiments (Mellacheruvu et al. 2013).
- **Proximity labelling** (BioID, APEX) fuses the bait to an enzyme that biotinylates all proteins within about 10 nm in the living cell, which are then purified and identified (Roux et al. 2012). It captures weak and transient interactions and works for insoluble structures, but labels neighbours as well as binding partners.
- **Co-fractionation MS** (CF-MS) separates native complexes from a cell extract by chromatography into many fractions and measures the proteins in each. Proteins that are always found in the same fractions are likely to be in the same complex. No tagging is needed, so the method can be applied to any organism or tissue (Havugimana et al. 2012; Wan et al. 2015).

8.5.3.1 hu.MAP: integrating proteomics experiments into a map of complexes

Each of these methods has its own biases and errors, so combining them gives more reliable maps. **hu.MAP**, developed by Kevin Drew and Edward Marcotte, integrates large public data sets of AP-MS (including BioPlex), CF-MS and proximity labelling. The approach is a typical machine-learning pipeline:

1. For each pair of proteins, features are computed from every experiment: co-purification scores from AP-MS, correlation of fractionation profiles from CF-MS, co-labelling from proximity labelling.
2. A classifier is trained to distinguish pairs of proteins known to be in the same complex, from curated databases, from pairs that are not.
3. The classifier scores all pairs, giving a weighted network of co-complex interactions.
4. The network is **clustered** to define complexes, at several levels of confidence.

hu.MAP 2.0 integrated more than 15,000 experiments into nearly 7,000 complexes (Drew et al. 2021), and hu.MAP 3.0 more than 25,000 experiments into more than 15,000 complexes, which place nearly 70% of human proteins in a physical context. hu.MAP 3.0 also used AlphaFold models of the complexes to identify subunits that are mutually exclusive (Fischer et al. 2025). As with any such map, the predictions are only as good as the training data, and the evaluation must avoid using the same known complexes for training and testing. hu.MAP is used as one of the large interactome maps in Chapter 11 and is described as a database in Section 2.7.

8.5.4 Structural mass spectrometry

MS also provides structural information, which complements X-ray crystallography, cryo-EM and structure prediction (Chapter 9):

- **Cross-linking MS** (XL-MS) covalently links amino acids that are close in space, typically lysines within about 30 Å, digests the proteins and identifies the cross-linked peptide pairs (O'Reilly and Rappsilber 2018). Cross-links give distance restraints for modelling complexes and reveal interactions in cells. The computational problem is hard: the search space is all pairs of peptides, which grows quadratically with the database, and the target–decoy approach must be adapted to pairs.
- **Hydrogen–deuterium exchange** (HDX-MS) measures how quickly backbone amide hydrogens exchange with deuterium from the solvent, which reports on solvent accessibility and dynamics.
- **Native MS** measures intact complexes, giving their stoichiometry.
- **Limited proteolysis** (LiP-MS) (Schopper et al. 2017) and **thermal proteome profiling** (Savitski et al. 2014) detect changes in protein structure or stability across the whole proteome, for example when a drug binds its targets.

8.5.5 Spatial proteomics

Where a protein is located is part of its function. **Organelle proteomics** separates cell compartments by density-gradient centrifugation and assigns proteins to organelles from their distribution across fractions, with machine-learning classifiers trained on known markers (Christoforou et al. 2016). Antibody-based imaging of human proteins in cells, in the Human Protein Atlas, has produced a subcellular map showing that about half of all proteins are found in more than one location (Thul et al. 2017) (Section 8.6).

In tissues, **MS imaging** with MALDI scans a laser across a tissue section and records a mass spectrum at each position (Caprioli et al. 1997). **Deep visual proteomics** combines microscopy and machine learning to identify cells of interest, cuts them out with a laser and analyses them by sensitive MS (Mund et al. 2022). **Single-cell proteomics** by MS, first demonstrated with isobaric labelling (Budnik et al. 2018), now measures a few thousand proteins in individual cells, still far fewer than single-cell transcriptomics (Section 7.6). Image-based methods for protein localisation and for tissues are described in Section 13.5 and Section 13.6.

8.6 Proteomics without mass spectrometry

Not all proteomics uses mass spectrometry. Methods based on binding reagents, such as antibodies and aptamers, are more sensitive for some applications, can be applied to thousands of samples, and can show where proteins are located in tissues and cells.

8.6.1 Antibody-based proteomics and the Human Protein Atlas

Antibodies have long been used to detect individual proteins: in Western blots, in enzyme-linked immunosorbent assays (ELISA), and in immunohistochemistry and immunofluorescence, which show where a protein is in a tissue or a cell. The **Human Protein Atlas** (HPA), started in Sweden in 2003 and led by Mathias Uhlén, has scaled this up to the whole human proteome. The project generated antibodies against most human proteins and used them to stain tissues and cell lines, combined with transcriptomics (Uhlén et al. 2015). It is organised as several atlases:

- the **tissue atlas**, describing the expression and localisation of proteins across human tissues and organs, and classifying genes by their tissue specificity (Uhlén et al. 2015);
- the **subcellular atlas**, based on immunofluorescence of cell lines, showing the location of proteins in organelles and substructures (Thul et al. 2017);
- the **pathology atlas**, linking expression to survival in cancers (Uhlen et al. 2017);
- the **single-cell type atlas**, based on single-cell RNA-seq (Karlsson et al. 2021), and further atlases for blood, brain and other systems.

The reliability of antibody-based data depends on the specificity of the antibodies, and many commercial antibodies bind other proteins than their target. The HPA consortium and others therefore proposed standard strategies for **antibody validation**, such as genetic knockdown, comparison with an independent antibody, or correlation with RNA levels (Uhlen et al. 2016). Even a validated antibody gives weaker evidence than MS: a signal shows that something the antibody binds is present, but, unlike a peptide identified by MS, it does not report the sequence of the molecule that was detected. Antibody detection of a protein should therefore not be treated as equivalent to sequence-resolved identification. The HPA data are freely available and are described as a database in Section 2.8.

8.6.2 Affinity proteomics of body fluids

Blood plasma is the most accessible human sample, but its protein concentrations span more than ten orders of magnitude, which makes deep measurement by MS difficult. **Affinity proteomics** measures predefined panels of proteins with binding reagents:

- The **proximity extension assay** (PEA), developed by Olink in Uppsala, uses pairs of antibodies coupled to DNA oligonucleotides. When both antibodies bind the same protein, the oligonucleotides come close together, hybridise and are extended by a polymerase into a DNA barcode, which is then quantified by PCR or sequencing (Assarsson et al. 2014). Only the specific pair produces a signal, which reduces cross-reactivity.
- **SomaScan** uses *aptamers*, short single-stranded DNA molecules selected to bind specific proteins, and measures them on DNA arrays (Gold et al. 2010).

Both platforms now measure thousands of proteins in microlitres of plasma, and have been applied to tens of thousands of individuals. Combined with genotypes, such studies map *protein quantitative trait loci* (pQTLs) and link plasma proteins to disease, as in the UK Biobank Pharma Proteomics Project (Sun et al. 2023). Affinity assays measure binding to an epitope, not the protein sequence, so specificity remains the main source of uncertainty. The two platforms agree well for some proteins and poorly for others, and a pQTL can reflect a variant that changes the binding site of the reagent rather than the amount of protein (an *epitope effect*). For single proteins at very low concentrations, *digital* immunoassays trap individual molecules in femtolitre wells and count them, which reaches sub-femtomolar sensitivity (Rissin et al. 2010).

8.6.3 Multiplexed imaging

Standard immunofluorescence measures a few proteins at a time. **Highly multiplexed imaging** measures dozens of proteins in the same tissue section, at single-cell resolution. In CODEX, antibodies are labelled with DNA barcodes that are read out in repeated cycles of fluorescent hybridisation (Goltsev et al. 2018). In **imaging mass cytometry**, antibodies are labelled with metal isotopes, and the tissue is ablated spot by spot with a laser and analysed by MS (Giesen et al. 2014). These methods are the protein counterparts of spatial transcriptomics (Section 7.6), and are analysed with similar computational methods: cell segmentation, cell-type assignment and analysis of spatial neighbourhoods.

8.6.4 Towards protein sequencing

All the methods above infer the identity of a protein indirectly. Several technologies are being developed to sequence single protein molecules directly, analogous to DNA sequencing. They include nanopores that read the current as a peptide passes through, fluorescent labelling of specific amino acids followed by sequential degradation, and binders that recognise the N-terminal amino acid (Alfaro et al. 2021). If successful, they would make it possible to count individual proteoforms with single-molecule sensitivity.

8.6.5 Orthogonal validation

Every protein measurement relies on a model of recognition: antibodies recognise epitopes, and MS recognises peptides through a search and inference pipeline. Validation is most informative when it tests the weakest link of the discovery method with an assay that does not share it. A second antibody against the same epitope is not independent of the first. A rough ordering of increasingly independent evidence is:

1. internal evidence from the MS data: co-eluting fragment ions, mass error, retention time and consistent peptides;
2. replication of the whole process (new extraction and digestion, or a new batch), not just a repeated injection;
3. targeted confirmation, for example PRM or SRM with heavy synthetic peptides, or comparison with the spectrum of a synthetic peptide;
4. biological tests: knockout or knockdown of the gene, perturbation of the modifying enzyme, or an expected localisation or time course;
5. replication in an independent cohort, laboratory or assay principle.

The appropriate level depends on the claim. A Western blot adds the size of the detected protein, which can show cleavage or a major isoform, and imaging adds localisation and cell-to-cell variation, but each needs its own controls. A biomarker intended for clinical use additionally needs calibration, defined detection limits, blinded samples and validation in independent cohorts.

8.7 Repositories and standards

Proteomics data are large and complex, and their reuse depends on public archives and common formats. As in genomics, depositing raw data has become a condition of publication.

- **PRIDE**, at EMBL-EBI, is the largest repository of MS proteomics data (Perez-Riverol et al. 2021, 2024).
- **ProteomeXchange** is a consortium of repositories, including PRIDE, PeptideAtlas, MassIVE, jPOST and iProX, which coordinates submission and gives each data set a stable identifier (Vizcaíno et al. 2014; Deutsch et al. 2022).
- **PeptideAtlas** reprocesses public data sets with a uniform pipeline and strict error control, and provides a compendium of observed peptides (Desiere 2006).

The Human Proteome Organization (HUPO) **Proteomics Standards Initiative** develops open data formats: **mzML** for raw spectra (Martens et al. 2011), mzIdentML for identifications and mzTab for summarised results. MIAPE (Minimum Information About a Proteomics Experiment) defines what should be reported, analogous to MIAME for microarrays (Taylor et al. 2007).

Public data are used for reanalysis, for building spectral libraries and for training the deep-learning models of Section 8.3. They also underlie the **Human Proteome Project**, launched by HUPO in 2010 to identify at least one protein product of every human protein-coding gene (Legrain et al. 2011). Two draft maps of the human proteome were published in 2014 (Kim et al. 2014; Wilhelm et al. 2014), but reanalysis showed that some of their claims, such as many proteins from non-coding regions, did not survive stringent error control (Ezkurdia, Vázquez, et al. 2014), an illustration of why protein-level FDR matters (Section 8.4). By 2023, credible MS or other protein evidence existed for about 93% of the predicted human proteins (Omenn et al. 2024). The remaining "missing proteins" are often expressed only in particular tissues or developmental stages, or are hard to detect by MS.

8.8 Key concepts

A checklist for revision.

- **History:** 2D gels; soft ionisation (ESI and MALDI); peptide mass fingerprinting; the proteome
- **Instruments:** m/z; quadrupole, ion trap, TOF, FT-ICR and Orbitrap; hybrid instruments (Q-TOF, Q-Orbitrap); ion mobility (TIMS) and PASEF; resolution, mass accuracy, charge states and isotope envelopes; m/z vs. neutral mass and charge-state deconvolution
- **Strategies:** bottom-up (shotgun) vs. middle-down vs. top-down proteomics and proteoforms; loss of connectivity between modifications after digestion; LC-MS/MS; MS1 and MS2; CID/HCD and b/y ions; ETD and c/z ions
- **Acquisition:** data-dependent (top N, dynamic exclusion, missing values) vs. data-independent (SWATH) vs. targeted (SRM/PRM); duty cycle, DIA window width and cycle time
- **Quantification:** label-free (intensity, spectral counting, MaxLFQ); SILAC; isobaric tags (iTRAQ, TMT) and ratio compression; absolute quantification (AQUA, iBAQ); why none of these are molecule counts

- **Design and quality control:** SILAC label swaps; TMT plexes, pooled bridging channels, MS3 and confounding with plex; run order and drift; blanks, carryover, pooled QC and process standards; biological vs. technical replicates
- **Database search:** candidate peptides and precursor mass; theoretical spectra; SEQUEST XCorr, Mascot, Andromeda/MaxQuant, MS-GF+; search scores are not probabilities of correctness; the search space; open search (MSFragger); proteogenomics and separate FDR for novel peptides
- **Terminology:** precursor, peptide ion, peptide sequence, PSM, protein group
- **Spectral libraries** and library search
- **De novo sequencing:** spectrum graphs and dynamic programming; PEAKS; deep learning (DeepNovo, Casanovo, InstaNovo); uses (antibodies, immunopeptidomics, unsequenced organisms)
- **Spectrum and retention-time prediction:** Prosit, MS²PIP, AlphaPeptDeep; rescoring; predicted libraries; peptide-centric DIA analysis (OpenSWATH, DIA-NN)
- **Error control:** target–decoy approach; q-values and posterior error probabilities; PeptideProphet; Percolator and semi-supervised learning; PSM-, peptide- and protein-level FDR (always state the level); concatenated target–decoy competition; FDR as a property of a list, not of one PSM; subgroup FDR
- **Protein inference:** shared peptides; parsimony and protein groups; razor peptides; ProteinProphet; why peptides rarely identify a single protein; shared peptides and isoform-level quantification
- **Quantitative statistics:** summarisation of peptides; missing values (censored and random) and imputation; match between runs; MSstats and limma; a multiplicative model of peptide intensity; normalisation and its assumptions; identification FDR vs. differential-abundance FDR
- **PTMs:** phosphoproteomics, enrichment and site localisation (localisation probability vs. peptide FDR); identification, localisation, abundance and occupancy as separate questions; normalising sites to protein abundance; ubiquitination, acetylation and glycosylation
- **Interaction proteomics:** AP-MS and its contaminants (SAINT, CRAPome); BioPlex; proximity labelling (BioID, APEX); co-fractionation MS; hu.MAP 2.0 and 3.0 and how they are built
- **Structural MS:** cross-linking MS and its search problem; HDX-MS; native MS; LiP-MS and thermal proteome profiling
- **Spatial proteomics:** organelle profiling; the HPA subcellular atlas; MS imaging; deep visual proteomics; single-cell proteomics
- **Non-MS proteomics:** antibodies and their validation; antibody detection vs. MS identification; the Human Protein Atlas; proximity extension assays (Olink) and aptamers (SomaScan); pQTLs and epitope effects; multiplexed imaging (CODEX, imaging mass cytometry); digital immunoassays; single-molecule protein sequencing; orthogonal validation and its levels
- **Repositories and standards:** PRIDE, ProteomeXchange, PeptideAtlas; mzML, mzIdentML, mzTab, MIAPE; the Human Proteome Project and missing proteins

8.9 Recommended reading

These papers are recommended for reading in full:

Titles, abstracts, links and the full texts are in Section A.8; a longer list of further papers is in Section B.8.

8.10 Background reading (open access)

- **Proteomics (Wikipedia)** — Proteomics is the large-scale study of proteins. The proteome is the entire set of proteins produced or modified by an organism or system. Proteomics is an interdisciplinary field that covers the exploration of proteomes from the overall level of protein composition, structure, and activity.
  https://en.wikipedia.org/wiki/Proteomics
- **Shotgun proteomics (Wikipedia)** — Shotgun proteomics refers to the use of bottom-up proteomics techniques in identifying proteins in complex mixtures using a combination of high performance liquid chromatography combined with mass spectrometry.
  https://en.wikipedia.org/wiki/Shotgun_proteomics
- **Mass spectrometry (Wikipedia)** — Mass spectrometry (MS) is an analytical technique that is used to measure the mass-to-charge ratio of ions. The results are presented as a mass spectrum, a plot of intensity as a function of the mass-to-charge ratio.
  https://en.wikipedia.org/wiki/Mass_spectrometry
- **Tandem mass spectrometry (Wikipedia)** — Tandem mass spectrometry, also known as MS/MS or MS2, is a technique in instrumental analysis where two or more stages of analysis using one or more mass analyzers are performed with an additional reaction step in between these analyses to increase their abilities to analyse chemical samples.
  https://en.wikipedia.org/wiki/Tandem_mass_spectrometry
- **Peptide mass fingerprinting (Wikipedia)** — Peptide mass fingerprinting (PMF), also known as protein fingerprinting, is an analytical technique for protein identification in which the unknown protein of interest is first cleaved into smaller peptides, whose absolute masses can be accurately measured with a mass spectrometer such as MALDI-TOF or ESI-TOF.
  https://en.wikipedia.org/wiki/Peptide_mass_fingerprinting
- **De novo peptide sequencing (Wikipedia)** — In mass spectrometry, de novo peptide sequencing is the method in which a peptide amino acid sequence is determined from tandem mass spectrometry.
  https://en.wikipedia.org/wiki/De_novo_peptide_sequencing
- **Data-independent acquisition (Wikipedia)** — In mass spectrometry, data-independent acquisition (DIA) is a method of molecular structure determination in which all ions within a selected m/z range are fragmented and analyzed in a second stage of tandem mass spectrometry.
  https://en.wikipedia.org/wiki/Data-independent_acquisition
- **SILAC (Wikipedia)** — Stable isotope labeling by amino acids in cell culture (SILAC) is a technique based on mass spectrometry that detects differences in protein abundance among samples using non-radioactive isotopic labeling. It is a popular method for quantitative proteomics.
  https://en.wikipedia.org/wiki/Stable_isotope_labeling_by_amino_acids_in_cell_culture
- **Isobaric labeling (Wikipedia)** — Isobaric labeling is a mass spectrometry strategy used in quantitative proteomics. Peptides or proteins are labeled with chemical groups that have nominally identical mass (isobaric), but vary in terms of distribution of heavy isotopes in their structure.
  https://en.wikipedia.org/wiki/Isobaric_labeling
- **Human Protein Atlas (Wikipedia)** — The Human Protein Atlas (HPA) is a Swedish-based program started in 2003 with the aim to map all the human proteins in cells, tissues and organs using integration of various omics technologies, including antibody-based imaging, mass spectrometry-based proteomics, transcriptomics and systems biology.
  https://en.wikipedia.org/wiki/Human_Protein_Atlas

8.11 Student recommendations

Recommended by students preparing for the exam: papers, reviews, online lectures, tutorials and short explanations. To suggest something, use the suggestion form (SU login).

No recommendations yet.

8.12 Review problems

These problems are adapted from Matteo Tadiello, *Modern Bioinformatics: From Foundations to Frontiers* (CC BY 4.0), used with permission. For a longer treatment of this topic, see the chapter "Proteomics and Mass-Spectrometric Inference" of that book. In the HTML version, click a box to show the extensions, solution outline and common errors.

8.12.1 Design a proteomics experiment

You want to discover differences in protein abundance between patients who respond to a treatment and patients who do not. How would you design the study?

Extensions, solution outline and common errors

Extensions:

1. What is the independent biological replicate?
2. Would you use DDA, DIA, TMT or a targeted panel?
3. How would you handle preparation batches and run order?
4. What controls would you add, and at which stage?
5. What can you conclude if a protein is not identified in the non-responders?

Solution outline:

- Define what is to be compared, the population, the clinical covariates, the expected effect size, and whether the study is for discovery or confirmation.
- Treat patients, not LC fractions, peptides, spectra or repeated injections, as the independent units, and plan the number of patients from realistic biological variability.
- Balance responders and non-responders across sample collection, preparation batches, acquisition batches and TMT plexes. Randomise the run order and keep paired or matched structure.
- Label-free DIA suits a large cohort that needs reproducible, broad coverage; TMT is an option when multiplexing improves throughput and the plexes can be balanced; targeted assays are for a predefined panel.
- Add process standards before digestion, system standards before and during acquisition, pooled QC samples throughout the run and blanks to detect carryover.
- Decide the rules for exclusion, normalisation, missing values, the statistical model and multiple testing in advance, and keep an independent cohort for validation.
- Non-detection is ambiguous: the protein may be absent, or lost in sampling, extraction or acquisition, below the dynamic range, or not identified.

Common errors:

- Calling repeated injections, or TMT channels from one sample, independent replicates.
- Confounding response with batch and proposing correction afterwards as a cure.
- Choosing the platform only from the number of proteins it claims to identify.
- Treating a missing value as zero expression.
- Validating only in the discovery cohort.

Connections: Section 8.2 (experimental design and quality control); batch effects and design matrices in Section 7.4; validation and multiple testing in 4.

8.12.2 LC-MS/MS and acquisition strategies

Explain how a peptide becomes an identification in LC-MS/MS, then compare DDA and DIA.

Extensions, solution outline and common errors

Extensions:

1. Why is chromatography necessary?
2. What information is in MS1 and MS2?
3. Why does DDA give missing values that vary from run to run?
4. Why are DIA spectra harder to analyse?
5. Where do targeted PRM and SRM fit?

Solution outline:

- Reversed-phase LC reduces the complexity of what enters the instrument at any moment and spreads peptides over the retention time; electrospray creates gas-phase ions with one or more charges.
- MS1 measures the precursor m/z, the isotope envelope (and hence the charge) and the intensity. MS2, after fragmentation, gives b- and y-ion series that carry sequence information.
- DDA selects a limited number of precursors, usually the most intense. Dynamic exclusion improves coverage, but the competition between precursors differs between runs, so different peptides are selected.
- DIA fragments all precursors in a series of windows, which is more reproducible but mixes fragments from several peptides. The analysis uses co-elution, mass accuracy, measured or predicted spectra, retention times and scores that account for interference.
- Narrower windows reduce interference, but each chromatographic peak must still be sampled several times for quantification, which limits the number of windows.
- PRM and SRM monitor predefined precursors and fragments and are used for verification, especially with heavy internal standards.

Common errors:

- Saying that the instrument reads the peptide sequence directly.
- Equating high precursor mass accuracy with a unique identification.
- Calling DIA “unbiased”: ionisation, mass range, windows and libraries still select what is seen.
- Claiming that DIA has no missing values.
- Ignoring chromatography and the duty cycle.

Connections: Section 8.2; peptide-centric DIA analysis in Section 8.3; AP-MS in Section 8.5 and Section 11.2.

8.12.3 Database search, de novo sequencing and FDR

How does a database search assign a tandem mass spectrum to a peptide, and how would you know that the accepted matches are reliable?

Extensions, solution outline and common errors

Extensions:

1. What changes when you allow many variable modifications?
2. How does target–decoy competition estimate the FDR?
3. What does a 1% PSM-level FDR mean?
4. When would you use de novo sequencing?
5. How would you validate a novel peptide?

Solution outline:

- Candidate peptides are generated from a specified protein database with rules for the enzyme, missed cleavages, charge, mass tolerance and modifications; their theoretical or predicted fragments are compared with the observed spectrum.
- A larger search space contains more competing candidates, increases the chance of high-scoring random matches and can reduce the number of identifications at a fixed FDR. A peptide that is not in the database can never be found by a standard search.
- In concatenated target–decoy competition, wrong matches are assumed to hit targets and decoys equally often, so the decoys accepted above a threshold estimate the false targets.
- A 1% PSM FDR is the expected fraction of wrong PSMs in the accepted list. It is not a 1% error probability for each PSM, and it does not imply a 1% FDR for peptides, sites or proteins.
- De novo sequencing is used when no suitable database exists, for antibodies and immunopeptides, or to find variant and novel peptides. Its large search space, incomplete fragmentation and isobaric residues require careful assessment of confidence.
- A novel peptide can be validated with the spectrum of a synthetic peptide, targeted MS, genomic or transcript evidence, independent samples, and a separate FDR for novel peptides.

Common errors:

- Defining the FDR as the probability that a particular result is false.
- Estimating the PSM-level FDR and reporting it as the protein-level FDR.
- Adding every possible PTM “to be safe”.
- Treating a high score from a deep-learning de novo model as proof of a new gene.
- Forgetting contaminants and the database version.

Connections: Section 8.3; Section 8.4; database size and statistical significance in sequence searching (Section 1.4); proteogenomics and gene annotation (Section 5.6).

8.12.4 Compare quantitative strategies

Compare label-free quantification, SILAC and TMT for a study of a perturbation with several conditions.

Extensions, solution outline and common errors

Extensions:

1. Why does early mixing help SILAC?
2. Why can TMT ratios be compressed?
3. How would you connect several TMT plexes?
4. What does normalisation assume?
5. Can the intensities of two different peptides be compared directly?

Solution outline:

- Label-free quantification compares peak areas between separate runs and scales to many samples, but retention-time alignment, drift, batches and missing values must be handled.
- SILAC labels proteins metabolically; light and heavy peptides co-elute, and mixing early means that later handling affects both equally. It suits cell culture, and needs checks of label incorporation and arginine-to-proline conversion, and often label swaps.
- TMT labels peptides with isobaric tags and quantifies reporter ions after fragmentation. It multiplexes samples and reduces missing values within a plex.
- Co-isolated peptides contribute reporter ions and pull ratios towards one. Narrow isolation, better separation, filtering of spectra with interference, or MS3 reduce this compression.
- Balance the conditions across plexes and include a pooled reference channel in each. Compare mainly within plexes and include the plex in the statistical model; a reference channel cannot rescue a condition that is confounded with a plex.
- Normalisation assumes that most proteins are unchanged, or relies on an internal standard or another reference. A global biological shift violates median scaling.
- Peptides differ in ionisation and recovery, so only changes in the same peptide between samples can be compared reliably.

Common errors:

- Saying that TMT gives absolute quantities.
- Treating the pooled reference channel as an independent biological sample.
- Claiming that SILAC removes variation that arose before labelling or mixing.
- Normalising until all groups overlap.
- Combining modified, shared and discordant peptides without inspection.

Connections: Section 8.2; normalisation and peptide intensities in Section 8.4; normalisation and linear models for RNA-seq in Section 7.4.

8.12.5 Protein inference and proteoforms

You identify three peptides from a gene: two are shared by two splice isoforms, and one is unique to the longer isoform. What can you report?

Extensions, solution outline and common errors

Extensions:

1. What if only the shared peptides were observed?
2. What does parsimony do?

3. How does the protein-level FDR differ from the PSM-level FDR?
4. Can the shared peptides be used to quantify the longer isoform?
5. When would top-down proteomics help?

Solution outline:

- Check that the "unique" peptide is unique in the exact database that was searched, and that it is accepted at an appropriate error rate.
- With reliable unique evidence, the longer isoform is supported, given that database. The shared peptides support the group of both isoforms.
- With only shared peptides, report a protein group; do not choose one isoform because it is the canonical one or expected to be expressed.
- Parsimony finds the smallest set of proteins that explains the observed peptides. It is a reporting rule, not evidence that the smallest set is what is present.
- The protein-level FDR must be estimated after PSMs and peptides have been combined into proteins, for example with the picked target–decoy approach.
- The abundance of shared peptides cannot be assigned to one isoform without further assumptions. Quantify the group, or use isoform-specific peptides and check the sensitivity of the conclusions.
- Top-down proteomics keeps the intact combination of sequence and modifications, but with lower depth and greater technical difficulty.

Common errors:

- Calling a gene-level group a specific isoform.
- Counting several spectra of one peptide as independent observations of the sequence.
- Treating parsimony as a law of nature.
- Assuming that a peptide unique in one database is unique in all proteomes and variants.
- Using RNA levels to override ambiguous peptide evidence.

Connections: Section 8.4; bottom-up and top-down proteomics in Section 8.2; alternative splicing in Section 3.5; gene models and annotation in Section 5.6.

8.12.6 PTMs and site occupancy

A phosphopeptide increases fourfold after stimulation. What does this result mean, and what further evidence do you need?

Extensions, solution outline and common errors

Extensions:

1. How do you distinguish identification from site localisation?
2. Could a change in the total amount of protein explain the result?
3. How would you estimate occupancy?
4. Why is the confidence in the site separate from the peptide FDR?
5. How would you test whether the site is a direct substrate of a kinase?

Solution outline:

- The direct result is that the signal of an enriched, modified peptide changed, given its identification, localisation, normalisation and acquisition.

- A peptide can be identified with confidence while the phosphate is ambiguous between neighbouring residues; site-determining fragment ions and a localisation score (such as the Ascore) are needed.
- Compare with a measurement of the unenriched proteome. A proportional change in the protein can explain the change in the phosphopeptide; an unchanged protein level makes a change in modification more plausible.
- Occupancy is the number of modified molecules divided by the number of modified plus unmodified molecules. It requires both forms and a correction for their different responses; a fold change in enriched material is not occupancy.
- Localisation errors are controlled separately from identification errors, and ambiguous sites should be reported as such.
- Direct substrates can be tested with kinase inhibition or knockout, time courses, in vitro kinase assays, sequence motifs, targeted MS with a synthetic phosphopeptide and mutation of the site. None of these is sufficient on its own.

Common errors:

- Calling every regulated site a direct substrate of the kinase.
- Confusing a localisation probability with the PSM-level FDR.
- Ignoring variation in enrichment and the total amount of protein.
- Equating phosphopeptide intensity with occupancy.
- Using a site-specific antibody without controls for specificity.

Connections: Section 8.5; protein function in Chapter 10; signalling networks in Section 11.3.

8.12.7 Missing values, QC and differential abundance

Half the values for a low-abundance protein are missing in the controls but observed in the treated samples. How would you analyse and interpret this?

Extensions, solution outline and common errors

Extensions:

1. Why not replace the missing values with the minimum intensity?
2. How can the acquisition strategy affect missing values?
3. Which quality-control plots would you inspect?
4. What is the number of replicates in the statistical test?
5. How would you validate apparent on/off expression?

Solution outline:

- Look at the peptide-level observations by sample, intensity, condition, batch and run order, and at the raw chromatograms and identification scores, before working with an imputed protein table.
- Consider detection that depends on abundance, competition between precursors in DDA, failed peak integration, batches, and real presence in only one condition. Several mechanisms may act together.
- Replacing every missing value with a fixed low value can create an artificial difference between groups and hides the uncertainty. Prefer a model that treats low values as censored, sensitivity analyses, or a presence/absence analysis with explicit assumptions.

- Inspect the coefficient of variation of pooled QC samples, retention-time drift, spray stability, mass errors, blanks, digestion metrics, normalisation factors, agreement between peptides and sample identity.
- Independent donors or cultures define the replicates; peptides and spectra are nested measurements within them.
- An on/off claim can be confirmed with targeted MS and heavy peptides, dilution series to establish the detection limit, process blanks and independent biological samples.

Common errors:

- Treating all missing values as censored, or all as random.
- Imputing before splitting the data into training and test sets for a classifier.
- Counting peptide observations as independent replicates.
- Removing an outlier because it weakens the significance.
- Equating "below the detection limit" with zero molecules.

Connections: Section 8.4; quality control in Section 8.2; data leakage and validation in 4.

8.12.8 Choose an orthogonal validation method

When should a discovery by MS be validated with targeted MS, a Western blot, ELISA, flow cytometry, a proximity extension assay or an aptamer panel?

Extensions, solution outline and common errors

Extensions:

1. What does "orthogonal" mean here?
2. How would you validate a claim about a specific isoform?
3. Which controls does an antibody-based assay require?
4. Why might MS and an affinity assay disagree?
5. Which methods can give absolute concentrations?

Solution outline:

- Choose a method that tests the weakest link of the claim. PRM with heavy peptides tests the identity of the peptide and its quantity; a Western blot adds the apparent size; ELISA gives sensitive targeted concentrations; flow cytometry and imaging add cell type and location; PEA and aptamer panels add multiplexed affinity measurements.
- Orthogonal means using recognition and error mechanisms that are at least partly independent, not just analysing the same spectra with different software.
- An isoform-specific claim can be validated with an isoform-unique peptide, intact-protein (top-down) evidence, isoform-specific genetic perturbation, or an antibody whose epitope distinguishes the isoforms.
- Antibodies need tests such as knockout or knockdown, the expected size, linear response on dilution, absence of saturation, and reproducibility between lots (Section 8.6).
- Disagreement can arise because the assays recognise different epitopes or proteoforms, because variants change binding (epitope effects), because complexes mask epitopes, or because one platform suffers from interference.
- Absolute concentration requires calibration and recovery controls, as in targeted MS with isotope-labelled standards or a calibrated immunoassay. Label-free intensities, TMT ratios, PEA units and aptamer signals are usually relative.

Common errors:

- Assuming that every antibody assay is independent and specific.
- Taking disagreement between platforms as proof that one result is false.
- Confusing a precise relative signal with an absolute concentration.
- Validating only on the same samples.
- Using RNA levels as direct validation of protein levels.

Connections: Section 8.6; mRNA and protein levels in Section 7.5; interaction evidence in Section 11.2.

9 Protein structure

> **From the exam description**
>
> Knowledge of protein structure including domains and different methods to predict protein structure.

9.1 Overview

Protein structure is a central topic of the exam and of bioinformatics. A protein's function depends on its three-dimensional structure, and predicting structure from sequence was a grand challenge of computational biology for fifty years. In 2020, deep learning made it possible to predict the static structure of many single-chain proteins, in particular globular domains, with close to experimental accuracy. Conformational ensembles, disordered regions, the effects of mutations, many complexes, and states that depend on ligands, ions or conditions remain open problems. The field is still moving very fast, from single chains to complexes, ligands, dynamics and design, and this chapter tries to be as up to date as possible. It covers:

- CASP, the blind experiment that has measured progress since 1994 (Section 9.2);
- background: amino acids, thermodynamics and binding, and enzymes (Section 9.3);
- the levels of protein structure and the experimental methods: X-ray crystallography, NMR, cryo-EM and integrative modelling (Section 9.4);
- protein folding: Anfinsen's dogma, stability, Levinthal's paradox and funnels, and misfolding, amyloid and prions (Section 9.5);
- structure comparison, what it has revealed about structure evolution, and the structure databases (Section 9.6 and Section 9.7);
- the history of structure prediction, from secondary structure (and how it is assigned from coordinates) and homology modelling with loops and side chains to AlphaFold3 and co-folding models, its limits, including intrinsically disordered proteins, and how to check a predicted model (Section 9.8);
- protein language models and structure (Section 9.9);
- membrane proteins (Section 9.10);
- molecular dynamics, Monte Carlo sampling, convergence and computational cost, optimisation and energy functions (force fields and statistical potentials), normal modes and docking (Section 9.11);
- protein design (Section 9.12).

The prediction of complexes is continued in Chapter 11, and the use of structure to predict function in Chapter 10.

9.2 CASP: a blind test of structure prediction

Much of the history of structure prediction can be told through one experiment. The **Critical Assessment of protein Structure Prediction** (CASP) was started in 1994 by John Moult and colleagues

(Moult et al. 1995). Before CASP, methods were usually tested on structures that were already known, often by the developers themselves, and claims of success were hard to evaluate. CASP introduced a simple principle: predictions must be made **blind**. In the original design, the organisers collected, every second year, sequences of proteins whose structures were about to be determined experimentally but were not yet public. Today the targets come from several routes, mostly unpublished structures contributed by experimental groups, and include not only single proteins but also assemblies, RNA, protein–ligand complexes and other categories. The principle is unchanged: predictors submit models before the structures are released, and independent assessors compare the models with the experimental structures. CASP has run every two years since then, and is now organised by the Protein Structure Prediction Center at UC Davis.

9.2.1 Categories and metrics

Targets were originally classified by how much information was available: *comparative modelling* targets, with a clear template in the PDB; *fold recognition* targets, with a template that is hard to find; and *free modelling* (originally *ab initio*) targets, with no known related structure. Over the years CASP added categories for residue contacts, model quality estimation, refinement, complexes (assembly), ligands, RNA, and conformational ensembles. Two community experiments complement it: **CAPRI** (Critical Assessment of PRedicted Interactions) for protein docking, running since 2001 (Janin et al. 2003), and **CAMEO**, which evaluates servers continuously every week on newly released PDB entries (Haas et al. 2017).

The experimental structure used as reference is itself a model of one state; for many proteins the native state is an ensemble of conformations (Section 9.5), and flexible regions may be absent or poorly defined. Comparing a model with the experimental structure requires measures that are robust to errors in part of the model:

- **RMSD** after optimal superposition is the classical measure, but it is dominated by the worst-predicted regions, so a model with a correct core and one misplaced loop gets a poor score (Section 9.6).
- **GDT_TS** (global distance test) is the average percentage of residues that can be superimposed within 1, 2, 4 and 8 Å of the experimental positions, maximised over many superpositions (Zemla 2003). It ranges from 0 to 100, and values above about 90 are considered competitive with experimental accuracy.
- The **TM-score** weights distances so that it is independent of protein length, and values above 0.5 indicate the same fold (Zhang and Skolnick 2004).
- **lDDT** (local distance difference test) does not superimpose at all. It measures the fraction of interatomic distances in the reference that are preserved in the model within given tolerances (Mariani et al. 2013). Because it is local, it is robust to domain movements, and its predicted version, pLDDT, is the confidence measure of AlphaFold (Section 9.8).
- For complexes, **DockQ** combines the fraction of native contacts and interface and ligand RMSDs into a single score between 0 and 1 (Basu and Wallner 2016).

9.2.2 What CASP has shown

The CASP record documents both slow progress and sudden jumps (Kryshtafovych et al. 2021):

- **1994–2004.** Comparative modelling was useful when templates were close, and fold recognition by threading and profile–profile alignment improved steadily. Ab initio predictions were mostly wrong, until fragment-assembly methods, especially Rosetta, produced the first correct folds of small proteins in CASP3–CASP5.

- **2006–2016.** Progress was incremental. Consensus methods (meta-servers) and model quality estimation became important. From CASP11 (2014) the *coevolution* methods made correct predictions of some large proteins without templates possible, when deep alignments were available.
- **2018 (CASP13).** Deep-learning prediction of residue distances, by several groups and most strikingly by DeepMind's first AlphaFold (Senior et al. 2020), gave a large jump for free-modelling targets.
- **2020 (CASP14). AlphaFold2** produced models with a median GDT_TS of about 92 across all targets, comparable to experimental accuracy for most single domains (Jumper, Evans, Pritzel, Green, Figurnov, Ronneberger, Tunyasuvunakool, Bates, Žídek, Potapenko, Bridgland, Meyer, Kohl, Ballard, Cowie, Romera-Paredes, Nikolov, Jain, Adler, Back, Petersen, Reiman, Clancy, Zielinski, Steinegger, Pacholska, Berghammer, Bodenstein, et al. 2021; Jumper, Evans, Pritzel, Green, Figurnov, Ronneberger, Tunyasuvunakool, Bates, Žídek, Potapenko, Bridgland, Meyer, Kohl, Ballard, Cowie, Romera-Paredes, Nikolov, Jain, Adler, Back, Petersen, Reiman, Clancy, Zielinski, Steinegger, Pacholska, Berghammer, Silver, et al. 2021). The organisers declared that the prediction of single-domain protein structures was largely solved; this referred to static structures of single chains, not to ensembles, complexes or ligands.
- **2022 (CASP15)** and **2024 (CASP16).** Almost all groups built on AlphaFold2 or, in CASP16, on the publicly available AlphaFold3 server, combined with better alignments, extensive sampling and model selection. AlphaFold3 was not a new entrant in the way AlphaFold2 was in CASP14: it was released during CASP16, and many participants used its public server as a component of their pipelines. In CASP16 no single-domain target was predicted with the wrong fold. The remaining challenges are large complexes, flexible and interaction-dependent regions, RNA, ligands and alternative conformations (Kryshtafovych et al. 2023; Yuan et al. 2025).

CASP's success inspired similar blind assessments in other fields, such as CAPRI for docking, CAFA for function prediction (Chapter 10) and CAMI for metagenomics (Section 5.7). Its lesson for the exam is general: a method is only as good as its performance on data it has not seen, a theme that returns in Chapter 12. Outside blind tests, benchmarks of structure predictors must control for overlap between the test proteins and the templates or training structures the method has access to; such leakage inflates apparent accuracy (4).

9.3 Background: amino acids, energetics and enzymes

Examiners expect you to know the chemistry behind the methods in this chapter, at the level of an undergraduate biochemistry course. This section summarises it. The corresponding background on nucleic acids, genes and cells is given in Section 6.2.

9.3.1 Amino acids

Proteins are linear polymers of 20 standard amino acids, joined by **peptide bonds**. The peptide bond is planar, so the conformation of the backbone is described by two torsion angles per residue, ϕ and ψ (Section 9.4). The amino acids differ in their side chains, and their properties explain much of protein structure and evolution:

- **hydrophobic** side chains (Ala, Val, Leu, Ile, Met, Phe, Trp) are buried in the core of soluble proteins and face the lipids in membrane proteins;
- **polar** side chains (Ser, Thr, Asn, Gln, Tyr) form hydrogen bonds and are common on the surface;
- **charged** side chains, positive (Lys, Arg, His at low pH) and negative (Asp, Glu), form salt bridges and are found on the surface and in active sites;
- special cases: **glycine**, without a side chain, is flexible and common in turns; **proline**, whose side chain is bonded to the backbone, is rigid and breaks helices; **cysteine** can form disulfide bonds.

Substitution matrices such as PAM and BLOSUM (Section 1.3) reflect these properties: substitutions between similar amino acids, such as Ile and Val, are frequent in evolution, while substitutions involving Cys, Trp or Gly are rare.

9.3.2 Thermodynamics and binding

Whether a protein folds, and how strongly molecules bind, are questions of **free energy**, $\Delta G = \Delta H - T\Delta S$, a balance of enthalpy (interactions) and entropy (disorder). The main forces are the **hydrophobic effect**, the main driver of folding, which is largely entropic: non-polar groups order the surrounding water, and burying them releases it; **hydrogen bonds**; **electrostatic** interactions; and **van der Waals** contacts. Folded proteins are only marginally stable (Section 9.5).

Binding of a ligand L to a protein P is described by the **equilibrium dissociation constant**, $K_d = [\mathrm{P}][\mathrm{L}]/[\mathrm{PL}]$, which has units of concentration and equals the free ligand concentration at which half of the protein is bound. K_d is an equilibrium constant, not a rate; it equals the ratio of the dissociation and association rate constants, $k_{\mathrm{off}}/k_{\mathrm{on}}$. It is not itself a free energy, but it is related to the **standard binding free energy** by

$$\Delta G^{\circ}_{\mathrm{bind}} = RT \ln \frac{K_d}{c^{\circ}},$$

where $c^{\circ} = 1$ M is the standard-state concentration (equivalently, $\Delta G^{\circ}_{\mathrm{bind}} = -RT \ln K_a$ with the dimensionless association constant $K_a = c^{\circ}/K_d$). The value of ΔG° therefore depends on the chosen standard state. A K_d of 1 nM corresponds to about -12.3 kcal/mol at 25 °C, and a tenfold lower K_d (tighter binding) to about 1.4 kcal/mol more favourable binding. Typical K_d values range from millimolar for weak, transient interactions to picomolar for antibodies and tight complexes. Predicting binding affinities is one of the hardest problems in computational biology (Section 9.11).

9.3.3 Enzymes

Enzymes accelerate reactions by lowering the free energy of the transition state, without changing the equilibrium. Many reaction rates are increased by factors of 10^{10} or more. For a simple enzyme, the rate depends on the substrate concentration [S] by the **Michaelis–Menten** equation,

$$v = \frac{V_{\max}[S]}{K_m + [S]}, \qquad V_{\max} = k_{\mathrm{cat}}[E]_{\mathrm{total}},$$

where K_m is the substrate concentration at half-maximal rate, and k_{cat} the turnover number, the number of reactions per enzyme per second. K_m is **not** in general the dissociation constant of the enzyme–substrate complex. For the scheme $\mathrm{E} + \mathrm{S} \rightleftharpoons \mathrm{ES} \rightarrow \mathrm{E} + \mathrm{P}$, with rate constants k_1, k_{-1} and k_{cat}, $K_m = (k_{-1} + k_{\mathrm{cat}})/k_1$, which equals $K_d = k_{-1}/k_1$ only when $k_{\mathrm{cat}} \ll k_{-1}$ (the rapid-equilibrium limit). A low K_m therefore does not by itself show tight substrate binding. k_{cat}/K_m measures catalytic efficiency. Inhibitors reduce activity, competitively by binding the active site or non-competitively elsewhere. Activity is **regulated**

by allosteric effectors, which bind away from the active site and shift the enzyme between conformations, and by post-translational modifications such as phosphorylation (Section 8.5). Enzymes are classified by the reactions they catalyse (EC numbers, Section 10.2), and their parameters are collected in BRENDA. Membranes and membrane proteins are described in Section 9.10, and metabolism in Section 11.3.

9.4 Protein structure and how it is determined

A protein's function depends on its three-dimensional structure. This section introduces the vocabulary of protein structure and the experimental methods that produced the roughly 260,000 structures in the Protein Data Bank (in 2026) (Section 2.5).

9.4.1 Levels of protein structure

Protein structure is described at four levels:

- **Primary structure**: the amino acid sequence.
- **Secondary structure**: local, regular conformations stabilised by backbone hydrogen bonds. Linus Pauling predicted the **α-helix** and the **β-sheet** in 1951 from the geometry of the peptide bond, before any protein structure was known (Pauling et al. 1951). The allowed combinations of the backbone torsion angles ϕ and ψ are summarised in the **Ramachandran plot** (Ramachandran et al. 1963), still the first check of any structure model. Regions without regular structure are called loops or coils.
- **Tertiary structure**: the three-dimensional fold of a whole chain. Hydrophobic side chains are buried in a core, polar ones exposed to the solvent. Secondary structure elements pack against each other in a limited number of ways: helices pack at preferred angles determined by how their side-chain "ridges" fit into "grooves", and β-sheets are twisted and pack face to face or roll into barrels (Chothia et al. 1977). Common combinations of a few elements, such as the β-hairpin, the helix–turn–helix or the β-α-β unit, are called **supersecondary structures** or motifs.
- **Quaternary structure**: the assembly of several chains into a complex.

Larger proteins consist of **domains**, compact units of typically 50–250 residues that often fold independently and are reused in different combinations during evolution (Section 1.9 and Section 3.5). Domains are classified by their **fold**, the arrangement and connectivity of their secondary structure elements, and grouped into **superfamilies** when there is evidence of common ancestry. From the first structures, Levitt and Chothia defined four **structural classes**: all-α, all-β, α/β (alternating helices and strands, mostly parallel sheets) and α+β (segregated helices and mostly antiparallel sheets) (Levitt and Chothia 1976). Jane Richardson's drawings and taxonomy of structures, which introduced the ribbon diagram, shaped how structures are still visualised (Richardson 1981).

9.4.2 X-ray crystallography

The first protein structures, of myoglobin (Kendrew et al. 1958) and haemoglobin (PERUTZ et al. 1960), were solved by **X-ray crystallography** in Cambridge; Kendrew and Perutz received the Nobel Prize in Chemistry in 1962. In crystallography, a protein is crystallised, and the crystal diffracts an X-ray beam into a pattern of spots. The intensities of the spots give the amplitudes of the Fourier transform of the electron density, but not their phases (*the phase problem*). Phases are obtained from heavy-atom derivatives, from anomalous scattering, or, most often today, by **molecular replacement** with a similar known structure, increasingly a predicted model. An atomic model is then built into the electron density and refined.

The quality of a crystal structure is described by:

- the **resolution**, the smallest spacing of the diffraction data used. At 3 Å, the backbone and most side chains can be traced; at better than 1.5 Å, individual atoms are resolved;
- the **R-factor**, the disagreement between the observed amplitudes and those calculated from the model. Because a model can be over-fitted to the data, Axel Brünger introduced the **free R-factor**, computed on a small set of reflections (typically 5%) that is excluded from refinement (Brünger 1992). R_{free} is a cross-validation statistic, the same idea as a held-out test set in machine learning (Chapter 12). A large gap between R and R_{free} indicates over-fitting.

Crystallography gives the most accurate structures and remains the main method for drug design, but proteins must crystallise, and crystal contacts can distort flexible regions. More than 80% of PDB entries (as of 2026) were determined by X-ray crystallography.

9.4.3 NMR spectroscopy

Nuclear magnetic resonance (NMR) spectroscopy determines structures of proteins in solution. Kurt Wüthrich's group solved the first protein structure by NMR in 1985 (Williamson et al. 1985), and Wüthrich shared the 2002 Nobel Prize in Chemistry. NMR measures interactions between atomic nuclei, such as the nuclear Overhauser effect, which gives distances between protons closer than about 5 Å. A structure is calculated as an **ensemble** of models consistent with these restraints. NMR provides information about dynamics that crystallography cannot, but it is limited to relatively small proteins, typically below 30–50 kDa.

9.4.4 Cryo-electron microscopy

In **cryo-electron microscopy** (cryo-EM), purified molecules are frozen in a thin layer of vitreous ice and imaged with an electron microscope. Each image is very noisy, so hundreds of thousands of particle images are aligned, classified and averaged to reconstruct a three-dimensional density map. Richard Henderson used electron crystallography to determine the structure of bacteriorhodopsin, a membrane protein, in 1990 (Henderson et al. 1990). For decades single-particle cryo-EM gave only low resolution, until direct electron detectors and new image-processing software, with Bayesian methods for classification and reconstruction (Scheres 2012), produced the **resolution revolution** around 2013 (Kühlbrandt 2014). Jacques Dubochet, Joachim Frank and Richard Henderson received the 2017 Nobel Prize in Chemistry. Cryo-EM needs no crystals, works best for large complexes and membrane proteins, and images individual molecules rather than an ordered lattice. Classification of the particle images can therefore separate several conformational or compositional states from the same sample, and newer methods model continuous variability between them. The relative numbers of particles give a rough indication of how populated the states are, which connects experimental structure to dynamics (Section 9.11), although sample preparation and freezing can shift these proportions. Cryo-EM now

produces a large share of new structures, and **cryo-electron tomography** images complexes inside cells. In cryo-EM, resolution is estimated from the agreement between maps reconstructed from two independent halves of the data (the Fourier shell correlation), another form of cross-validation.

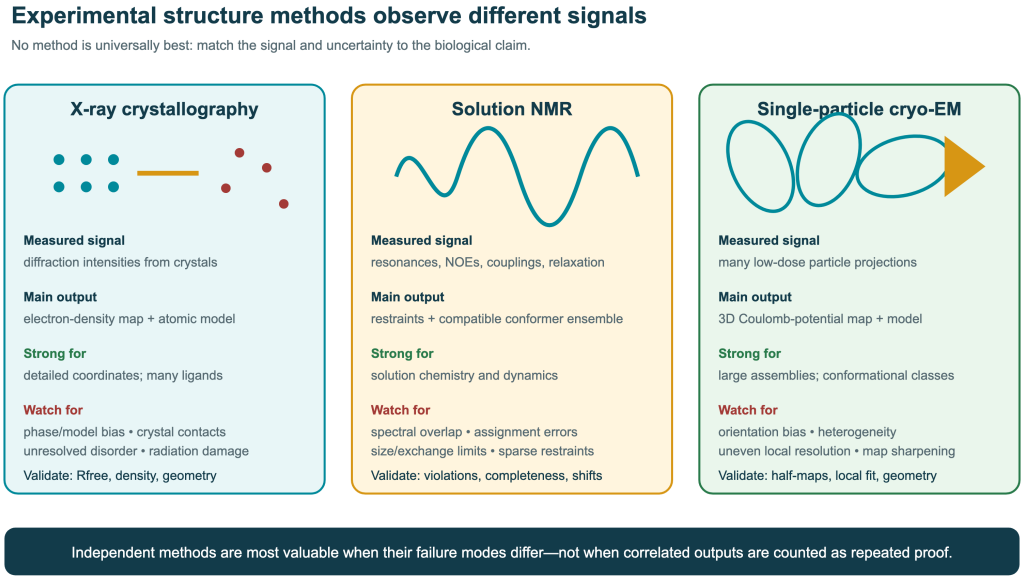

Figure 9.1: X-ray crystallography, solution NMR and single-particle cryo-EM compared: the signal each method measures, its main output, what it is strong for, its typical problems, and how its models are validated. Figure: Matteo Tadiello, *Modern Bioinformatics: From Foundations to Frontiers* (CC BY 4.0).

9.4.5 Integrative and lower-resolution methods

Many systems are too large, flexible or heterogeneous for any one of the three main methods. **Integrative structural biology** combines several kinds of data, each too sparse to determine a structure alone, into models that satisfy all of them (Rout and Sali 2019). Common sources of restraints are:

- **small-angle X-ray scattering** (SAXS), which gives the overall size and shape of molecules in solution, averaged over all orientations and conformations;
- **cross-linking mass spectrometry**, which shows which residues are within the reach of a chemical cross-linker (Section 11.2);
- **hydrogen–deuterium exchange MS**, which shows which parts of the backbone are protected from the solvent, for example by an interface (Section 8.5);
- FRET and electron paramagnetic resonance, which measure distances between labelled sites, together with mutagenesis, low-resolution cryo-EM or tomography maps, and atomic structures or predicted models of the components.

A landmark example is the yeast nuclear pore complex, a ring of more than 500 protein copies whose architecture was determined by combining cryo-electron tomography, cross-links, SAXS and structures of subcomplexes (Kim et al. 2018). Integrative models are archived in PDB-IHM (Section 2.5). Their reliability is assessed as for other models: by how precise the ensemble of solutions is, and, most convincingly, by whether they agree with data that were *not* used to build them. Fitting the same data repeatedly, or several data sets with correlated errors, increases apparent precision without adding evidence. The same principle applies when experimental data are used to check a predicted model (Section 9.8).

9.4.6 Experimental structures and predicted models

All experimental structures are models fitted to data, with errors that depend on the method and the resolution. Validation reports from the wwPDB compare each model with its data and with expected geometry (Burley et al. 2018). Since 2021, predicted structures have become as important as experimental ones for many purposes (Section 9.8). Experiments and prediction are now integrated: predicted models are used to phase crystallographic data, to interpret cryo-EM maps and to guide experiments, while experimental structures remain the ground truth on which predictors are trained and evaluated.

9.5 Protein folding

Many proteins fold from a chain of amino acids into a well-defined three-dimensional structure. The folding problem has three parts: the physical question of what determines the native structure, the kinetic question of how proteins fold so fast, and the computational question of predicting the structure from the sequence (Dill and MacCallum 2012). The third is the subject of Section 9.8. This section covers the first two, and what happens when folding goes wrong.

9.5.1 Anfinsen's dogma

In the 1950s and 1960s Christian Anfinsen showed that ribonuclease A, unfolded by urea and with its disulfide bonds reduced, refolds spontaneously into its active structure when the denaturant is removed. He concluded that, for a small globular protein **in a given environment** (solvent, pH, temperature, and any required cofactors or partners), **the information needed to specify the native structure is contained in the amino acid sequence**, and that the native structure is the conformation of lowest free energy under those conditions, the *thermodynamic hypothesis* (Anfinsen 1973). He received the 1972 Nobel Prize in Chemistry. The hypothesis is not the claim that sequence alone always determines a single structure. Anfinsen's dogma is the justification for predicting structure from sequence, and it has important exceptions and qualifications: the structure depends on the environment (a membrane, bound metals, cofactors or partner proteins); some proteins need chaperones to avoid aggregation (although chaperones do not change the final structure); some are kinetically trapped in states that are not the global minimum; some switch between folds; and many proteins or regions are intrinsically disordered (Section 9.8 and Section 3.5).

Even a well-folded protein does not have one rigid structure. The **native state** is an ensemble of closely related conformations, with side chains, loops and sometimes whole domains in motion, and some proteins populate two or more distinct functional states. A crystal structure or a predicted model shows one representative of this ensemble, often the most populated state or one stabilised by crystal contacts or bound ligands. Accuracy measures for predictions (Section 9.2) should be read with this in mind; dynamics and ensembles are discussed in Section 9.11.

9.5.2 Free energy and marginal stability

The native state is stable because of a balance of large opposing contributions. The **hydrophobic effect**, the tendency of non-polar side chains to avoid water, drives the burial of the core. Hydrogen bonds, van der Waals packing and electrostatic interactions stabilise the folded state, while folding costs a large loss of conformational entropy of the chain. The net result is that most proteins are only **marginally stable**: the free energy of unfolding, ΔG, is typically only 5–15 kcal/mol, the equivalent of a few hydrogen bonds. A single mutation can change it by 1–3 kcal/mol, which is why many disease mutations act by destabilising proteins, and why stability constrains evolution (Section 3.5). Small single-domain proteins often fold in a cooperative **two-state** transition, with only the unfolded and the native states populated at equilibrium (Jackson and Fersht 1991).

9.5.3 Levinthal's paradox and folding funnels

In the late 1960s Cyrus Levinthal pointed out that if each residue of a 100-residue chain could adopt only three conformations, there would be $3^{100} \approx 10^{48}$ conformations. Sampling them at a rate of 10^{13} per second would take far longer than the age of the universe, yet real proteins fold in microseconds to seconds (Levinthal 1966). Folding therefore cannot be a random search. Levinthal suggested that folding follows specific **pathways** guided by local interactions.

The modern resolution of the paradox is the **energy landscape** theory (Bryngelson et al. 1995; Dill and Chan 1997). Proteins evolved to have **funnel-shaped** free-energy landscapes: as the chain forms more native contacts, its energy decreases, so most moves lead downhill towards the native state, and there are many parallel routes rather than a single pathway. The width of the funnel represents the conformational entropy, which decreases as the chain folds. Real landscapes are rugged, with local minima in which the chain can be temporarily trapped, which explains intermediates and misfolding. Natural sequences are thought to be *minimally frustrated*: their interactions are mostly consistent with the native structure, unlike random sequences.

Experiments with protein engineering, measuring how mutations affect folding rates (*φ-value analysis*), showed which parts of the structure are formed in the transition state. Molecular dynamics simulations on the special-purpose computer Anton finally made it possible to watch small proteins fold and unfold repeatedly at atomic detail (Shaw et al. 2010; Lindorff-Larsen et al. 2011) (Section 9.11). They showed that fast-folding proteins fold along a small number of routes, often starting with native secondary structure, consistent with the funnel picture.

9.5.4 Misfolding, amyloid and prions

The native state is not the only deep minimum. Partly folded or unfolded chains expose hydrophobic segments and can **aggregate**, and one ordered aggregate is accessible to almost any polypeptide: the **amyloid fibril** (Chiti and Dobson 2017). Amyloid has a **cross-β** structure, in which β-strands run perpendicular to the fibril axis and are hydrogen-bonded into sheets that run along it, giving the characteristic X-ray fibre diffraction spacings of about 4.7 Å between strands and about 10 Å between sheets. Crystal structures of short amyloid-forming peptides showed pairs of sheets whose side chains interlock in a dry **steric zipper** (Sawaya et al. 2007). Because the backbone hydrogen bonds are shared by all sequences, amyloid can be more stable than the native fold at high concentration, so the native state of many proteins is only kinetically protected, by chaperones, degradation and their sequences, against aggregation. Anfinsen's hypothesis concerns the folding of a single chain, not this concentration-dependent alternative.

Aggregation is usually nucleated by short **aggregation-prone regions** of five to ten residues that are hydrophobic, have a high β-strand propensity and a low net charge. In folded proteins they are mostly

buried, and they are often flanked by charged residues or prolines that act as *gatekeepers*. Predictors identify them from sequence: **TANGO** uses a statistical-mechanics model of competing conformations (Fernandez-Escamilla et al. 2004), and **Waltz** uses position-specific scoring matrices trained on amyloid-forming hexapeptides (Maurer-Stroh et al. 2010). They are used to explain disease mutations and to reduce aggregation in therapeutic and designed proteins.

Prions are proteins whose misfolded, aggregated form converts the normal form into more of itself. Stanley Prusiner proposed that the agent of scrapie, and later of Creutzfeldt–Jakob disease and bovine spongiform encephalopathy, is a protein, the prion protein PrP, without nucleic acid (Prusiner 1982) (Nobel Prize in Physiology or Medicine, 1997). Wickner proposed, from genetic evidence, that the yeast trait [URE3] is a prion form of the Ure2 protein (Wickner 1994); yeast prions such as [URE3] and [PSI+] are inherited through the cytoplasm, so protein conformation can carry heritable information. The same templated growth occurs, in a less infectious form, in the spread of aggregates between cells in neurodegenerative diseases.

Fibrils are not crystals, and their atomic structures were long unknown. Since 2017, **cryo-EM** has determined many of them at near-atomic resolution (Section 9.4): tau filaments from the brain of a patient with Alzheimer's disease (Fitzpatrick et al. 2017), amyloid-β(1–42) (Gremer et al. 2017) and α-synuclein, the protein of Parkinson's disease (Guerrero-Ferreira et al. 2018). Each layer of a fibril is one chain folded into a flat, often intricate, arrangement of β-strands, quite different from its native or disordered state. The same protein can form several **polymorphs**; different tauopathies have different tau folds, which supports the idea that structural strains underlie different diseases, and fibrils formed *in vitro* often differ from those extracted from patients. AlphaFold and similar predictors, trained mainly on globular proteins and predicting single chains or defined complexes, do not reliably predict these folds.

Not all amyloid is pathological. **Functional amyloids** include the curli fibres of *Escherichia coli* biofilms, which are assembled by a dedicated secretion and nucleation machinery (Chapman et al. 2002), fibres in mammalian melanosomes, and stores of peptide hormones in secretory granules (Sawaya et al. 2021). Their existence shows that cells can control amyloid formation, and that the cross-β fold is part of normal biology.

9.5.5 Folding and prediction

AlphaFold and related methods predict the native structure of many proteins very accurately without simulating folding at all (Section 9.8). They learn the mapping from sequence and evolutionary information to structure from the PDB. This largely solved the practical problem of predicting a static structure for most single-chain globular proteins, but not the physical question of how folding happens. The models do not give folding pathways, are less reliable for the effects of single mutations on stability, and predict one structure even for proteins that switch between several.

9.6 Structure comparison and evolution

Comparing structures is needed to evaluate predictions, to classify proteins, and to detect evolutionary relationships that are no longer visible in the sequence. Among homologues, structure usually changes much more slowly than sequence: proteins with less than 20% sequence identity, in the "midnight zone" of sequence comparison (1), often have the same fold and superimpose closely (Chothia and Lesk 1986). This is an empirical tendency, not a law. A few mutations can switch a protein to a different fold, and similar folds can arise independently by convergence, so structural similarity alone does not prove common ancestry. With these caveats, structural similarity is often the most sensitive evidence for distant homology.

9.6.1 Measures of similarity

The simplest measure is the **root-mean-square deviation** (RMSD) between equivalent atoms (usually Cα atoms) after optimal superposition,

$$\mathrm{RMSD} = \sqrt{\frac{1}{N}\sum_{i=1}^{N} \lVert \mathbf{x}_i - \mathbf{y}_i \rVert^2},$$

where the optimal rotation is found analytically, for example with the Kabsch algorithm. RMSD has two problems. It requires a known correspondence between residues, and it is dominated by the largest deviations, so two structures with an identical core and one different loop or a domain movement get a large RMSD. It also depends on the length of the protein.

The **TM-score** solves the last two problems (Zhang and Skolnick 2004):

$$\text{TM-score} = \max \frac{1}{L}\sum_{i=1}^{N} \frac{1}{1 + (d_i/d_0(L))^2},$$

where d_i is the distance between the ith pair of aligned residues, L the length of the reference protein, and $d_0(L)$ a length-dependent scale chosen so that random structure pairs give similar scores regardless of size. The maximum is taken over superpositions. Each residue contributes between 0 and 1, so distant pairs contribute little instead of dominating. TM-scores above 0.5 indicate generally the same fold, and below about 0.17 random similarity. **GDT_TS** and **lDDT**, used in CASP, are described in Section 9.2.

9.6.2 Structural alignment

Structural alignment finds the residue correspondence that makes two structures as similar as possible, without using the sequence. Since the correspondence and the superposition depend on each other, the problem is hard, and all programs use heuristics (Kolodny et al. 2005):

- **DALI**, by Liisa Holm and Chris Sander, compares the matrices of intramolecular Cα–Cα distances of the two proteins. It looks for sub-matrices (fragment pairs) with similar distance patterns and assembles them into an alignment with Monte Carlo optimisation (Holm and Sander 1993). Because it compares internal distances, it needs no superposition and can align structures with different topologies of the same contacts. DALI was used to map the protein structure universe (Holm and Sander 1996) and is still widely used (Holm 2019).

- **TM-align** iterates between superposition and alignment: it starts from several initial alignments, computes the superposition that maximises the TM-score, and realigns the residues with dynamic programming using the distances after superposition (Zhang and Skolnick 2005).
- **Foldseek** made structure search as fast as sequence search (van Kempen et al. 2023). It describes the local tertiary environment of each residue with a letter from a learned 20-letter *3Di* structural alphabet, so that each structure becomes a string, which can be searched with the fast prefilters and alignment algorithms of MMseqs2 (Section 1.4). Foldseek is thousands of times faster than DALI or TM-align with similar sensitivity, and made it possible to search and cluster the hundreds of millions of predicted structures in the AlphaFold Database (Barrio-Hernandez et al. 2023).

9.6.3 What structure comparison has shown

Comparisons of the growing number of structures showed that the number of distinct folds is limited. Chothia estimated in 1992 that there might be about 1,000 folds (Chothia 1992), and the structure classifications show that a few hundred *superfolds*, such as the TIM barrel, the Rossmann fold and the immunoglobulin fold, account for most domains. As more structures were determined, new folds became rarer. The AlphaFold Database, covering almost all known proteins, confirmed this. Clustering its 214 million predicted structures with Foldseek gave 2.3 million non-singleton clusters. About 31% of the clusters had no annotation and may represent previously undescribed structures, but together they contain only 4% of the proteins: most proteins belong to known families. The comparison also revealed remote relationships, for example between human immune-related proteins and prokaryotic ones (Barrio-Hernandez et al. 2023). Structure comparison has also shown that proteins with the same function can have different folds (convergent evolution), and that the same fold can carry very different functions, which limits how far function can be transferred by structural similarity (Chapter 10).

9.7 Protein structure databases

The databases of structures are described in detail in Section 2.5, and the domain classifications in Section 1.9. In brief:

- The **Protein Data Bank** (PDB), founded in 1971, is the single archive of experimental structures, about 260,000 entries in 2026 (Berman et al. 2000; Burley et al. 2018).
- **SCOP** (1995) classifies domains manually by class, fold, superfamily and family, with superfamilies defined by evidence of common ancestry (Murzin et al. 1995; Andreeva et al. 2019). Its four structural classes go back to

  2.

- **CATH** classifies domains by Class, Architecture, Topology (fold) and Homologous superfamily, with more automation (Sillitoe et al. 2020).
- **ECOD** emphasises evolutionary relationships, with a level of "possible homology" above the superfamily, and is updated weekly (Cheng et al. 2014).
- **TED** (The Encyclopedia of Domains) applied automatic domain parsing and classification to the AlphaFold Database, identifying hundreds of millions of domains in predicted structures (Lau et al. 2024).
- The **AlphaFold Protein Structure Database** contains predicted structures for more than 200 million proteins, almost all of UniProt (Varadi et al. 2023; Bertoni et al. 2025).
- The **ESM Metagenomic Atlas** contains more than 600 million structures of metagenomic proteins predicted with ESMFold (Lin et al. 2023) (Section 9.9).

9.8 Protein structure prediction

Predicting the structure of a protein from its sequence was one of the grand challenges of computational biology for fifty years. Anfinsen's dogma (Section 9.5) said that it should be possible; the size of the conformational space and the inaccuracy of energy functions made it hard. The history of the field is a sequence of ideas, each of which used more of the information hidden in evolution, until deep learning combined them in 2020. Progress was measured throughout by CASP (Section 9.2).

9.8.1 Secondary structure prediction

The first methods predicted only secondary structure, the state (helix, strand or coil) of each residue.

- **Chou–Fasman** (1974) used the propensity of each amino acid to occur in helices and strands, computed from the few structures then known, with rules for nucleating and extending elements (Chou and Fasman 1974a, 1974b).
- **GOR** (1978) used information theory to include the influence of neighbouring residues in a window of 17 residues (Garnier et al. 1978).

Both reached about 60% accuracy (Q3, the percentage of residues correctly predicted in three states), little better than chance because local sequence only partly determines local structure. The breakthrough came from evolution. **PHD**, by Burkhard Rost and Chris Sander, fed **multiple sequence alignments** of homologous proteins into a neural network, raising accuracy above 70% (Rost and Sander 1993): a family of sequences shows which positions are conserved, hydrophobic or variable, which the single sequence cannot. **PSIPRED** used PSI-BLAST profiles and reached about 77–80% (Jones 1999). Modern deep-learning methods reach about 85%, close to the limit set by the ambiguity of assigning secondary structure in experimental structures.

9.8.2 Assigning secondary structure from coordinates

To train and test predictors, the "true" secondary structure must first be assigned from experimental coordinates, and this is less objective than it sounds. **DSSP** (Kabsch and Sander, 1983), the standard program, finds backbone hydrogen bonds with a simple electrostatic model: partial charges on the C=O and N–H groups give an energy, and a hydrogen bond is counted if it is below -0.5 kcal/mol (Kabsch and Sander 1983). Secondary structure is then defined by *patterns* of hydrogen bonds: repeated $i \to i+4$ turns form an α-helix, and ladders of bridges between strands form a β-sheet. DSSP assigns eight states:

- **H**: α-helix; **G**: 3_{10}-helix; **I**: π-helix;
- **E**: strand in a β-ladder; **B**: isolated β-bridge;
- **T**: hydrogen-bonded turn; **S**: bend (a geometric criterion only);
- and blank (often written C or "–"): none of these, loosely called coil.

For prediction, the eight states are reduced to three. A common reduction is H, G, I → helix; E, B → strand; everything else → coil, but some benchmarks map only H and E, and the choice changes Q3 by a few percentage points, so the reduction must be stated when methods are compared. **STRIDE** combines hydrogen-bond energies with backbone torsion angles, with parameters tuned to agree with the assignments made by crystallographers (Frishman and Argos 1995). DSSP and STRIDE agree for most residues but differ at the ends of helices and strands, for 3_{10} and π helices, for irregular or bulged strands, and in low-resolution structures; NMR models of one protein can differ among themselves. This disagreement is one reason why Q3 cannot reach 100%.

Q3 also has a weakness as a measure: it counts residues, not elements. A prediction that shifts the ends of every helix by one residue, and one that breaks a helix into fragments or misses a short strand completely, can have the same Q3. The **segment overlap score** (SOV) compares predicted and observed *segments* and tolerates small shifts at their boundaries, so it rewards predictions that get the number, type and approximate position of the elements right (Rost et al. 1994; Zemla et al. 1999). Q3 and SOV are usually reported together.

9.8.3 Homology modelling

If a protein of known structure is homologous to the query, the structure of the query can be modelled on it, since homologous proteins usually have similar structures (Section 9.6). **Homology modelling** (comparative modelling) has four steps:

1. **Template search**: finding related structures, with sequence or profile searches against the PDB (Chapter 1).
2. **Alignment** of query and template, the most critical step; errors here cannot be corrected later.
3. **Model building**: copying the coordinates of aligned regions, and modelling loops and side chains. **MODELLER** builds the model by satisfying spatial restraints derived from the template, such as distances and angles, together with stereochemical rules (Šali and Blundell 1993).
4. **Evaluation** of model quality.

The accuracy of the model depends mainly on the sequence identity to the template: above about 50%, models are close to medium-resolution experimental structures, while below 30% alignment errors dominate. Tools such as SWISS-MODEL made homology modelling routine.

9.8.4 Loops and side chains

After the aligned core has been copied, two parts of a homology model remain: loops and side chains. **Loops**, the insertions relative to the template and the regions where the template differs, are usually the least accurate part of a model, and accuracy falls with loop length. *Database* methods search known structures for fragments whose ends fit the geometry of the two anchor residues and whose sequences are similar; they work well for short loops. *Ab initio* (conformational search) methods sample loop conformations and score them with an energy function, as MODELLER does (Fiser et al. 2000). A loop must close exactly between its anchors, which makes random sampling inefficient. **Kinematic closure** (KIC) in Rosetta, borrowed from robotics, samples the torsions of most loop residues freely and solves analytically for six torsions that close the chain, and reconstructed many 12-residue loops with sub-ångström accuracy (Mandell et al. 2009).

Side chains adopt a limited number of preferred combinations of their torsion angles $\chi_1, \chi_2, \ldots$, called **rotamers**, mostly with staggered torsions. **Rotamer libraries** list them with their frequencies (Ponder and Richards 1987). Dunbrack and Karplus showed that the frequencies depend on the backbone torsions ϕ and ψ, and the **backbone-dependent rotamer library** (Dunbrack and Karplus 1993), now a smoothed version derived from high-resolution structures (Shapovalov and Dunbrack 2011), is used by most

modelling and design programs. Placing side chains then becomes a combinatorial problem: choose one rotamer per residue to minimise an energy with terms for each rotamer and each pair of rotamers. **Dead-end elimination** removes rotamers that cannot be part of the global minimum (Desmet et al. 1992); **SCWRL4** splits the graph of interacting residues into small clusters that can be solved exactly (Krivov et al. 2009); and the Rosetta **packer** uses Monte Carlo with simulated annealing over rotamers (Section 9.11). The packer is the same algorithm used for design, where the rotamers of all allowed amino acids compete at each position (Section 9.12). Buried side chains are placed much more accurately than exposed ones, and accuracy drops when the backbone itself is inaccurate.

Rosetta, which began as a fragment-assembly program (below), grew into a software suite that shares one energy function (Alford et al. 2017) across loop modelling, packing, refinement, docking and design (Leman et al. 2020). MODELLER instead optimises all restraints of the model together, and SWISS-MODEL builds models from templates with its own loop and side-chain modelling. Deep-learning predictors removed these separate steps. AlphaFold2 predicts side-chain torsion angles in its structure module, and AlphaFold3 generates all atoms with diffusion, so loops and side chains are predicted together with the rest of the structure and are generally reliable where pLDDT is high. Rotamer libraries and packers remain essential in design, for modelling mutations and for refining models against experimental data.

9.8.5 Fold recognition and threading

Many proteins have a known fold but no detectable sequence similarity to it. **Fold recognition** asks which known fold a sequence is most compatible with. Bowie, Lüthy and Eisenberg described each structure as a **3D profile**, the environment of each position (buried or exposed, in which secondary structure), and scored sequences against it (Bowie et al. 1991). David Jones and colleagues introduced **threading**: the query sequence is placed onto the backbone of each template and scored with statistical pair potentials derived from known structures (Jones et al. 1992). Later methods combined sequence profiles with predicted secondary structure and solvent accessibility (Fischer and Eisenberg 1996), and **profile–profile** comparison (HHpred and similar methods) became the most sensitive way to detect templates (Section 1.6).

9.8.6 De novo prediction and fragment assembly

For proteins with no template, structures must be predicted from scratch, by searching conformational space for low-energy structures. Two problems make this hard: the search space is enormous (Section 9.5), and the energy functions are not accurate enough to recognise the native state reliably. **Fragment assembly** reduced the search space: short fragments (three and nine residues) from known structures, chosen by local sequence similarity, are combined by Monte Carlo search, and scored with knowledge-based energy functions. David Baker's **Rosetta** (Simons et al. 1997) and David Jones's **FRAGFOLD** (Jones 2001) produced the first successful de novo predictions of small proteins in CASP. With extensive sampling and all-atom refinement, Rosetta could reach atomic accuracy for some small proteins (Bradley et al. 2005). In general, however, de novo methods worked only for proteins smaller than about 100 residues.

9.8.7 Coevolution

The idea that would eventually lead to the breakthrough was old. Residues in contact in a structure must remain compatible: if one mutates, its partner often mutates in a compensating way. Such **correlated mutations** should be visible in multiple sequence alignments (Göbel et al. 1994). For two decades this

had little practical effect, because correlations are also transmitted *indirectly*: if A contacts B and B contacts C, A and C appear correlated without being in contact.

The solution was to fit a **global statistical model** of the whole alignment, a Potts model (a Markov random field) with fields for each position and couplings for each pair, so that direct couplings can be separated from indirect correlations. This **direct-coupling analysis** (DCA) (Weigt et al. 2009; Morcos et al. 2011), and fast approximations such as pseudo-likelihood methods and sparse inverse covariance estimation (PSICOV) (Jones et al. 2011), predicted contacts accurate enough to fold proteins from sequence alone (Marks et al. 2011; Marks et al. 2012). The method requires many sequences, typically more than a few times the protein length. Metagenomic sequences extended it to many more families (Ovchinnikov et al. 2017).

Contacts form patterns, such as the parallel diagonals of β-sheets, so the next step was to predict contact maps with machine learning that recognised these patterns (Skwark et al. 2014), and then with deep convolutional networks that treated the coevolution matrix as an image (Wang et al. 2017). In CASP13 (2018), networks predicting full distance distributions rather than binary contacts, combined with gradient-descent optimisation of the structure, gave a large improvement; DeepMind's first AlphaFold was the best of these (Senior et al. 2020).

9.8.8 AlphaFold2

At CASP14 (2020), **AlphaFold2** produced models comparable to experimental structures for most targets (Jumper, Evans, Pritzel, Green, Figurnov, Ronneberger, Tunyasuvunakool, Bates, Žídek, Potapenko, Bridgland, Meyer, Kohl, Ballard, Cowie, Romera-Paredes, Nikolov, Jain, Adler, Back, Petersen, Reiman, Clancy, Zielinski, Steinegger, Pacholska, Berghammer, Bodenstein, et al. 2021). Its main components are:

- **Inputs**: a multiple sequence alignment of the query, built with sensitive searches of large sequence databases including metagenomes, and optionally structural templates. Even when no template is supplied, the trained network has encoded structural knowledge from the PDB, so "template-free" should be read as "no explicit template used", not as prediction without prior structural knowledge.
- **The Evoformer**: a deep network of 48 blocks that maintains two representations, an MSA representation (sequences × residues) and a pair representation (residues × residues). Attention operates along rows and columns of the MSA, information flows between the two representations, and *triangle updates* on the pair representation enforce geometric consistency, analogous to the triangle inequality of distances.
- **The structure module** converts the pair and single representations into 3D coordinates. Each residue is treated as a rigid body (a frame), positioned with an attention mechanism that is invariant to global rotation and translation (*invariant point attention*), and side-chain torsion angles are predicted.
- **Recycling**: the output is fed back through the network several times.
- **Training** on structures in the PDB, followed by *self-distillation* on high-confidence predictions of unlabelled sequences, with a loss based on frame-aligned errors and auxiliary losses on distances and on the masked MSA.

AlphaFold2 also predicts its own accuracy. These measures are the network's estimates, not measured accuracy, and each answers a different question:

- **pLDDT** is a predicted lDDT score for each residue: the model's confidence in the *local* structure around that residue. It is not the probability that the region is folded, and says nothing about the relative placement of domains. Low pLDDT often indicates intrinsically disordered regions (see below).

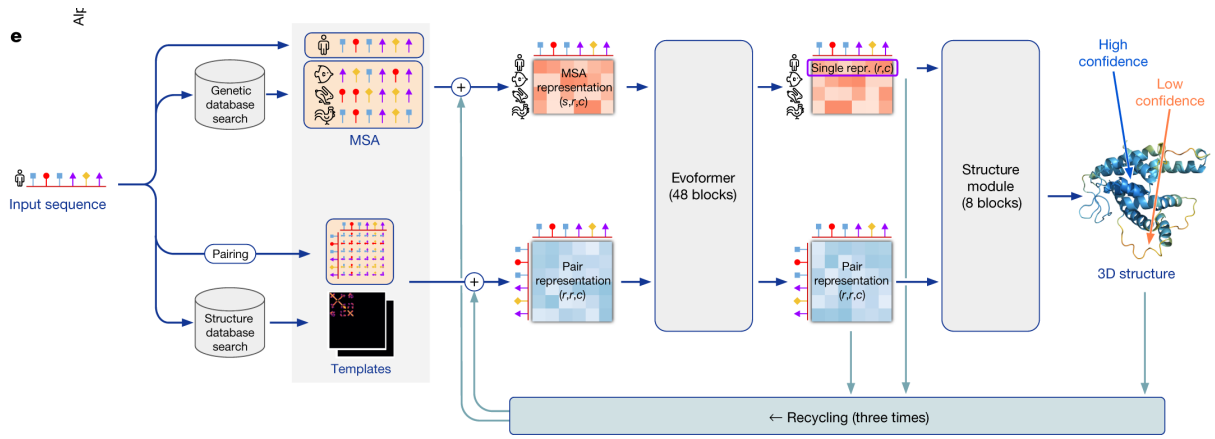

Figure 9.2: The AlphaFold2 architecture. The input sequence is used to search genetic databases for an MSA and structure databases for templates; the MSA and pair representations are updated by the 48 Evoformer blocks; the structure module (8 blocks) turns the single and pair representations into 3D coordinates with per-residue confidence; and the outputs are recycled three times. Figure 1e from Jumper, Evans, Pritzel, Green, Figurnov, Ronneberger, Tunyasuvunakool, Bates, Žídek, Potapenko, Bridgland, Meyer, Kohl, Ballard, Cowie, Romera-Paredes, Nikolov, Jain, Adler, Back, Petersen, Reiman, Clancy, Zielinski, Steinegger, Pacholska, Berghammer, Bodenstein, et al. (2021) (CC BY 4.0), cropped by Matteo Tadiello, *Modern Bioinformatics: From Foundations to Frontiers* (CC BY 4.0).

- The **predicted aligned error** (PAE) is the expected error in the position of residue j when the predicted and true structures are aligned on residue i. It shows whether the relative positions of domains, or of chains in a complex, are reliable.
- **pTM** and, for complexes, **ipTM** are global scores derived from the PAE for the whole model and for the interfaces between chains (Section 11.4). Confident individual chains (high pLDDT) do not imply a correct interface.

Using these measures correctly is essential: a predicted structure is a hypothesis with an estimated reliability, not a measurement.

The code was released in 2021, and DeepMind and EMBL-EBI used it to predict structures for almost all known proteins (Section 9.7). Demis Hassabis and John Jumper shared the 2024 Nobel Prize in Chemistry with David Baker. **RoseTTAFold**, from Baker's group, used a three-track network (sequence, distance and 3D coordinates) and reached similar accuracy (Baek et al. 2021). **ColabFold** made prediction fast and accessible by replacing the slow alignment step with MMseqs2 searches (Mirdita et al. 2022), and **OpenFold** retrained AlphaFold2 from scratch, showing how it learns (Ahdritz et al. 2024).

9.8.9 Complexes and co-folding: AlphaFold3 and successors

Soon after its release, AlphaFold2 was found to predict the structures of protein complexes when sequences of several chains were joined, and **AlphaFold-Multimer** was trained specifically for complexes (Evans et al. 2021; Bryant, Pozzati, and Elofsson 2022) (Chapter 11).

AlphaFold3 generalised the approach to almost all molecules in the PDB: proteins, DNA, RNA, small-molecule ligands, ions and modified residues (Abramson et al. 2024). It replaced the Evoformer with a simpler *Pairformer*, which uses the MSA less, and the structure module with a **diffusion model** that generates all-atom coordinates directly, starting from noise and denoising them step by step. On several retrospective benchmarks, this *co-folding* of all components predicted protein–ligand poses substantially better than classical docking methods (Section 9.11). Classical docking still has advantages

in some workflows, for example for explicit sampling, scoring very many ligands or adding constraints, so the question is not settled. Because AlphaFold3 was initially released without code, several groups reimplemented and extended the approach with open code: **Chai-1** (Boitreaud et al. 2024), **Boltz-1** (Wohlwend et al. 2024) and **Protenix** (Chen et al. 2025) report AlphaFold3-level accuracy, and **Boltz-2** also predicts binding affinities (Passaro et al. 2025) (all first released as preprints).

Three systems released in 2026 show different ways of moving beyond AlphaFold3. They are very recent, and their status (as of October 2026) differs: a preprint, a company technical report and a software repository. None of them is a peer-reviewed publication.

- **ESMFold2** (Candido et al., bioRxiv preprint, June 2026), from the ESM team, joins the large protein language model ESM C (Section 9.9) to an AlphaFold3-style diffusion structure module. Unlike the original ESMFold, it predicts complexes of proteins, nucleic acids and ligands, from single sequences or with an optional alignment. The authors report that it outperforms established methods for complex prediction, including antibody–antigen interactions, and that it can be used to design binders with nanomolar affinity (Candido et al. 2026). According to the authors, the model weights are openly released.
- **IsoDDE**, the drug design engine of Isomorphic Labs, DeepMind's drug-discovery sister company, is proprietary. Its technical report (February 2026, not peer reviewed) claims more than twice AlphaFold3's accuracy for the protein–ligand complexes least similar to the training data, 2.3 times AlphaFold3's success rate at high accuracy (DockQ > 0.8) for new antibody–antigen complexes, affinity predictions that can compete with physics-based free-energy calculations, and the identification of binding pockets from sequence (Isomorphic Labs Team 2026). There is no code, no model and no independent test, so these are claims, not results. Notice that the claimed gains are largest for examples unlike the training data, where AlphaFold3 is weakest.
- **OpenDDE** (a GitHub software repository, 2026) is not a new model and not a publication, but a community project that chains existing open tools behind one interface: AlphaFold3 for complexes, P2Rank for pockets, Boltz-2 for affinity, ImmuneBuilder for antibodies, and ChEMBL and RDKit for known ligands (OpenDDE contributors 2026). It has no benchmarks of its own. It shows what a drug design "engine" is: a pipeline of separate models, each of which can, and should, be evaluated on its own.

The contrast matters for science. Open tools such as ESMFold2, Boltz-2 and OpenFold can be tested by anyone on data they have never seen, while a closed system can only be judged by what its owners choose to report. Claims of accuracy on "new" targets should always be checked for overlap with the training data (4).

9.8.10 Intrinsically disordered proteins

Not all proteins fit the picture of one sequence, one stable structure. **Intrinsically disordered proteins and regions** (IDPs and IDRs) have no stable tertiary structure on their own and exist as dynamic ensembles of conformations. They are common in eukaryotes, especially in signalling and transcription regulation, and they evolve differently from folded domains (Section 3.5) (Lee et al. 2014; Brown et al. 2011; Light et al. 2013). Many fold, partly or fully, only when they bind a partner (*folding upon binding*) or under particular conditions, for example after phosphorylation: their structure is *conditional*.

Disorder can be predicted from sequence, because disordered regions have a characteristic composition: few hydrophobic and aromatic residues, many charged and polar residues, prolines and glycines, and often low sequence complexity. Dedicated **disorder predictors** exploit this, from IUPred, which estimates whether a segment can form enough favourable inter-residue contacts to fold (Erdős et al. 2021), to neural networks using alignments or language-model embeddings; they are assessed in blind community experiments (CAID) in the spirit of CASP (Necci et al. 2021). AlphaFold2's **low pLDDT**

(below about 50) is also a competitive disorder predictor, which is why models of eukaryotic proteins in the AlphaFold Database often contain long, extended, low-confidence regions (Tunyasuvunakool et al. 2021). These regions should not be read as structures. Two caveats apply. Low pLDDT means only that no confident structure was predicted, which may reflect disorder or simply a lack of information. Conversely, conditionally folded regions are sometimes predicted with high confidence in their bound conformation, which is then a hypothesis about the bound state, not about the free protein (Alderson et al. 2023). Neither a single model nor a confidence score describes the ensemble of a disordered region; that requires simulation and experiments such as NMR (Section 9.11).

9.8.11 Limitations and current questions

Prediction is not finished. Current methods:

- predict a single structure, while many proteins have several functional conformations; sampling alternative states, for example by clustering the MSA, is an active research area (Wayment-Steele et al. 2023), but such samples are plausible alternative states, not a thermodynamic ensemble with equilibrium populations (Section 9.11);
- depend on the MSA, and are less accurate for orphan proteins, rapidly evolving proteins and designed or mutated sequences, and do not reliably predict the effects of point mutations;
- are much less reliable for antibody–antigen and other complexes without coevolution between the partners, for RNA, and for large flexible assemblies;
- can produce confident but wrong predictions ("hallucinations"), particularly for disordered regions in diffusion-based models, and ligand poses that are physically implausible (Buttenschoen et al. 2024);
- by default predict the bare polypeptide: cofactors, metal ions, glycans and post-translational modifications are absent unless they are given explicitly (AlphaFold3 and similar models accept some of them as input), so the model may not represent the biologically relevant molecular state, for example a metal-binding site without its metal, or a protein whose conformation depends on phosphorylation;
- learn from the PDB, so they reflect its biases, and they say nothing about the folding process (Section 9.5).

9.8.12 Checking a predicted model

Before conclusions are drawn from a predicted structure, check:

- **Confidence**: pLDDT for local structure, PAE for the relative placement of domains and chains, and ipTM or a similar score for interfaces; read each for what it measures.
- **Stereochemistry**: clashes, bond geometry, Ramachandran outliers and, for ligands, chemically valid poses, with the same validation tools as for experimental structures (Burley et al. 2018; Buttenschoen et al. 2024).
- **Leakage**: whether the protein, or a close homologue, was among the templates or training structures; if so, high accuracy is expected rather than impressive (4).
- **Oligomeric state**: whether the protein acts as a monomer or in a complex; a single subunit predicted alone may have exposed interface surfaces or unstructured segments (Chapter 11).
- **Ligands, cofactors and modifications**: whether the biologically relevant state includes metals, cofactors, glycans or modifications that were not modelled.
- **Consistency with experiments**: agreement with available data such as mutagenesis, crosslinking, small-angle scattering, cryo-EM maps or known functional residues.

9.9 Protein language models and structure

Protein language models (pLMs) are trained on hundreds of millions of protein sequences to predict masked or next amino acids, in the same way as language models for text. Their architecture and training are described in Section 1.10. This section covers what they contribute to structure prediction. The key observation is that, to predict missing residues well, a model must learn which positions co-vary, which is the coevolution signal of Section 9.8, and this information appears in the attention maps and embeddings without any structure ever being shown to the model.

9.9.1 ESMFold and the ESM Metagenomic Atlas

The **ESM-2** models from Meta AI, with up to 15 billion parameters, showed that structural information in the embeddings increases with model size. **ESMFold** adds a folding trunk and an AlphaFold-like structure module on top of ESM-2, and predicts structures from a **single sequence**, without an MSA (Lin et al. 2023). It is less accurate than AlphaFold2 for proteins with few homologues, but an order of magnitude or more faster, since the slow alignment step is not needed. Its accuracy correlates with how well the language model "understands" the sequence (its perplexity), which suggests that it relies on evolutionary information stored in the weights rather than on physics.

This speed made it possible to predict the structures of more than 600 million proteins from metagenomes, the **ESM Metagenomic Atlas** (Lin et al. 2023). About a third of these predictions had high confidence, and many had no similarity to known structures, giving a first view of the structural diversity of uncultured organisms (Section 5.7). The Atlas can be searched with Foldseek (Section 9.6).

9.9.2 ESM C and ESM3

After Meta's protein team became the company EvolutionaryScale, it released two successors:

- **ESM C** (ESM Cambrian, 2024) is a family of representation models with 300 million, 600 million and 6 billion parameters, trained on UniRef and metagenomic sequences, intended as a more efficient drop-in replacement for ESM-2: the 300-million-parameter model matches the 650-million parameter ESM-2 (EvolutionaryScale 2024). It was described in a technical blog post rather than a peer-reviewed paper. **ESMFold2** combines ESM C with a diffusion structure module to predict complexes (Section 9.8; a 2026 preprint) (Candido et al. 2026).
- **ESM3** is a generative model that reasons jointly over sequence, structure (encoded as discrete tokens) and function annotations (Hayes et al. 2025). It can be prompted with any combination of these, for example with a partial structure and a function keyword, and generates the rest. ESM3 was used to design a new fluorescent protein distant from all known ones (Section 9.12).

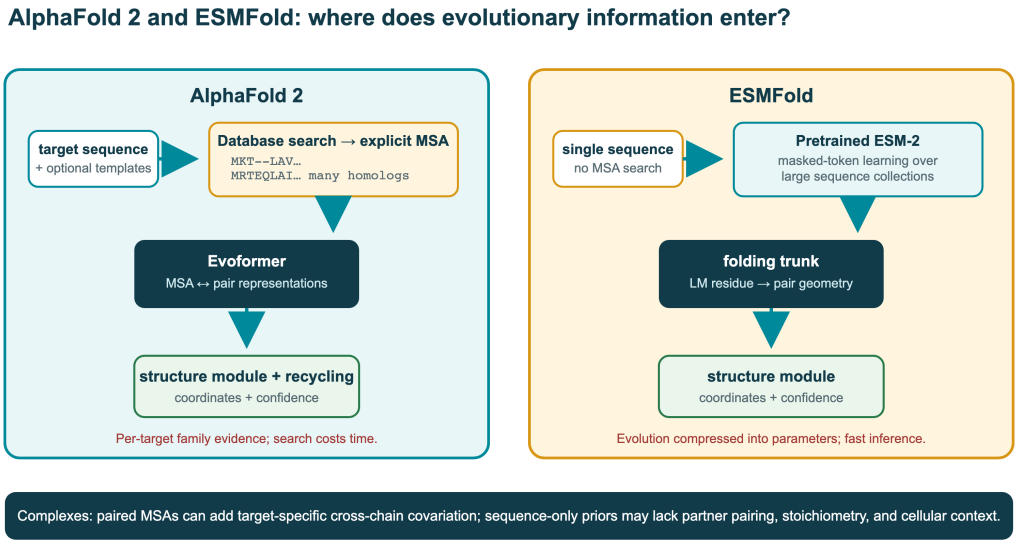

Figure 9.3: Where evolutionary information enters AlphaFold2 and ESMFold. AlphaFold2 searches databases for an explicit MSA of the target family, which the Evoformer combines with a pair representation; ESMFold takes a single sequence and uses the ESM-2 language model, in which information from millions of sequences has been compressed into the parameters during pre-training. For complexes, paired MSAs can add coevolution between chains, which a single-sequence model lacks. Figure: Matteo Tadiello, *Modern Bioinformatics: From Foundations to Frontiers* (CC BY 4.0).

9.9.3 Structure-aware language models: ProstT5

A complementary idea is to teach language models structure explicitly. Foldseek's **3Di alphabet** (Section 9.6) turns each structure into a string, so sequence and structure can be treated as two languages. **ProstT5** is a protein language model fine-tuned to translate between amino acid sequences and 3Di strings (Heinzinger et al. 2024). Predicting 3Di sequences from amino acid sequences allows structure-based search with Foldseek even for proteins with no predicted structure, thousands of times faster than predicting the structure first. The reverse direction, from 3Di to amino acids, is a form of inverse folding, related to protein design (Section 9.12).

9.9.4 Language models versus alignments

Language models remove the need to build an MSA for each query, which is often the slowest step in prediction, and work for single sequences such as designed proteins and antibodies. MSA-based methods remain more accurate when many homologues are available. Whether the models learn general principles of protein structure, or mainly memorise the evolutionary information of protein families seen during training, is debated, and affects how well they generalise to sequences unlike those in nature (Chapter 12).

9.10 Membrane proteins

Membrane proteins make up about a quarter of the proteins in most genomes and about half of all drug targets, but for a long time they were a small fraction of the PDB, because they are hard to express, purify and crystallise (Elofsson and Heijne 2007). Their structures are strongly constrained by the membrane, which made their topology one of the first aspects of structure that could be predicted reliably. There are two structural classes: **α-helical** proteins, found in all cell membranes, and **β-barrel** proteins, found in the outer membranes of Gram-negative bacteria, mitochondria and chloroplasts.

9.10.1 α-helical membrane proteins

The hydrophobic core of a lipid bilayer is about 30 Å thick. A polypeptide crossing it must satisfy the hydrogen bonds of its backbone, which an α-helix does internally. A **transmembrane helix** is therefore a stretch of about 20 mostly hydrophobic residues. Candidate segments can be found with **hydrophobicity plots**, which average a hydrophobicity scale over a sliding window. A hydropathy plot alone is not a sufficient predictor, however: signal peptides and some soluble helices are also hydrophobic; some transmembrane helices are only marginally hydrophobic and insert only together with neighbouring helices; and **re-entrant** loops or helices dip into the membrane and leave it on the same side.

The **topology** of a membrane protein, which segments cross the membrane and which side the loops are on, is largely governed by a few rules. The most important is the **positive-inside rule**, discovered by Gunnar von Heijne in Stockholm: loops on the cytoplasmic side are enriched in the positively charged residues lysine and arginine (Heijne 1992). The first topology predictors combined hydrophobicity with the positive-inside rule. **TMHMM** formulated the problem as a hidden Markov model, with states for helix cores, helix caps, cytoplasmic and non-cytoplasmic loops, whose grammar enforces the alternation of inside and outside loops (Krogh et al. 2001). It predicts transmembrane helices with about 97% accuracy and full topologies correctly for most proteins. Predictors must also distinguish transmembrane helices from **signal peptides**, which are also hydrophobic but are cleaved off (Chapter 10). **DeepTMHMM** replaced the hand-crafted features with embeddings from a protein language model, combined with a constrained output layer that keeps the grammar of the HMM, and predicts α-helical and β-barrel proteins and signal peptides together (Hallgren et al. 2022).

The structure of membrane proteins is now mostly predicted with general methods such as AlphaFold, which perform well on them. Topology predictors remain useful as fast tools for whole proteomes and to orient predicted structures in the membrane.

9.10.2 β-barrel membrane proteins

Outer membrane proteins of Gram-negative bacteria have a completely different architecture: an antiparallel β-sheet of 8 to 26 strands closed into a **barrel**, with hydrophobic residues facing the lipids and polar residues lining the interior (Wimley 2003). They include porins, transporters and enzymes. In each membrane-crossing strand, residues alternate between pointing into the membrane and into the barrel, so the strands are shorter (about 9–11 residues) and less hydrophobic on average than transmembrane helices, and hydrophobicity plots do not find them. β-barrel predictors therefore use the alternating pattern, the even number of strands and the fact that loops alternate between the periplasm and the outside. PRED-TMBB used a hidden Markov model (Bagos et al. 2004), and BOCTOPUS added the dyad-repeat pattern of strands (Hayat et al. 2016). DeepTMHMM predicts both classes with a single model (Hallgren et al. 2022).

9.11 Dynamics and docking

Proteins are not static. They vibrate, side chains rotate, loops and domains move, and many proteins switch between conformations as part of their function. They also bind other molecules. This section describes physics-based simulation of protein motion and the prediction of how proteins bind small molecules.

9.11.1 Molecular dynamics

Molecular dynamics (MD) simulates the motion of every atom by integrating Newton's equations of motion, $m_i \ddot{\mathbf{x}}_i = -\nabla_i U(\mathbf{x})$, in time steps of about 2 femtoseconds. The forces come from a **force field**, an empirical potential energy function $U(\mathbf{x})$ with terms for bond lengths, bond angles and torsions, and non-bonded van der Waals and electrostatic interactions, with parameters fitted to quantum-mechanical calculations and experimental data. Water is included explicitly as thousands of molecules, or approximated as a continuum.

The first simulation of a protein, the bovine pancreatic trypsin inhibitor for 9 picoseconds in vacuum, was published in 1977 (McCammon et al. 1977). Levitt and Warshel had already simulated protein folding with a simplified model (Levitt and Warshel 1975), and Warshel and Levitt introduced combined quantum mechanical/molecular mechanical (QM/MM) methods for enzyme reactions (Warshel and Levitt 1976). Martin Karplus, Michael Levitt and Arieh Warshel received the 2013 Nobel Prize in Chemistry for these multiscale models (Karplus and McCammon 2002).

The main limitation of MD is **time scale**. Biologically important events, such as folding, large conformational changes and ligand unbinding, take microseconds to seconds, while a simulation needs about a billion steps per microsecond. Advances in hardware, from graphics processors to the special-purpose supercomputer **Anton**, reached millisecond simulations and allowed small proteins to be folded at atomic detail (Shaw et al. 2010; Lindorff-Larsen et al. 2011). *Enhanced sampling* methods, such as replica exchange and metadynamics, accelerate the crossing of energy barriers. The other limitation is **accuracy of the force field**: simulations are only as good as the energy function, and systematic comparisons with experimental data have driven steady improvements (Lindorff-Larsen et al. 2012). MD is used to study mechanisms, to refine structures, to calculate free energies of binding and to sample the conformational ensembles that static structure prediction misses.

9.11.2 Normal modes and elastic network models

Large-scale, slow motions of proteins, such as hinge bending between domains, can be studied without full MD. **Normal mode analysis** approximates the energy around a minimum as a harmonic function and computes the vibrational modes of the structure. Tirion showed that a very simple model, in which all atoms within a cutoff distance are connected by identical springs, reproduces the slowest modes well (Tirion 1996). **Elastic network models**, such as the Gaussian network model (Bahar et al. 1997) and the anisotropic network model (Atilgan et al. 2001), use only the Cα atoms. The few lowest-frequency modes often describe functional motions, and the models predict which residues are flexible, in agreement with crystallographic temperature factors, at a tiny fraction of the cost of MD.

9.11.3 Structures versus ensembles

Predicting a structure and predicting a conformational ensemble are different problems. A structure predictor returns one or a few static models. A protein in solution populates an ensemble of conformations, with relative populations set by their free energies (Section 9.5). Function often depends on the ensemble: in **allostery**, an effector shifts the populations between states; and a ligand may bind a conformation that is rare without it (*conformational selection*) or induce a change on binding (*induced fit*). Running AlphaFold with different random seeds, with subsampled or clustered MSAs or with dropout gives structural diversity, which can reveal alternative states (Wayment-Steele et al. 2023). It does not, however, sample a thermodynamic ensemble, and the frequencies of the models are not equilibrium populations. Ensembles and populations come from MD and enhanced sampling, from experiments such as NMR and cryo-EM classification (Section 9.4), or from methods that combine learned models with physics, an active research area.

9.11.4 Sampling, convergence and computational cost

At equilibrium, the population of a conformational state i with free energy G_i follows the **Boltzmann distribution**,

$$p_i = \frac{e^{-G_i/RT}}{\sum_j e^{-G_j/RT}},$$

so a free-energy difference of about 1.4 kcal/mol at 25 °C corresponds to a tenfold difference in population (Section 9.3). Simulation methods aim to sample from this distribution. **Monte Carlo** methods do so without following time: a random move that changes the energy from U to U' is accepted with the Metropolis probability

$$P_{\text{accept}} = \min\left\{1, e^{-(U'-U)/k_B T}\right\},$$

so downhill moves are always accepted and uphill moves sometimes (Metropolis et al. 1953). If the moves can reach all states, the samples follow the Boltzmann distribution of the energy function. The same algorithm is used for Bayesian phylogenetics (Section 4.3), for fragment assembly in Rosetta (Section 9.8) and for sequence design (Section 9.12); lowering the temperature gradually (*simulated annealing*) turns it into a search for low-energy states.

Sampling is the main source of error in both MD and Monte Carlo. Successive frames of a trajectory are strongly correlated, so a long simulation that stays in one basin contains less information than its length suggests. Convergence is tested by running independent simulations from different starting structures, comparing averages over separate blocks of the trajectory, and comparing computed observables with experiments such as NMR or SAXS. A longer simulation cannot correct a wrong starting point, for example a missing ligand or a wrong protonation state.

The cost of each method grows differently with the size of the system. In MD, short-range forces are computed with neighbour lists at a cost roughly proportional to the number of atoms N, and long-range electrostatics with particle-mesh Ewald methods at a cost close to $N \log N$; with time steps of 2 fs, one microsecond needs some 5×10^8 steps. In AlphaFold-like networks, the pair representation stores L^2 entries for L residues, and the triangle updates take time proportional to L^3, so long chains and large complexes are limited by memory, which is one reason why large assemblies are built from predicted subcomplexes (Section 11.4). Direct-coupling models have about $L^2 \times 21^2$ coupling parameters, which must be estimated from a finite alignment. Structure search avoids expensive all-atom comparisons by encoding structures as strings, as Foldseek does (Section 9.6), at some cost in sensitivity.

9.11.5 Optimisation and energy functions

Structure prediction, docking and design are all **search problems** on an **energy landscape**: an energy or score function $E(\mathbf{x})$ is defined over conformations, ligand poses or sequences, and the task is to find its lowest minimum. Two separate things must work. The energy function must give the correct answer the lowest energy, and the search must find it. The two failures can be told apart: if the experimental structure scores better than the best model, sampling failed; if it scores worse, the energy function is wrong. In both cases the landscape is rugged and of very high dimension, with many local minima (Section 9.5).

Local optimisation, or energy minimisation, moves downhill from a starting point with gradient descent or related methods (conjugate gradients, L-BFGS) until it reaches the nearest local minimum. It removes clashes and strained geometry, for example in the final relaxation of AlphaFold2 models, but it cannot cross barriers. **Global optimisation** accepts some uphill moves. Monte Carlo with the Metropolis criterion and simulated annealing were described above (Kirkpatrick et al. 1983). **Replica exchange** runs copies of the system at several temperatures and swaps them with a Metropolis-like rule, so that conformations trapped at low temperature can escape at high temperature (Sugita and Okamoto 1999). **Genetic algorithms** evolve a population of solutions by mutation, recombination and selection, and are used in some docking programs. Discrete problems, such as choosing side-chain rotamers, have their own exact or pruning methods (see *Loops and side chains* in Section 9.8). The same ideas appear elsewhere in the book: heuristic tree search with rearrangements in phylogenetics is hill climbing in tree space, with the same risk of local optima (Section 4.3); docking searches poses (below and Section 11.4); design searches sequence space (Section 9.12); and training a neural network is gradient descent on a loss function with millions of parameters (4). In CASP13, the first AlphaFold folded proteins by gradient descent on a predicted distance potential (Senior et al. 2020).

There are two kinds of energy function. **Physics-based force fields** (see *Molecular dynamics* above) describe interactions between atoms and are transferable, but treating solvent and entropy accurately is expensive. **Knowledge-based** or **statistical potentials** are derived from known structures. The frequency of a feature, such as the distance r between two residue types, is compared with its frequency in a *reference state* that lacks specific interactions, and converted to an energy with the **inverse Boltzmann relation**:

$$\Delta E(r) = -k_B T \ln \frac{P_{\text{obs}}(r)}{P_{\text{ref}}(r)}.$$

Features that are observed more often than expected get favourable energies. Miyazawa and Jernigan derived residue–residue contact energies in this way (Miyazawa and Jernigan 1985), and Sippl derived distance-dependent **potentials of mean force** (Sippl 1990), which were used for threading (Section 9.8) (Jones et al. 1992) and for model quality assessment.

The derivation rests on assumptions that are not strictly true: that the structures in the PDB are a Boltzmann ensemble at one temperature, when they are many different proteins; that pair terms are independent and additive; and that the reference state is correct, although the result depends strongly on how it is chosen. Preferences that arise from chain connectivity or composition are also absorbed into the "energies" (Thomas and Dill 1996). Statistical potentials nevertheless work, because they summarise effective free energies, including solvation averaged over many environments, and because their task is usually to *discriminate* native-like from wrong structures, not to compute absolute stabilities. A deep network trained on the PDB can be seen as an extremely detailed learned potential of this kind.

Practical scoring functions mix both. The **Rosetta energy function** (REF2015) combines physical terms (Lennard-Jones packing, electrostatics, implicit solvation and orientation-dependent hydrogen bonds) with statistical terms (backbone torsion and rotamer probabilities, and reference energies for

each amino acid used in design), and its weights are fitted so that native structures and sequences score best and measured stabilities are reproduced (Alford et al. 2017). Its "Rosetta energy units" are roughly calibrated against kcal/mol but are not free energies.

9.11.6 Docking and scoring functions

Molecular docking predicts how a small molecule binds to a protein: its position and orientation (the *pose*) in a binding site, and, less reliably, how strongly it binds. Docking has two parts: a **search** over poses and ligand conformations, and a **scoring function** that ranks them.

- DOCK, from Irwin Kuntz's group, was the first docking program. It matched ligand atoms to spheres filling the binding site (Kuntz et al. 1982), and later added force-field-based scoring (Meng et al. 1992).
- Scoring functions are of three kinds: **force-field** based (van der Waals and electrostatic terms), **empirical** (weighted terms for hydrogen bonds, hydrophobic contacts and lost rotational entropy, fitted to measured affinities (Böhm 1994)), and **knowledge-based** (statistical potentials derived from known complexes (Muegge and Martin 1999)).
- **AutoDock Vina** combined an empirical scoring function with efficient gradient-based optimisation and became one of the most widely used tools (Trott and Olson 2009).

Docking reproduces known binding poses reasonably well, but scoring functions rank compounds by affinity poorly (Warren et al. 2005), because they neglect solvation, entropy and protein flexibility. Docking scores are often reported in kcal/mol-like units, but they are not binding free energies (Section 9.3). Ranking poses of one ligand, ranking ligands against one target, and estimating absolute affinities are different problems of increasing difficulty. More rigorous free-energy calculations with MD (free-energy perturbation, FEP) are more accurate but expensive. Still, **virtual screening** of large libraries, now billions of compounds, has found new drug leads for many targets. Protein–protein docking uses similar ideas; the classical approach used fast Fourier transforms to scan rigid shape complementarity (Katchalski-Katzir et al. 1992) (Chapter 11).

Deep learning has entered docking from two directions. Co-folding methods such as AlphaFold3 and its successors (Section 9.8) predict the protein and ligand together, and often outperform classical docking, especially when no experimental structure of the protein exists. Benchmarks such as PoseBusters showed, however, that some deep-learning methods produce physically impossible poses, with clashes and distorted geometry, and that their accuracy drops for ligands and pockets unlike those in the training data (Buttenschoen et al. 2024). Generalisation to new chemistry is the main challenge for the drug-design engines described above.

9.12 Protein design

Protein design reverses structure prediction: instead of finding the structure of a given sequence, it finds sequences that fold into a desired structure or carry out a desired function. It tests our understanding of proteins in the most direct way, since a design either works in the laboratory or not, and it has produced new enzymes, binders, vaccines and materials. Like prediction, it has been transformed by deep learning (Kortemme 2024).

9.12.1 Physics-based design

The first fully automated design of a protein sequence was reported by Dahiyat and Mayo in 1997. They designed a zinc-finger fold that folded without zinc, by searching over all sequences and side-chain rotamers for the lowest energy with a fixed backbone (Dahiyat and Mayo 1997). The search is combinatorial, and was solved with dead-end elimination and other optimisation methods.

David Baker's group extended this with the **Rosetta** energy function and sampling methods developed for prediction (Section 9.8). In 2003 they designed **Top7**, a protein with a fold not seen in nature, whose crystal structure matched the design almost exactly (Kuhlman et al. 2003). Over the next decade, rules for designing ideal proteins from scratch were worked out (Koga et al. 2012), and Rosetta was used to design enzymes for reactions with no natural catalyst (Jiang et al. 2008), symmetric assemblies, nanocages and vaccines (Huang et al. 2016). Most designs still failed, however, and success often required testing many designs and laboratory evolution.

9.12.2 Deep-learning design

Since 2021, design has been reorganised around deep networks, typically in two steps: generate a **backbone** structure, then design a **sequence** for it, and check the result by predicting its structure.

A central warning applies to all the methods below. A confident structure prediction of a design is an *in silico* filter: it shows that the design is consistent with what a predictor has learned, not that the sequence folds, is soluble, expresses, or binds its target specifically. Designs are often optimised against the same kind of network that is used to check them, which makes high confidence easier to obtain than real success. Only experiments validate a design.

- **Inverse folding. ProteinMPNN** is a graph neural network that takes a backbone and predicts a sequence that will fold into it (Dauparas et al. 2022). It replaced Rosetta's sequence design, is much faster, and increased the experimental success rate dramatically.
- **Hallucination.** A structure-prediction network can be run "in reverse": starting from a random sequence, the sequence is changed by Monte Carlo or gradient descent to maximise the network's confidence that it folds into a well-defined structure. Hallucination produced new folds that were confirmed experimentally (Anishchenko et al. 2021), and could build scaffolds around functional sites (Wang et al. 2022). **BindCraft** uses AlphaFold2 in this way to design protein binders against a target in a single step, with experimental success rates often from 10% to 100% (Pacesa et al. 2025).
- **Diffusion models.** Generative diffusion models, trained to remove noise from protein structures, generate new backbones from noise. **RFdiffusion**, fine-tuned from RoseTTAFold, can be conditioned on symmetry, a binding target or a functional motif, and has produced high-affinity binders, symmetric assemblies and enzymes (Watson et al. 2023). **Chroma** is a diffusion model whose generation can be steered by "programmable" conditions such as shape, symmetry or natural language (Ingraham et al. 2023). RFdiffusion All-Atom extends design to proteins that bind small molecules (Krishna et al. 2024).

- **Combining prediction and generation. Protein Hunter** exploits the tendency of diffusion-based structure predictors such as AlphaFold3 and Boltz to "hallucinate" folded structures even for poor sequences. It alternates structure prediction and sequence redesign, starting from an uninformative sequence, to converge on a sequence and structure that are consistent with each other (a preprint) (Cho et al. 2025).
- **Generative language models** such as ESM3 generate sequences directly, conditioned on structure and function (Section 9.9).

In all these pipelines, structure prediction serves as the *in silico* filter described above: designs are kept only if AlphaFold or a similar method predicts, with high confidence, that they fold into the intended structure or complex. This filter enriches for successful designs, but the most promising designs must always be tested in the laboratory. David Baker received half of the 2024 Nobel Prize in Chemistry for computational protein design.

9.12.3 Negative design and specificity

Most of these methods perform **positive design**: they make the intended structure or complex favourable. A useful protein must also avoid competing states, such as misfolded or swapped conformations, unwanted oligomers and aggregates, and, for binders, binding to off-targets such as close homologues of the target. **Negative design** makes these alternatives unfavourable, for example by also scoring a design against off-target proteins or alternative conformations and rejecting designs predicted to form them. It is essential for specific binders, for designed protein–protein interfaces that must pair only with their intended partner, and for proteins designed to switch between states. A high confidence score for the intended complex says nothing about whether the design also binds something else.

9.13 Key concepts

A checklist for revision.

- **CASP:** blind prediction; target categories; RMSD, GDT_TS, TM-score, lDDT and DockQ; CAPRI and CAMEO; key moments (Rosetta in CASP3–5, coevolution in CASP11, AlphaFold in CASP13 and CASP14, the AlphaFold3 server as a tool used by many groups in CASP16); template and training-set overlap (leakage) in benchmarks
- **Biochemical background:** the 20 amino acids and their properties; the peptide bond; free energy, the hydrophobic effect and other forces; K_d and the standard binding free energy; enzymes, transition states, Michaelis–Menten kinetics ($K_m \neq K_d$), inhibition and allostery
- **Levels of structure:** primary to quaternary; α-helix and β-sheet; Ramachandran plot; helix and sheet packing; supersecondary motifs; domains, folds and superfamilies; structural classes
- **Experimental methods:** X-ray crystallography, the phase problem and molecular replacement; resolution, R and R-free; NMR and ensembles; cryo-EM, the resolution revolution, Fourier shell correlation and conformational heterogeneity; validation; integrative structural biology (SAXS, cross-linking MS, HDX-MS, FRET/EPR; the nuclear pore complex; PDB-IHM; validation with data not used for modelling); integration with prediction

- **Folding:** Anfinsen's thermodynamic hypothesis and its exceptions; the native state as an ensemble; the hydrophobic effect and marginal stability; two-state folding; Levinthal's paradox; energy landscapes and funnels; minimal frustration; folding simulations on Anton
- **Misfolding and amyloid:** cross-β structure and steric zippers; amyloid as a generic, concentration-dependent state; aggregation-prone regions, gatekeepers, TANGO and Waltz; prions (PrP, yeast [URE3] and [PSI+]); cryo-EM structures of tau, amyloid-β and α-synuclein fibrils and polymorphs; functional amyloids
- **Structure comparison:** RMSD and its problems; TM-score; DALI, TM-align and Foldseek with the 3Di alphabet; structure usually more conserved than sequence (a tendency, not a law); the limited number of folds; clustering the AlphaFold Database
- **Structure databases:** PDB; SCOP, CATH, ECOD and TED; AlphaFold Database; ESM Metagenomic Atlas
- **Secondary structure prediction:** Chou–Fasman, GOR, PHD and PSIPRED; why alignments helped; Q3 accuracy
- **Secondary-structure assignment:** DSSP (hydrogen-bond energy, eight states) and STRIDE; reduction to three states; why assignments differ; Q3 vs. the segment overlap score (SOV)
- **Homology modelling and fold recognition:** template search, alignment, MODELLER; dependence on sequence identity; loop modelling (database, ab initio, kinematic closure); rotamers and backbone-dependent rotamer libraries; side-chain packing (dead-end elimination, SCWRL4, Rosetta packer); the Rosetta suite; deep-learning predictors model side chains implicitly; 3D profiles, threading, profile–profile methods
- **De novo prediction:** fragment assembly (Rosetta, FRAGFOLD), energy functions and sampling
- **Coevolution:** correlated mutations; direct vs. indirect correlations; DCA, pseudo-likelihood and PSICOV; contact and distance prediction with deep networks
- **AlphaFold2:** MSA and pair representations, Evoformer, triangle updates, structure module and invariant point attention, recycling, self-distillation; pLDDT, PAE and ipTM and what they do not measure; RoseTTAFold, ColabFold, OpenFold
- **Complexes and co-folding:** AlphaFold-Multimer; AlphaFold3, Pairformer and diffusion; Chai-1, Boltz-1/2 and Protenix; ESMFold2, IsoDDE and OpenDDE (2026; preprint, technical report, software); open vs. closed systems; limitations (single conformations, MSA dependence, antibodies, hallucinations, physically invalid poses, missing cofactors and modifications)
- **Intrinsically disordered proteins:** disordered regions, folding upon binding and conditional folding; disorder prediction; low pLDDT as a disorder proxy
- **Validating a predicted model:** confidence measures, stereochemistry, leakage, oligomeric state, ligands and cofactors, consistency with experiments
- **Language models:** ESM-2 and ESMFold; the ESM Metagenomic Atlas; ESM C, ESMFold2 and ESM3; ProstT5 and the 3Di alphabet; language models vs. alignments
- **Membrane proteins:** α-helical vs. β-barrel; hydrophobicity plots and their limits; positive-inside rule; TMHMM and DeepTMHMM; signal peptides; β-barrel predictors
- **Dynamics:** structure prediction vs. ensemble prediction; molecular dynamics, force fields, time scales and enhanced sampling; QM/MM; normal modes and elastic network models
- **Sampling and cost:** the Boltzmann distribution (1.4 kcal/mol ≈ tenfold population at 25 °C); Monte Carlo and the Metropolis criterion; simulated annealing; correlated frames and tests of convergence; scaling of MD (N, $N \log N$), of the pair representation (L^2 memory, L^3 triangle updates) and of DCA parameters
- **Optimisation and energy functions:** prediction, docking and design as search on an energy landscape; search vs. energy-function failures; local minimisation vs. global search (Monte Carlo, simulated annealing, replica exchange, genetic algorithms); physics-based force fields vs. knowledge-based potentials; inverse Boltzmann relation, potentials of mean force (Sippl) and contact energies (Miyazawa–Jernigan), their assumptions and why they work; the Rosetta energy function

- **Docking:** search and scoring; force-field, empirical and knowledge-based scoring functions; docking scores are not binding free energies; DOCK and AutoDock Vina; virtual screening; FEP; deep-learning docking and PoseBusters
- **Protein design:** Dahiyat and Mayo; Rosetta and Top7; ideal proteins, enzymes and nanocages; ProteinMPNN; hallucination and BindCraft; diffusion (RFdiffusion, Chroma, RFdiffusion All-Atom); Protein Hunter; ESM3; negative design and specificity; prediction as an *in silico* filter, not validation

9.14 Recommended reading

These papers are recommended for reading in full:

- Anfinsen (1973) — why the sequence determines the structure; the basis for all structure prediction.
- Marks et al. (2012) — protein structure prediction from sequence variation; coevolution explained.
- Jumper, Evans, Pritzel, Green, Figurnov, Ronneberger, Tunyasuvunakool, Bates, Žídek, Potapenko, Bridgland, Meyer, Kohl, Ballard, Cowie, Romera-Paredes, Nikolov, Jain, Adler, Back, Petersen, Reiman, Clancy, Zielinski, Steinegger, Pacholska, Berghammer, Bodenstein, et al. (2021) — AlphaFold2; the method that largely solved single-chain structure prediction.
- Abramson et al. (2024) — AlphaFold3; co-folding of proteins with nucleic acids, ligands and ions by diffusion.
- Lin et al. (2023) — ESMFold and the ESM Metagenomic Atlas; structure from a language model.
- Watson et al. (2023) — RFdiffusion; de novo design of protein structure and function with diffusion models.

Titles, abstracts, links and the full texts are in Section A.9; a longer list of further papers is in Section B.9.

9.15 Background reading (open access)

- **Protein structure (Wikipedia)** — Protein structure is the three-dimensional arrangement of atoms in an amino acid-chain molecule. Proteins are polymers – specifically polypeptides – formed from sequences of amino acids, which are the monomers of the polymer.
  https://en.wikipedia.org/wiki/Protein_structure
- **Protein domain (Wikipedia)** — In molecular biology, a protein domain is a region of a protein's polypeptide chain that is self-stabilizing and folds independently from the rest. Each domain forms a compact, folded three-dimensional structure. Many proteins consist of several domains, and a domain may appear in a variety of different proteins.
  https://en.wikipedia.org/wiki/Protein_domain
- **Protein folding (Wikipedia)** — Protein folding is the physical process by which a protein, after synthesis by a ribosome as a linear chain of amino acids, changes from an unstable random coil into a more ordered three-dimensional structure. This structure permits the protein to become biologically functional or active.
  https://en.wikipedia.org/wiki/Protein_folding
- **Anfinsen's dogma (Wikipedia)** — Anfinsen's dogma, also known as the thermodynamic hypothesis, is a postulate in molecular biology. It states that, at least for a small globular protein in its standard physiological environment, the native structure is determined only by the protein's amino acid sequence.
  https://en.wikipedia.org/wiki/Anfinsen%27s_dogma

- **Levinthal's paradox (Wikipedia)** — Levinthal's paradox is a thought experiment in the field of computational protein structure prediction that concerns the mechanism through which peptides reach a stable native configuration, given the large amount of folding conformations.
  https://en.wikipedia.org/wiki/Levinthal%27s_paradox
- **X-ray crystallography (Wikipedia)** — X-ray crystallography is the experimental science of determining the atomic and molecular structure of a crystal, in which the structure causes a beam of incident X-rays to diffract in specific directions.
  https://en.wikipedia.org/wiki/X-ray_crystallography
- **Cryogenic electron microscopy (Wikipedia)** — Cryogenic electron microscopy (cryo-EM) is a transmission electron microscopy technique applied to samples cooled to cryogenic temperatures. Developed in the 1970s, advances in detector technology and software allow biomolecular structures to be imaged at near-atomic resolution.
  https://en.wikipedia.org/wiki/Cryogenic_electron_microscopy
- **Protein structure prediction (Wikipedia)** — Protein structure prediction is the inference of the three-dimensional structure of a protein from its amino acid sequence—that is, the prediction of its secondary and tertiary structure from primary structure. Structure prediction is different from the inverse problem of protein design.
  https://en.wikipedia.org/wiki/Protein_structure_prediction
- **Homology modeling (Wikipedia)** — Homology modeling, also known as comparative modeling of protein, refers to constructing an atomic-resolution model of the "target" protein from its amino acid sequence and an experimental three-dimensional structure of a related homologous protein.
  https://en.wikipedia.org/wiki/Homology_modeling
- **Threading (Wikipedia)** — In molecular biology, protein threading, also known as fold recognition, is a method of protein modeling which is used to model those proteins which have the same fold as proteins of known structures, but do not have homologous proteins with known structure.
  https://en.wikipedia.org/wiki/Threading_(protein_sequence)
- **AlphaFold (Wikipedia)** — AlphaFold is an artificial intelligence (AI) program developed by DeepMind, a subsidiary of Alphabet, which performs predictions of protein structure. It is designed using deep learning techniques.
  https://en.wikipedia.org/wiki/AlphaFold
- **CASP (Wikipedia)** — Critical Assessment of Structure Prediction (CASP), sometimes called Critical Assessment of Protein Structure Prediction, is a community-wide, worldwide experiment for protein structure prediction taking place every two years since 1994.
  https://en.wikipedia.org/wiki/CASP
- **Membrane topology (Wikipedia)** — Topology of a transmembrane protein refers to locations of N- and C-termini of membrane-spanning polypeptide chain with respect to the inner or outer sides of the biological membrane occupied by the protein.
  https://en.wikipedia.org/wiki/Membrane_topology
- **Molecular dynamics (Wikipedia)** — Molecular dynamics (MD) is a computer simulation method for analyzing the physical movements of atoms and molecules. The atoms and molecules are allowed to interact for a fixed period of time, giving a view of the dynamic "evolution" of the system.
  https://en.wikipedia.org/wiki/Molecular_dynamics
- **Docking (molecular) (Wikipedia)** — In the field of molecular modeling, docking is a method which predicts the preferred orientation of one molecule to a second when a ligand and a target are bound to each other to form a stable complex.
  https://en.wikipedia.org/wiki/Docking_(molecular)
- **Protein design (Wikipedia)** — Protein design is the rational design of new protein molecules to design novel activity, behavior, or purpose, and to advance basic understanding of protein function. Proteins can be designed from scratch or by making calculated variants of a known protein structure and its sequence.

9.16 Student recommendations

Recommended by students preparing for the exam: papers, reviews, online lectures, tutorials and short explanations. To suggest something, use the suggestion form (SU login).

No recommendations yet.

9.17 Review problems

These problems are adapted from Matteo Tadiello, *Modern Bioinformatics: From Foundations to Frontiers* (CC BY 4.0), used with permission. For a longer treatment of this topic, see the chapters "Protein Structure: Evidence, Models, and Dynamics" and "Structural AI and Generative Biology" of that book. In the HTML version, click a box to show the extensions, solution outline and common errors.

9.17.1 Explain structure and folding from first principles

What determines the three-dimensional structure of a protein?

Extensions, solution outline and common errors

Extensions:

- What do the ϕ and ψ angles represent?
- Is the hydrophobic effect responsible for a fixed fraction, such as 90%, of the folding free energy?
- Why is glycine common in turns but not a general helix stabiliser?
- Does Anfinsen's hypothesis mean that every protein folds spontaneously in a cell?

Solution outline:

1. Begin with the planarity of the peptide bond, the backbone torsions, steric restrictions (the Ramachandran plot), side-chain chemistry and the solvent.
2. Explain secondary structures as recurring backbone hydrogen-bond patterns, and folds and domains as tertiary organisation.
3. Write $\Delta G = G_N - G_U = -RT \ln K$, with $K = [N]/[U]$, and separate equilibrium stability from kinetic barriers.
4. Describe a free-energy landscape with many microstates rather than a single deterministic path (funnels, Levinthal's paradox).
5. State that the hydrophobic effect, hydrogen bonds, packing, electrostatics, entropy, cofactors, membranes and partners all contribute in a context-dependent way, and reject universal percentage claims; proteins are only marginally stable.
6. Correct the glycine claim: lacking a side chain, it can adopt unusual torsions and fits turns, but its flexibility (conformational entropy) makes it a poor helix former.
7. Qualify Anfinsen's hypothesis with chaperones, kinetic traps, oligomerisation, modifications and conditional or metamorphic states.

Common errors:

- Calling the folded state “low energy” without specifying free energy, solvent and conditions.
- Treating every loop as disordered.
- Saying that one sequence always has exactly one structure.

Connections: Section 9.3 and Section 9.5; evolutionary constraints on stability in Section 3.5; ensembles in Section 9.11.

9.17.2 Choose an experimental structure method

Compare X-ray crystallography, NMR and cryo-EM for determining a protein structure.

Extensions, solution outline and common errors

Extensions:

- What is the crystallographic phase problem?
- What does an NMR ensemble represent?
- How is cryo-EM resolution estimated?
- Is a cryo-EM structure necessarily more native than a crystal structure?

Solution outline:

1. Define the observations: diffraction intensities, magnetic-resonance restraints, or many low-dose particle images.
2. Explain how each becomes a model: phasing (molecular replacement, anomalous scattering), map fitting and refinement; calculation of conformers that satisfy the restraints; particle alignment, classification, reconstruction and map fitting.
3. Compare sample requirements and strengths: crystals and detailed density; solution restraints and dynamics for smaller proteins; large non-crystalline assemblies and several conformational classes.
4. Name method-specific failures: crystal contacts and model bias; size limits and incomplete restraints; preferred orientation, radiation damage and uneven local resolution.
5. Validate with held-out data (R_{free}), restraint violations, or independent half-maps (Fourier shell correlation) plus map–model fit, and check stereochemistry for all.
6. Choose by the biological question, and combine orthogonal data (integrative modelling) when one method cannot distinguish the alternatives.

Common errors:

- Equating nominal resolution with uniform accuracy of every atom.
- Reading the spread of an NMR ensemble as measured thermodynamic populations.
- Claiming that vitrification guarantees an unperturbed native ensemble.

Connections: Section 9.4; the PDB and validation reports in Section 2.5; cross-linking MS in Section 8.5.

9.17.3 Compare classical prediction strategies

How do comparative (homology) modelling, threading, de novo (fragment- or physics-based) prediction and coevolution-based prediction differ?

Extensions, solution outline and common errors

Extensions:

- Where do comparative models usually fail?
- What makes de novo prediction computationally difficult?
- Why are raw correlations between alignment columns not direct contacts?
- What happens when the MSA is shallow?

Solution outline:

1. Comparative modelling transfers spatial restraints from a homologous template through an alignment (MODELLER); errors in the choice of template or state and in the alignment dominate.
2. Threading and fold recognition test how well a sequence fits known folds when sequence similarity is weak.
3. Fragment assembly and physics-based methods sample conformations under approximate energy or scoring functions; both the search and the ranking can fail.
4. Coevolution methods fit a global (Potts) model to a deep, diverse MSA to separate direct from indirect correlations (DCA, PSICOV) and derive contact restraints.
5. Compare information sources, computational cost, interpretability and failure modes rather than claiming one universal hierarchy.
6. Validate with blind targets (CASP), local geometry, domain-wise scores and independent experiments.

Common errors:

- Defining homology modelling by a fixed percentage identity threshold.
- Saying that de novo prediction enumerates every conformation with exact physics.
- Treating a strong coupling as proof of a contact within one chain (it may be between chains, or reflect alternative conformations).

Connections: Section 9.8; profiles and alignments in Section 1.6; phylogenetic confounding of coevolution in Chapter 4.

9.17.4 Explain AlphaFold2 and its confidence

At a high level, how does AlphaFold2 predict structure, and how should its output be evaluated?

Extensions, solution outline and common errors

Extensions:

- What information do the Evoformer and the structure module exchange?
- Contrast pLDDT, PAE and pTM.
- Can a high pLDDT prove a catalytic mechanism?
- How would you assess a predicted two-domain protein?

Solution outline:

1. Describe the inputs (sequence, MSA and optional templates); the Evoformer jointly updates the MSA and residue-pair representations, with triangle updates enforcing geometric consistency.
2. Explain how the structure module generates coordinates with invariant point attention, and the role of recycling.
3. Interpret pLDDT as local confidence, PAE as confidence in the relative placement of residues and domains, and pTM as a global score.
4. For a multidomain protein, inspect the pLDDT of each domain and the off-diagonal blocks of the PAE matrix: high local confidence can coexist with uncertain packing of the domains.
5. Check the MSA and templates, possible training-set leakage, alternative seeds, stereochemistry, disorder and the biological state (ligands, cofactors, oligomers).
6. Treat the model as a hypothesis, and validate the intended fold, active site or state independently.

Common errors:

- Calling pLDDT the probability that the structure is correct.
- Reading a low-confidence ribbon as an atomic model of a disordered ensemble.
- Inferring substrate specificity from a confident global fold.

Connections: Section 9.8; language-model alternatives in Section 9.9; function transfer in Section 10.4; learned confidence and leakage in 4.

9.17.5 Evaluate AlphaFold-Multimer and AlphaFold3 complexes

AlphaFold predicts a high-confidence protein–ligand or protein–protein complex. What does that result establish?

Extensions, solution outline and common errors

Extensions:

- What changed from AlphaFold2 to AlphaFold-Multimer and AlphaFold3?
- Which confidence measures matter at an interface?
- Does AlphaFold3 predict affinity?
- Which errors specific to co-folding models should you look for?

Solution outline:

1. AlphaFold-Multimer added training on complexes and interface confidence (ipTM); AlphaFold3 represents proteins, nucleic acids, ligands and ions as tokens and uses a Pairformer with a diffusion module that generates atomic coordinates.
2. Confirm the construct, stoichiometry, ligands, modifications, ions and biological state before prediction.
3. Inspect inter-chain PAE, ipTM, interface pLDDT, convergence across seeds and alternative partners or states.
4. Check stereochemistry, chirality, clashes, protonation, metals and the plausibility of the ligand pose (PoseBusters).
5. State explicitly that giving two sequences as input can force a plausible interface, and that confidence is not K_d, kinetics, occupancy or evidence of interaction in the cell.

6. Test a discriminating prediction about the interface with binding measurements, mutations with folding controls, cross-links, cellular perturbation or an experimental structure.

Common errors:

- Calling two proteins interactors because a server returned a complex.
- Treating the top-ranked ligand pose as a measured bound state.
- Ignoring static-state bias, hallucinated order, chirality errors and clashes.

Connections: Section 9.8; interaction assays and complex prediction in Section 11.2 and Section 11.4; out-of-distribution prediction in 4.

9.17.6 Select and interpret structural accuracy metrics

Compare RMSD, GDT_TS, TM-score, lDDT and DockQ.

Extensions, solution outline and common errors

Extensions:

- Why can two accurately predicted domains give a poor whole-chain RMSD?
- Which measures need a global superposition?
- What does lDDT compare?
- How would you score a predicted ligand-binding site?

Solution outline:

1. RMSD averages squared distances between matched atoms after a chosen superposition, and is sensitive to outliers and domain motion.
2. GDT_TS reports the fractions of residues within several distance cutoffs (1, 2, 4 and 8 Å), and is more robust to a single badly placed region.
3. TM-score normalises by length and emphasises the global topology.
4. lDDT compares local inter-atomic distances without a global superposition, and tolerates relative domain motion.
5. DockQ combines the fraction of native contacts and interface and ligand RMSDs for complexes.
6. Match the measure to the claim (global topology, domains, interface, ligand pose or active-site geometry), and always report coverage and residue correspondence.

Common errors:

- Quoting universal "good" RMSD thresholds independent of size and alignment.
- Comparing scores computed over different residue subsets without saying so.
- Assuming that a correct global topology ensures accurate side chains or ligands.

Connections: Section 9.2 and Section 9.6; interface quality in Section 11.4; choosing evaluation measures in 4.

9.17.7 Use docking and molecular dynamics responsibly

How should docking and molecular dynamics be combined to study ligand binding?

Extensions, solution outline and common errors

Extensions:

- What are the search and scoring problems in docking?
- Why might docking into an apo structure fail?
- Can ordinary MD show the formation of a covalent bond?
- How do you show that a set of trajectories has converged?

Solution outline:

1. Define the receptor state, the protonation and tautomer of the ligand, cofactors, waters, membrane, and whether binding is expected to be covalent.
2. Dock by sampling translations, rotations, ligand torsions and selected receptor flexibility, then rank poses with an approximate scoring function.
3. Validate docking by redocking and cross-docking known ligands, decoys, alternative receptor states and experimental data.
4. Parameterise and equilibrate MD carefully; standard MD integrates Newton's equations under an empirical force field and does not make or break covalent bonds (QM/MM is needed for reactions).
5. Use independent simulations from different starts, block averages and comparison with experimental observables; distinguish sampling failure from force-field error.
6. Report mechanistic hypotheses, not a trajectory as proof. Affinities require free-energy methods (such as FEP) with uncertainties, not a raw docking score.

Common errors:

- Defining a ligand as something that binds irreversibly.
- Assuming that a longer simulation automatically corrects a wrong protonation or conformational state.
- Describing one spontaneous-looking event as a rate or an equilibrium population.

Connections: Section 9.11 and Section 9.3; biophysical validation of binding in Section 11.2.

9.17.8 Design a protein and validate it

Describe a modern computational protein-design workflow, and specify how its products should be validated.

Extensions, solution outline and common errors

Extensions:

- How do backbone generation and inverse folding differ?
- What do RFdiffusion and ProteinMPNN contribute?
- Why is AlphaFold confidence insufficient as validation?
- How would you detect memorisation of training structures or an unwanted oligomer?

Solution outline:

1. Specify the design objective and the negative constraints: topology, motif geometry, partner, affinity, specificity, solubility and oligomeric state.

2. Generate or scaffold candidate backbones (for example with RFdiffusion), and use inverse folding (ProteinMPNN) to propose sequences compatible with each backbone.
3. Filter with independent structure prediction, checks for alternative states and oligomers, energy and geometry, sequence diversity, and aggregation.
4. Search structure and sequence databases to assess novelty and similarity to training structures.
5. Test experimentally: expression, monodispersity, folding, stability, oligomeric state, structure, affinity and kinetics, specificity, and function.
6. Feed failures back into the design while keeping held-out assays as genuine validation.

Common errors:

- Calling a design with a high-confidence prediction experimentally validated.
- Optimising only for binding and ignoring specificity (negative design) or aggregation.
- Testing one design and generalising its success to the method.

Connections: Section 9.12; structure search for novelty in Section 9.6; binding assays in Section 11.2; generative models in Section 12.5.

9.17.9 Statistical potentials and the search for the native structure

In a set of non-redundant protein structures, leucine–leucine contacts are observed 2.5 times more often than expected from a reference state. Convert this to an energy, explain the assumptions behind the conversion, and discuss why a de novo prediction with such a potential can fail.

Extensions, solution outline and common errors

Extensions:

- Why does the result depend on the choice of reference state?
- How would you decide whether a failed prediction was caused by the energy function or by the search?
- How do local minimisation, simulated annealing and replica exchange differ?
- In what sense is a network such as AlphaFold a learned statistical potential, and in what sense is it not?

Solution outline:

1. Apply the inverse Boltzmann relation, $\Delta E = -k_B T \ln(P_{\text{obs}}/P_{\text{ref}})$; with $k_B T \approx 0.6$ kcal/mol at 300 K, $\Delta E \approx -0.6 \ln 2.5 \approx -0.55$ kcal/mol, a favourable contact.
2. State the assumptions: the structures behave like a Boltzmann ensemble at one temperature, pair terms are independent and additive, and the reference state removes everything but the specific interaction. None holds exactly: the database is many different proteins, and connectivity and composition leak into the "energies" (Thomas and Dill).
3. Explain why they still work: they are effective free energies that include solvation, and they are mainly used to discriminate native-like from wrong structures (threading, model quality assessment).
4. Separate the two failure modes: compare the energy of the experimental structure (after minimisation) with that of the best model; if the native scores better, sampling failed; if worse, the energy function failed.

5. Describe the search: local gradient-based minimisation finds only the nearest minimum; Monte Carlo, simulated annealing and replica exchange accept uphill moves to cross barriers; fragment assembly reduces the search space.
6. Relate to deep learning: networks learn far richer, context-dependent preferences from the PDB and output a structure directly, but they still reflect the biases of their training data.

Common errors:

- Treating a statistical potential as a physical free energy of binding or folding.
- Assuming that a lower score always means a more correct model, without checking for search failure.
- Forgetting that more sampling cannot fix an energy function that prefers a wrong structure.

Connections: Section 9.11 (optimisation and energy functions); fragment assembly and threading in Section 9.8; heuristic tree search in Section 4.3; gradient descent in 4.

9.17.10 Amyloid and aggregation

A patient carries a missense mutation in a secreted protein that replaces a lysine with an isoleucine. The protein is found in extracellular fibrils. Explain how the mutation could cause disease, and how you would use computational and structural methods to investigate it.

Extensions, solution outline and common errors

Extensions:

- What is the cross-β structure, and how is it detected?
- What is a prion, and how does it differ from other amyloids?
- Why would AlphaFold not show the fibril structure?
- Give an example of a functional amyloid.

Solution outline:

1. Describe amyloid: cross-β fibrils with strands perpendicular to the axis, about 4.7 Å and 10 Å spacings, steric zippers; a generic, concentration-dependent state that competes with the native fold.
2. Consider two mechanisms: the mutation destabilises the native fold, increasing the population of unfolded or partly folded chains, or it strengthens an aggregation-prone region by removing a charged gatekeeper and increasing hydrophobicity and β-propensity.
3. Predict aggregation-prone regions with TANGO or Waltz for the wild type and the mutant, and predict the stability change of the native structure (Section 10.6).
4. Check the location of the residue in an experimental or predicted native structure: buried or exposed, in a strand or a gatekeeper position.
5. Determine the fibril structure by cryo-EM, preferably from patient tissue, since in vitro fibrils can be different polymorphs; test aggregation kinetics experimentally.
6. Mention prions (PrP, yeast [URE3] and [PSI+]) as aggregates that template conversion and spread, and functional amyloids such as curli.

Common errors:

- Assuming that a predicted native structure describes the aggregated state.
- Assuming that all amyloid is pathological.
- Treating one in vitro fibril structure as the disease structure.

Connections: Section 9.5 (misfolding, amyloid and prions); cryo-EM in Section 9.4; variant effects in Section 10.6.

> Classifications, prediction methods, and definitions.

10.1 Overview

Predicting what a protein does is the ultimate goal of most sequence analysis. It is also a broad and messy topic, because "function" can mean many things, the data are incomplete and biased, and almost every method in this book contributes to it. This chapter cannot cover everything; it concentrates on the main ideas:

- what function is and how it is described: the Gene Ontology, evidence codes, the structure of GO annotations and EC numbers (Section 10.2);
- how function is determined experimentally: forward and reverse genetics, knockout collections, RNAi and CRISPR screens, DepMap, and why many knockouts have no visible phenotype (Section 10.3);
- how function is predicted: transfer by homology and its pitfalls, families and domains, genomic context, networks, structure, functional and modification sites, disordered regions and machine learning, and how evidence is combined (Section 10.4);
- subcellular localisation and the sorting signals that determine it, and how such predictors are evaluated (3);
- predicting the effects of missense variants (Section 10.6);
- how function prediction is evaluated, and why that is hard (Section 10.7).

The databases used for function annotation are described in Section 2.6, protein families and domains in Section 1.9, and interaction networks in Chapter 11.

10.2 Definitions of function

Predicting what a protein does is the ultimate goal of most sequence analysis, yet "function" has no single definition. It can mean the biochemical activity of a protein ("serine protease"), the process it contributes to ("blood coagulation"), the place where it acts ("extracellular space"), its phenotypic effect when mutated, or the role it plays in a pathway or complex. Function is also context dependent: the same protein can have different roles in different cells, and some proteins have several unrelated functions (*moonlighting*), while many enzymes catalyse side reactions besides their main one (*promiscuity*). Any computational definition must choose which of these aspects to describe, and with what vocabulary. Two systems dominate: the Gene Ontology and the Enzyme Commission numbers.

10.2.1 The Gene Ontology

The **Gene Ontology** (GO) (Ashburner et al. 2000; The Gene Ontology Consortium et al. 2023), described as a resource in Section 2.6, describes gene products along three separate aspects:

- **Molecular function** (MF): the activity of the gene product itself, such as "protein kinase activity" or "DNA binding";
- **Biological process** (BP): the larger programme the activity contributes to, such as "DNA repair" or "T cell activation";
- **Cellular component** (CC): where the activity takes place, such as "nucleus" or "mitochondrial inner membrane".

These are three independent dimensions of annotation, not three definitions of the same thing. Only molecular function describes what the protein itself does biochemically; a protein can be annotated in all three aspects, and a process or location annotation says little about its activity.

GO has tens of thousands of terms (roughly 40,000 non-obsolete terms in 2026), organised as a **directed acyclic graph** in which more specific terms are linked to more general ones by relations such as *is a* and *part of*. Under the *true path rule*, an annotation to a term propagates to its ancestors along these relations (an annotation to "serine-type endopeptidase activity" also implies "peptidase activity"). This holds for *is a* and *part of*, but not for every relation: a protein annotated to "regulation of" a process is not thereby involved in the process itself. Predictions can be made at different levels of specificity: "hydrolase activity" is easy to predict and nearly useless, "serine-type endopeptidase activity" is harder and more informative.

Every annotation carries an **evidence code** that records its source: experimental codes (such as IDA, *inferred from direct assay*, and IMP, *inferred from mutant phenotype*), phylogenetic and sequence-based codes (IBA, ISS), author and curator statements, and **IEA** (*inferred from electronic annotation*), assigned automatically without review. Only a very small fraction of the sequences in UniProtKB, well below 1% in 2026, have a GO annotation supported by an experimental evidence code; the exact figure depends on the release and on which evidence codes are counted as experimental. The other proteins have only predicted annotations, if any, mostly from the methods described in Section 10.4. Experimental annotations are themselves biased. A handful of model organisms and well-studied proteins account for most of them, and a few high-throughput experiments contribute many annotations to general terms (Schnoes et al. 2013). These biases matter both for training predictors and for evaluating them (Section 10.7).

The kinds of evidence are not equivalent. A **direct assay** (IDA), such as an enzyme assay of the purified protein, shows a molecular function under the assay conditions, but not that the protein performs it in the cell. A **mutant phenotype** (IMP) shows that the gene is needed for a process, but not what the protein does in it; the effect may be indirect. **Physical interactions** (IPI) and **expression patterns** (IEP) show association, not activity. **Computational transfer** (ISS, IBA, IEA) is a prediction whose reliability depends on the method and on the evidence for the source protein. A strong claim about function therefore usually combines several kinds of evidence.

10.2.2 The structure of a GO annotation

A GO annotation is more than a link between a protein and a term. It is a statement with several parts: the gene product (sometimes a specific isoform), a **relation** such as *enables* (for molecular function), *involved in* (for process) or *located in* or *part of* (for component), the GO term, the evidence code, the reference that supports it, and the group that made the annotation. Annotations can also carry:

- a **NOT qualifier**, an explicit statement, based on evidence, that the gene product does *not* have a function or location. This is different from the absence of an annotation, and it does not propagate to ancestor terms: a protein that is NOT a kinase may still have transferase activity;
- **annotation extensions**, which add context, for example the substrate of an enzyme, the cell type in which a process occurs, or the target of a regulator.

GO follows an **open-world assumption**: a missing annotation means that nothing has been recorded, not that the protein lacks the function. This is why predictions that are absent from the database cannot simply be counted as wrong (Section 10.7). Annotations change with every release, as terms are added, merged or made obsolete, so analyses should record the ontology and annotation versions. Standard annotations describe each gene product separately. **GO-CAM** models link several annotations into a causal model of a pathway, in which one activity regulates or provides input to another, in a specified location and process (Thomas et al. 2019).

10.2.3 EC numbers

Enzymes are classified by the **Enzyme Commission** (EC) of the International Union of Biochemistry, established in 1955, whose first list appeared in 1961. An EC number has four levels, for example EC 3.4.21.4 for trypsin:

1. the **class** of reaction: 1 oxidoreductases, 2 transferases, 3 hydrolases, 4 lyases, 5 isomerases, 6 ligases and 7 translocases;
2. the **subclass**, for example 3.4, hydrolases acting on peptide bonds (peptidases);
3. the **sub-subclass**, for example 3.4.21, serine endopeptidases;
4. the **serial number** of the specific reaction, for example 3.4.21.4, trypsin.

In 2026 there are more than 6,000 active EC numbers. Importantly, the EC system classifies **reactions**, not proteins: unrelated enzymes that catalyse the same reaction get the same number (*analogous* enzymes, Section 3.4), and homologous enzymes in the same family can have different numbers. Detailed data on each enzyme, such as kinetic parameters, substrates, inhibitors and organism, are collected in BRENDA (Chang et al. 2020), and the reactions themselves are described with chemical structures in Rhea (Bansal et al. 2021), which UniProt now uses for enzyme annotation.

10.2.4 Other descriptions of function

Function can also be described by membership in **families** and **pathways**: Pfam and InterPro families (Section 1.9), KEGG Orthology groups and Reactome pathways (Section 2.6), or by **interactions** with other proteins (Chapter 11). For human genes, **phenotypes** and diseases associated with mutations (for example in OMIM) describe function at the level of the organism. Each description is useful for different purposes, and a complete picture of a protein's function combines several of them.

i Sources

Parts of this section are adapted from the Wikipedia articles Protein function prediction, Gene Ontology, Enzyme Commission number and Moonlighting protein (CC BY-SA 4.0, retrieved 4 October 2026). Parts of this section are adapted from Matteo Tadiello, *Modern Bioinformatics: From Foundations to Frontiers*, chapter "Protein Function and Annotation" (CC BY 4.0), used with permission.

10.3 Experimental determination of function

Every prediction method in this chapter is ultimately trained on, or transfers from, functions that were determined by experiment. The most general experimental approach is genetic: change or remove a gene and observe what happens to the organism or cell. Large-scale genetic screens are also a major source of data for bioinformatics, and analysing them is a bioinformatics problem in its own right.

10.3.1 Forward and reverse genetics

Forward genetics starts from a phenotype and looks for the genes responsible. Organisms are mutagenised at random, with chemicals, radiation or transposons, and individuals with an interesting phenotype are selected. The classical screens for mutations that disrupt the body plan of the *Drosophila* embryo identified many of the genes that control development (Nüsslein-Volhard and Wieschaus 1980). The difficult step used to be finding the causal mutation, which required genetic mapping by crosses. Today the mutant genomes are sequenced, and the causal variant is found among the many induced mutations by combining mapping with sequencing, for example by looking for the region in which all mutant offspring share the same variants. Forward screens are unbiased: they can find genes that nobody suspected.

Reverse genetics goes the other way: it starts from a gene, usually identified by sequencing, and disrupts it to see what happens. Since genome sequencing made all genes known, reverse genetics has dominated, and the question "what does this gene do?" is often answered by systematically removing every gene.

10.3.2 Genome-wide knockout collections

The first systematic collection was the **yeast deletion collection**, in which each of the roughly 6000 open reading frames of *Saccharomyces cerevisiae* was replaced by a marker cassette (Winzeler et al. 1999; Giaever et al. 2002). Each deletion carries two unique 20-nucleotide **barcodes**, so that thousands of strains can be grown together in one culture and the abundance of each strain measured by counting its barcode, first with microarrays and later by sequencing. About 1000 genes (around 19%) were essential for growth in rich medium. Pooled growth of barcoded mutants became the model for later CRISPR screens, and the same collection was used to map genetic interactions (Section 11.2).

In mouse, the International Mouse Phenotyping Consortium (IMPC) aims to knock out every protein-coding gene and phenotype the mice in a standardised pipeline. Of the first 1751 genes, about a quarter were lethal when homozygous and more were subviable, and many genes without previous annotation produced phenotypes (Dickinson et al. 2016); overall, roughly 30% of mouse gene knockouts are lethal before or around birth, which is why embryonic phenotyping became part of the pipeline (Adams et al. 2013). Knockout phenotypes are a major source of experimental GO annotations for biological process (Section 10.2).

10.3.3 RNAi and CRISPR

In other organisms, and in human cells, genes are perturbed by interfering with their expression rather than by homologous recombination:

- **RNA interference** (RNAi) uses double-stranded RNA, or short interfering RNAs (siRNAs) and short hairpin RNAs (shRNAs), to degrade the matching mRNA (Fire et al. 1998). It produces a *knockdown*: expression is reduced, usually incompletely. Its main problem is **off-target effects**: an siRNA can act like a microRNA and repress hundreds of transcripts that match its seed region (Jackson et al. 2003). Many hits of early RNAi screens were artefacts of this kind.
- **CRISPR–Cas9** knockouts use a guide RNA (sgRNA) to direct Cas9 to a target site, where it cuts both DNA strands. Error-prone repair introduces small insertions or deletions that usually shift the reading frame and produce a *knockout*. Off-target cutting at similar sites occurs, but is rarer than RNAi off-target effects.
- **CRISPR interference** (CRISPRi) and **activation** (CRISPRa) use a catalytically dead Cas9 fused to a repressor or an activator domain. It binds near a promoter without cutting, and turns expression down or up (Gilbert et al. 2014). CRISPRa allows gain-of-function screens, which are impossible with knockouts.

Knockdown and knockout phenotypes can disagree for several reasons. A knockdown leaves some protein, which may be enough. A knockout may be compensated: in zebrafish, mutants of some genes were normal while morpholino knockdowns of the same genes were not, because the mutation induced the expression of related genes (Rossi et al. 2015). Off-target effects can create phenotypes in either method, and an in-frame indel may leave a partly functional protein. Agreement between independent reagents, such as several guides or siRNAs against the same gene, and rescue by re-expressing the gene, are therefore the standard of evidence.

10.3.4 Pooled CRISPR screens

In a **pooled screen**, a library of lentiviruses carrying several guides per gene for every gene in the genome is introduced into a population of cells at a low dose, so that each cell receives about one guide. The cells are grown, or selected for a phenotype such as drug resistance, and the guides are counted by sequencing them from genomic DNA before and after (Shalem et al. 2014; T. Wang et al. 2014). The integrated guide acts as a barcode, as in the yeast deletion collection. Guides against genes needed for growth drop out of the population; guides against genes whose loss confers resistance become enriched.

The analysis resembles that of RNA-seq counts (Section 7.4):

1. Guide counts are normalised for sequencing depth, and a log fold change is computed for each guide between the end and the start of the experiment.
2. The guide-level changes are combined into a **gene-level score**. Since some guides do not cut efficiently, robust methods are used. MAGeCK models the counts with a negative binomial distribution and ranks genes with a modified robust rank aggregation, which asks whether a gene's guides are ranked higher than expected by chance (Li et al. 2014).
3. Genes are called significant with a false discovery rate, and the quality of the screen is assessed by how well it separates reference sets of known essential and non-essential genes (Hart et al. 2015).

An important artefact concerns **copy number**. Cas9 cutting at many sites in an amplified region causes DNA damage and kills cells regardless of which gene is targeted, so genes in amplified regions appear essential (Aguirre et al. 2016). Methods such as CERES and Chronos model this effect, and Chronos also models the dynamics of cell growth and the delay between cutting and loss of the protein (Meyers et al. 2017; Dempster et al. 2021).

Screens across many cell lines distinguish **core essential genes**, needed in every cell line, from *context-specific dependencies*, needed only in some (Hart et al. 2015). The **Cancer Dependency Map** (DepMap) has screened around a thousand cancer cell lines, first with RNAi and then with CRISPR, and relates the dependencies to the mutations, expression and copy number of each line (Tsherniak et al. 2017).

A gene on which only lines with a particular mutation depend is a candidate drug target (Section 7.7). Genes with similar dependency profiles across cell lines tend to work together, so DepMap is also used to predict function by co-essentiality, an idea related to the genetic interaction profiles of Section 11.2.

10.3.5 Arrayed, imaging and single-cell screens

Pooled screens can only measure phenotypes that change the number of cells carrying a guide, through growth or sorting. In an **arrayed screen**, each well of a plate receives one perturbation, so any phenotype can be measured, including cell shape and the localisation of proteins under a microscope. Image-based profiling turns such images into feature vectors that can be compared between perturbations (Section 13.4). **Perturb-seq** instead reads out both the guide and the whole transcriptome of each cell in a pooled screen, so that the transcriptional effect of every perturbation is measured (Section 11.2, Section 7.6). Such high-content screens give a rich phenotype for every gene, which can be used to group genes into pathways and complexes (Bock et al. 2022).

10.3.6 Why many knockouts show no phenotype

A large fraction of genes show no visible phenotype when they are knocked out, even in a carefully phenotyped organism. In yeast, most deletions grow normally in rich medium, although nearly all of them showed a growth defect under at least one of more than a thousand chemical and environmental conditions (Hillenmeyer et al. 2008). Several explanations apply:

- **Redundancy.** A paralogue or an alternative pathway can take over. Such genes often show synthetic lethality with their partner (Section 11.2).
- **Condition dependence.** The gene may only be needed in a condition that was not tested, such as a particular nutrient, stress or developmental stage.
- **Small effects.** A fitness defect of a few per cent is invisible in a single experiment, but matters over evolutionary time.
- **Pleiotropy.** Conversely, a gene with many roles can give a complex phenotype, such as lethality early in development, that hides its later functions.

The absence of a phenotype is therefore not evidence that a gene has no function. The phenotype that is observed is also not the molecular function: a growth defect says that a gene matters, not what its protein does. Experimental annotations from screens therefore mostly concern biological processes, and are best combined with the prediction methods of Section 10.4.

Systematic mutation can also be applied within a single protein: **deep mutational scanning** measures the effect of every possible substitution, and is described with the prediction of variant effects in Section 10.6.

10.4 Function prediction

Since only a tiny fraction of proteins has been studied experimentally, the function of almost all proteins is predicted. The methods use different kinds of information: similarity to characterised proteins, membership in families, the genomic and network context of a gene, and structure. They are increasingly combined with machine learning.

10.4.1 Annotation transfer by homology

The most common approach is to transfer the annotation of the most similar characterised protein (Whisstock and Lesk 2003). It rests on the assumption that homologous proteins have similar functions, which holds approximately but with important exceptions:

- **Sequence identity thresholds.** Function is more conserved between closely related proteins. Studies of enzymes found that the first three digits of the EC number were usually conserved above about 40% sequence identity, but that the full EC number could differ even above 50% identity (Devos and Valencia 2000; Rost 2002; Tian and Skolnick 2003). Below about 30%, in the twilight zone (1), specific functions are often not shared, and usually only more general functions are conserved. These figures are empirical tendencies in particular data sets, not decision rules. There is no universal identity threshold for safe transfer: it also depends on the length and coverage of the alignment, the protein family, whether active-site residues are conserved, the domain architecture, and how specific the transferred function is.
- **Domain architecture.** Multidomain proteins are common, especially in eukaryotes. A BLAST hit that covers one domain says nothing about the others, so transferring the annotation of a whole protein from a partial match is a common source of errors. Annotation should consider whether the domain architectures match (Section 1.9).
- **Orthologues vs. paralogues.** Orthologues, separated by speciation, are expected to keep the same function more often than paralogues, which may have diverged after duplication (Section 3.4). This *ortholog conjecture* is widely used, for example in eggNOG-mapper, which transfers annotations from precomputed orthologous groups (Cantalapiedra et al. 2021), although the evidence for it is weaker than often assumed (Nehrt et al. 2011; Altenhoff et al. 2012). Orthology is useful evidence, not a guarantee: orthologues can change function, and many paralogues keep the same function. It should not be read as a rule that transfer from orthologues is safe and transfer from paralogues is not.
- **Error propagation.** Annotations transferred from proteins whose own annotations were predicted can spread errors through databases (Gilks et al. 2002). Analyses of enzyme superfamilies found high rates of misannotation in automatically annotated databases (Schnoes et al. 2009), which is why evidence codes and the provenance of annotations matter (Section 10.2).

10.4.2 Family- and domain-based annotation

Rather than transferring function from a single best hit, family-based methods assign proteins to curated families with profile HMMs and other signatures, and attach annotations to the family or domain (Section 1.9). **InterPro** integrates Pfam and the other member databases, and maps many entries to GO terms (InterPro2GO) (Blum et al. 2024). More specific resources define families of proteins with the same full-length function and curated annotation rules, used by UniProt to annotate unreviewed entries automatically. The CATH functional families (FunFams) divide structural superfamilies into functionally coherent groups. Deep learning models can also classify sequences into Pfam families directly (Bileschi et al. 2022).

10.4.3 Genomic context

Comparative genomics provides information that does not depend on similarity to a characterised protein. Three kinds of genomic context suggest that two proteins are **functionally linked**, typically in the same pathway or complex (Marcotte, Pellegrini, Ng, et al. 1999; Enright and Ouzounis 2001; Dandekar 1998; Overbeek et al. 1999; Pellegrini et al. 1999):

- **Gene fusion** (the *Rosetta stone* method): two proteins that are separate in one organism are fused into a single chain in another, which suggests that they interact (Marcotte, Pellegrini, Ng, et al. 1999; Enright and Ouzounis 2001).
- **Conserved gene neighbourhood**: genes that are adjacent in many distantly related prokaryotic genomes, often in operons, tend to work together (Dandekar 1998; Overbeek et al. 1999).
- **Phylogenetic profiles**: proteins that are present or absent together across many genomes are likely to be needed together (Pellegrini et al. 1999).

These methods predict links, not functions: the function of an uncharacterised protein is inferred from its known partners. They work best for prokaryotes, where gene order is conserved and many genomes are available, and they were among the first sources of evidence integrated into STRING (Chapter 11).

10.4.4 Networks: guilt by association

More generally, proteins that interact physically, are co-expressed, or share genetic interactions tend to share functions. **Network-based prediction** propagates annotations through such networks (Sharan et al. 2007; Marcotte, Pellegrini, Thompson, et al. 1999). The simplest version assigns to a protein the most common functions of its neighbours (*guilt by association*). More advanced methods consider the whole network, for example by diffusion, label propagation or graph neural networks. The networks themselves are described in Chapter 11. Predicted structures of complexes have made it possible to add structural evidence to interactome-based annotation of whole proteomes (Garzón et al. 2016).

10.4.5 Structure-based prediction

Structure is more conserved than sequence (Section 9.6), so structural similarity can reveal homology, and therefore possibly function, when sequence similarity is lost. Structure also shows features directly related to function: binding pockets, conserved surface patches and catalytic sites. Methods compare a structure with libraries of **active-site templates**, such as the catalytic triad of serine proteases, or combine several structure-based analyses (Laskowski et al. 2005). Graph neural networks predict GO terms from the contact graph of a structure together with language-model features (Gligorijević et al. 2021). With AlphaFold models of almost all proteins and fast search with Foldseek (Section 9.6), structure-based annotation can now be applied to whole proteomes. Its limits are those of homology transfer: the same fold often carries different functions.

10.4.6 Predicting functional sites

Function often depends on a few residues: the catalytic residues of an enzyme, the residues that bind a ligand or metal, or a modification site. Predicting these sites is useful in itself, for example to choose residues for mutagenesis, and it makes annotation transfer more reliable, since a homologue that has lost a catalytic residue has probably lost the activity. Three kinds of information are used:

- **Sequence motifs.** Short patterns and profiles, such as those in PROSITE (Sigrist et al. 2012), describe catalytic sites, binding sites and modification sites (Section 1.9). Short patterns match by chance, so a motif hit alone is weak evidence.
- **Conservation.** Functional residues are usually among the most conserved positions in a multiple alignment of a family. Conservation also reflects structural constraints, so conserved residues on the surface, or residues conserved within a subfamily but different between subfamilies (*specificity-determining positions*), are more informative than conservation alone (Ashkenazy et al. 2016).
- **Structure.** Geometric methods detect pockets and clefts that can bind ligands (Le Guilloux et al. 2009), and catalytic sites can be recognised by matching the three-dimensional arrangement of residues to templates of known active sites, such as those collected in the Mechanism and Catalytic Site Atlas (M-CSA) (Ribeiro et al. 2017). Combining pockets with conservation is more reliable than either alone, and predicted structures make these methods applicable to almost any protein.

10.4.7 Predicting post-translational modification sites

Post-translational modifications (PTMs) are a special kind of functional site: a residue that is covalently modified, often by an enzyme that recognises a short sequence around it. Predictors exist for the most common types:

- **Phosphorylation.** Kinases phosphorylate serine, threonine and tyrosine. NetPhos used neural networks trained on known sites to predict whether a residue is phosphorylated (Blom et al. 1999), and NetPhosK and later methods such as GPS predict *which kinase* modifies it (Blom et al. 2004). Kinase-specific prediction rests on the preferred sequence around the site, for example arginine at position −3 for basophilic kinases such as PKA, or proline at +1 for proline-directed kinases such as CDKs and MAP kinases. Substrate preferences measured with peptide libraries for almost all human serine/threonine kinases now give a systematic basis for such predictions (Johnson et al. 2023). Deep-learning methods predict many PTM types from sequence (D. Wang et al. 2020).
- **Glycosylation.** N-linked glycans are attached to asparagine in the *sequon* N-X-S/T (X not proline), but only in proteins that enter the secretory pathway, and only on the side of the membrane facing the lumen. NetNGlyc predicts which sequons are used. O-linked glycosylation on serine and threonine has no simple motif, and NetOGlyc was trained on sites mapped by mass spectrometry in engineered cell lines (Steentoft et al. 2013).
- **Lipidation.** N-myristoylation of an N-terminal glycine, S-palmitoylation of cysteines, prenylation of a C-terminal CaaX box and the GPI anchor

  (3) attach proteins to membranes, and have their own predictors (Xie et al. 2016).

The key caveat is that **a predicted motif is not the same as a modified site**. A motif says that a residue *could* be modified by an enzyme with that preference. Whether it is modified in a given cell depends on whether the protein meets the enzyme: the right compartment, the right expression time, the right docking sites, and a residue that is accessible on the surface or in a disordered region. For example, many N-X-S/T sequons in secreted proteins are not glycosylated, and the topology of the protein constrains which can be (Zielinska et al. 2010). Motifs are short, so most proteins contain many matches by chance, and precision on a proteome scale is low.

Most training data now come from **mass spectrometry**. Phosphoproteomics has mapped hundreds of thousands of sites (Section 8.5), collected in databases such as PhosphoSitePlus (Hornbeck et al. 2014). These data have their own biases: abundant proteins and well-ionising peptides are over-represented, and a site that was not observed is not necessarily unmodified, so true negatives are lacking, as for protein interactions (Section 11.4). Moreover, being modified does not mean being functional: many observed phosphosites are poorly conserved and may be the result of non-specific kinase activity (Landry

et al. 2009). A machine-learning score that combines conservation, structure and other features has been used to rank the human phosphosites by their likely functional importance (Ochoa et al. 2019). For annotation, a predicted PTM site is a hypothesis, an observed site is a fact about modification, and a functional site needs further evidence, such as a phenotype of mutating the residue.

10.4.8 Disordered regions and short linear motifs

Not all function is carried by folded domains. Many proteins, especially in eukaryotes, contain long **intrinsically disordered regions** that do not fold on their own (Section 3.5) (Lee et al. 2014). They are rich in **short linear motifs** (SLiMs) (Kumar et al. 2021) of a few residues that bind folded domains of other proteins, carry modification sites, or act as degradation and targeting signals; the nuclear localisation signals and the KDEL motif in 3 are examples. Many regulatory and signalling functions depend on such regions. They are hard to annotate with the methods above: motifs are short, so they match by chance, they appear and disappear quickly in evolution, and disordered regions align poorly. Family- and domain-based annotation therefore says little about them, and a protein whose domains are all annotated may still have unannotated functions in its disordered regions.

10.4.9 Machine learning and language models

Most current methods combine several sources of evidence with machine learning. DeepGOPlus combines a convolutional network on the sequence with homology-based transfer (Kulmanov and Hoehndorf 2019). **Protein language models** (Section 1.10) provide embeddings that capture function beyond simple sequence similarity: annotations can be transferred from the protein that is nearest in embedding space rather than in sequence alignment, which works also for distant homologues (Littmann et al. 2021). For enzymes, contrastive learning on embeddings predicts EC numbers more accurately than alignment, especially for poorly characterised families (Yu et al. 2023). The best methods in recent CAFA rounds combine language models, homology, structure and networks (Section 10.7).

As for all supervised predictors, the reported accuracy of a function predictor depends on how the test proteins are related to the training proteins. If test proteins have close homologues among the training proteins, a method can score well by recognising the homologue rather than by learning anything general, and performance on new families is overestimated. Fair evaluations therefore split data by sequence similarity or by time (4), as CAFA does by design.

10.4.10 Combining evidence and the specificity of a claim

In practice, a function is assigned by combining several kinds of evidence: domains, characterised homologues, conserved functional residues, structure, localisation signals and genomic or network context. Two principles limit what can be concluded.

The first is that evidence must be **independent** to be counted twice. In Bayesian terms, the posterior odds for a function are the prior odds multiplied by a likelihood ratio for each piece of evidence, as in the functional association networks of Section 11.3, but only if the pieces are independent. They often are not. Two databases may display the same annotation because one copied it from the other, a network edge may be text-mined from the paper that supplied the GO term, and member databases of InterPro share seed sequences. Agreement among descendants of one annotation is *pseudo-replication*, and multiplying their confidences exaggerates the certainty (Figure 10.1).

The second is that an annotation should be no more **specific** than the evidence supports. Membership of an enzyme superfamily, a probable enzyme class (an EC number to three digits) and a specific substrate (four digits) are separate claims, each needing stronger evidence. **Rule-based annotation** makes the

required evidence explicit. A rule assigns a function only if, for example, a protein matches the family signatures, has the required active-site residues and a compatible domain architecture, belongs to an allowed taxonomic range, and has no excluding feature. UniProt uses such rules (UniRule and ARBA) for unreviewed entries (Section 2.3), and InterPro2GO maps a GO term to an InterPro entry only if the term holds for all members of the entry, so broad families get broad terms (Burge et al. 2012). Withholding an over-specific term is a correct decision, not a failure.

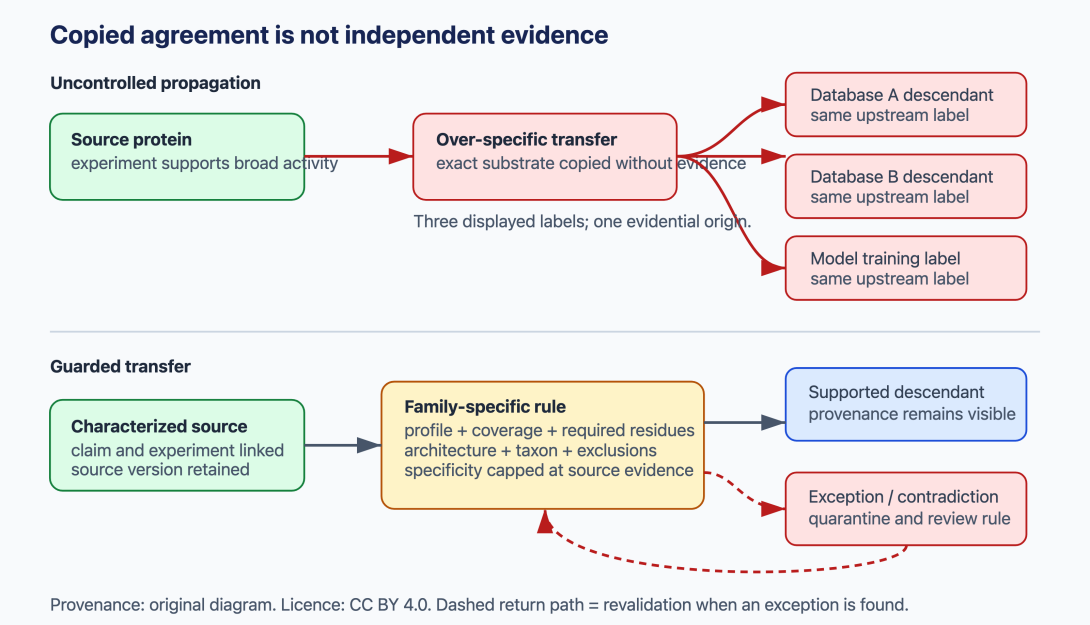

Figure 10.1: Copied agreement is not independent evidence. Above: an over-specific transfer (an exact substrate copied without evidence) spreads to several databases and to the training data of a predictor, which then appear to agree although they share one origin. Below: a family-specific rule that checks the profile, coverage, required residues, architecture and taxon, caps the specificity at that of the source evidence, keeps the provenance visible, and is revised when an exception is found. 10.5 Subcellular localisation

Where a protein is located constrains what it can do: an enzyme in the mitochondrial matrix, a receptor in the plasma membrane and a transcription factor in the nucleus act in different contexts. Localisation is also one of the aspects of function that can be predicted most directly from sequence, because proteins are sorted to their destinations by signals in their own sequence.

10.5.1 Sorting signals

Günter Blobel proposed the **signal hypothesis** in the 1970s: proteins destined for secretion carry an N-terminal **signal peptide** that directs the ribosome to the endoplasmic reticulum, where the protein is translocated across the membrane and the signal is cleaved off (Blobel and Dobberstein 1975). Blobel received the 1999 Nobel Prize in Physiology or Medicine. Many kinds of sorting signal are now known:

- **Secretory signal peptides**, 15–30 residues at the N-terminus, with a positively charged *n-region*, a hydrophobic *h-region* and a polar *c-region* ending in a cleavage site recognised by signal peptidase, with small residues at positions −3 and −1 (the "−3, −1 rule") (Heijne 1986). Similar signals exist in bacteria, for export across the cytoplasmic membrane, including lipoprotein signals and twin-arginine (Tat) signals.
- **Transit peptides** at the N-terminus target proteins to mitochondria (amphipathic helices rich in positive residues), chloroplasts and the thylakoid lumen.
- **Nuclear localisation signals** (short basic motifs) and nuclear export signals, which can lie anywhere in the sequence.
- **Peroxisomal targeting signals**, such as the C-terminal tripeptide SKL (PTS1).
- **Retention and anchoring signals**, such as the C-terminal KDEL motif that keeps proteins in the ER, and signals for the attachment of GPI anchors.
- **Transmembrane segments**, which anchor proteins in membranes and are predicted as described in Section 9.10.

10.5.2 Predicting signal peptides

Signal peptides were first predicted with weight matrices around the cleavage site (Heijne 1986). **SignalP**, developed in Copenhagen, introduced neural networks (Nielsen et al. 1997), and later versions largely solved the main source of errors: hydrophobic **transmembrane helices** near the N-terminus resemble the h-region of signal peptides, so early predictors predicted many membrane proteins as secreted (Petersen et al. 2011). SignalP 6 uses a protein language model and predicts all five types of signal peptide in all domains of life, including their regions and cleavage sites (Teufel et al. 2022). Its predictions are among the most accurate in bioinformatics, because the signal is compact, well defined and supported by many experimentally verified examples.

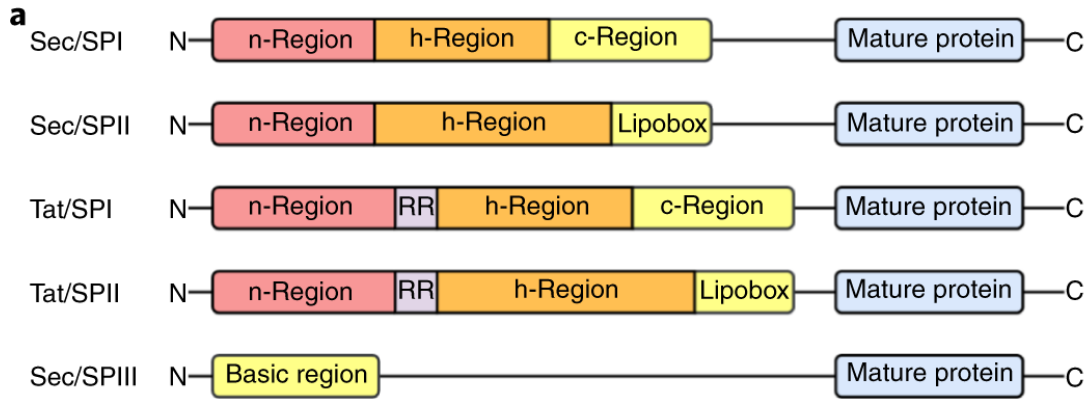

Figure 10.2: The five types of signal peptide predicted by SignalP 6.0: Sec/SPI (standard secretory signal peptides, cleaved by signal peptidase I), Sec/SPII (lipoprotein signal peptides with a lipobox, cleaved by signal peptidase II), the corresponding twin-arginine (RR) Tat/SPI and Tat/SPII signals, and Sec/SPIII (prepilin-like signals with a basic region). Figure 1a from Teufel et al. (2022) (CC BY 4.0), cropped by Matteo Tadiello, *Modern Bioinformatics: From Foundations to Frontiers* (CC BY 4.0).

10.5.3 Evaluating signal peptide and topology predictors

Signal peptide and transmembrane topology predictors label each residue, and their evaluation has some pitfalls of its own. The task can be posed in different ways: does the protein have a signal peptide (one label per sequence), where is the cleavage site (one position), or which residues belong to the n-, h- and c-regions (one label per residue). These are not interchangeable: a predictor can recognise a signal peptide without placing the cleavage site correctly, and residue-level accuracy is dominated by the many residues outside the signal. Performance should therefore be reported at the sequence level, as cleavage-site accuracy within a stated tolerance, and separately for each organism group and signal type. As for all predictors, training and test sets must be separated by homology, not randomly (4). Agreement between several predictors is not an experimental confirmation when they share training data, and a cleavage site observed by N-terminal proteomics is stronger evidence than any prediction.

10.5.4 Predicting localisation

Predicting the final location of a protein is harder, since it depends on signals anywhere in the sequence, on interactions and on regulation. Early programs such as PSORT encoded known sorting rules as an expert system (Nakai and Horton 1999). TargetP used neural networks to predict N-terminal targeting peptides for the secretory pathway, mitochondria and chloroplasts (Emanuelsson et al. 2000), and TargetP 2.0 used deep learning with attention to show which residues the network relied on (Almagro Armenteros et al. 2019). **DeepLoc** predicted ten locations from the whole sequence with a recurrent neural network with attention (Almagro Armenteros et al. 2017), and **DeepLoc 2** uses protein language model embeddings and predicts multiple locations for each protein, since many proteins are found in more than one compartment (Thumuluri et al. 2022). Training data come from UniProt annotations and, for human proteins, from imaging in the Human Protein Atlas, which showed that about half of all proteins are found in more than one location (Thul et al. 2017) (Section 8.6).

Localisation predictors are useful for annotating proteomes, for finding secreted proteins and drug targets, and for interpreting proteomics data. Their limitations are those of the training data: proteins that move between compartments, are targeted by unusual signals, or have locations that depend on the cell type are predicted poorly. How localisation is measured and classified from images is described in Section 13.5.

10.6 Predicting the effects of mutations

Every human genome contains about 10,000 missense variants, which change one amino acid in a protein. Most are harmless, a few cause disease, and for most of those found in patients the effect is unknown. Such *variants of uncertain significance* are one of the main obstacles in clinical genetics. **Variant effect prediction** estimates whether an amino acid substitution damages the function of a protein. It is function prediction at the level of single residues.

Three different properties are often mixed up under this heading. **Evolutionary constraint** describes whether substitutions like this one are tolerated at the position over evolution. A **molecular effect** is a change in the stability, activity or binding of the protein, as measured in an assay. **Pathogenicity** is a clinical label: whether the variant causes disease in a person. They are related but not the same. A variant can change the molecular function of a protein without causing disease, for example in a gene where one working copy is enough, and whether a damaging variant causes disease depends on the phenotype, the mode of inheritance, penetrance and the population. Most predictors are trained on, or evaluated against, only one of these, and their scores should be read accordingly.

10.6.1 Conservation-based predictors

The basic principle is evolutionary: positions that are conserved across homologues are functionally constrained, so substitutions there are likely to be harmful, while substitutions to amino acids seen at the same position in other species are likely to be tolerated.

- **SIFT** predicts whether a substitution is tolerated from the amino acid frequencies at the position in a multiple alignment of homologues (Ng 2003).
- **PolyPhen-2** combines conservation with structural features, such as burial and proximity to functional sites, in a naive Bayes classifier trained on known disease mutations (Adzhubei et al. 2010).
- **CADD** scores all possible variants in the genome, coding and non-coding, with a model trained to separate variants that have survived natural selection from simulated new mutations, using dozens of annotations (Kircher et al. 2014).

Supervised predictors trained on databases of known pathogenic and benign variants, such as ClinVar (Landrum et al. 2017), face a problem of **circularity**: the same variants, or variants from the same genes, are often used for training and for evaluation, and some clinical annotations were themselves based on earlier predictions. This inflates the apparent performance (Grimm et al. 2015). It is a form of the data leakage discussed in 4, and evaluations should keep genes and their homologues, not only individual variants, apart between training and test sets.

10.6.2 Unsupervised models of evolutionary sequences

A second generation of methods avoids labelled training data altogether. They learn the distribution of sequences in a protein family and score a variant by how much less likely the mutated sequence is than the wild type, under the model.

- **EVmutation** uses the same Potts model as coevolution-based structure prediction (Section 9.8), so that the effect of a mutation can depend on the rest of the sequence (*epistasis*) (Hopf et al. 2017).
- **DeepSequence** replaced the Potts model with a variational autoencoder (Riesselman et al. 2018), and **EVE** applied this approach to human disease genes, classifying variants without using any clinical labels, with accuracy comparable to supervised methods (Frazer et al. 2021).
- **Protein language models**, trained across all proteins rather than one family at a time, predict variant effects from the likelihood of the substituted amino acid at a masked position. ESM-1v (Meier et al. 2021) and ESM-1b, which was used to score all possible missense variants in the human proteome (Brandes et al. 2023), work even for proteins with few homologues.
- **AlphaMissense** fine-tuned an AlphaFold-based model, combining structural context and evolutionary information, on population frequency data as weak labels: variants common in humans and primates were treated as benign. It provides predictions for all 71 million possible human missense variants, and classifies most of them as likely benign or likely pathogenic (Cheng et al. 2023).

10.6.3 Experimental benchmarks

Deep mutational scanning measures the functional effect of thousands of variants of a protein in a single experiment, by linking a library of variants to a selection for function and counting each variant by sequencing before and after selection (Fowler and Fields 2014). These data provide benchmarks that are independent of clinical annotation, and unsupervised predictors correlate surprisingly well with them. Population data are a complementary source: variants that are common in healthy people are unlikely to cause severe disease, and genes in which damaging variants are rarer than expected are intolerant to mutation (Chen et al. 2023).

10.6.4 Using predictions

Clinical guidelines for interpreting variants allow computational predictions to be used only as supporting evidence, together with population frequency, segregation in families and functional data (Richards et al. 2015). Predictions are probabilities, not diagnoses, and they estimate whether a variant disrupts protein function, not whether it causes a particular disease: a damaging variant in a gene that tolerates loss of one copy may be harmless.

Most predictors also do not identify the **mechanism**. They largely measure constraint, or how deleterious a substitution is, and a high score does not say whether the variant causes **loss of function** (for example by destabilising the protein or removing a catalytic residue) or **gain of function** (for example mutations that make a kinase constitutively active, or the activating KRAS G12 mutations in cancer), or acts as a dominant negative. The distinction matters for interpretation: genes can cause disease through one mechanism and not the other, and gain-of-function variants can occur at positions where substitutions are not destabilising, so they may be scored as damaging for the wrong reason or be missed.

The Critical Assessment of Genome Interpretation (CAGI) evaluates these methods in blind challenges, much as CASP does for structure (The Critical Assessment of Genome Interpretation Consortium 2024).

10.7 Benchmarking function prediction

How good are function predictions? Answering this is harder than for structure prediction, for reasons that are instructive for any field of bioinformatics.

10.7.1 CAFA

The **Critical Assessment of Functional Annotation** (CAFA) evaluates predictions **prospectively**, in the same spirit as CASP (Section 9.2). Organisers release the sequences of tens of thousands of proteins that lack experimental annotations. Participants predict GO terms for them, and after a waiting period of several months to years the predictions are evaluated on the proteins that have gained experimental

annotations in the meantime (Radivojac et al. 2013). Five rounds had been completed by 2024. CAFA2 and CAFA3 showed that methods improved, but that simple baselines, such as transferring annotations from the best BLAST hit or predicting the most frequent terms, were hard to beat by a large margin, particularly for biological process and cellular component (Jiang et al. 2016; Zhou et al. 2019). CAFA5 was run as a Kaggle competition, which brought in a large community of data scientists. Its methods improved on all methods from the previous rounds, helped by protein language models, predicted structures and the growth of curated experimental annotations. CAFA5 also introduced evaluation on proteins that already had some (incomplete) annotations, and showed that methods should make better use of existing annotations to predict new ones (De Paolis Kaluza et al. 2026).

Predictions are scored as precision and recall over the GO graph, summarised by the maximum F-measure over all score thresholds ($F_{\max}$). Before scoring, both the predicted and the experimental terms are propagated to their ancestors, so that the hierarchy is taken into account: a prediction of the parent of a correct term counts as partly correct rather than wrong. Because general terms are easy to predict and say little, measures that weight terms by their **information content**, such as the minimum semantic distance $S_{\min}$, reward predictions of specific terms (Clark and Radivojac 2013).

10.7.2 The CAFA measures

For protein i with experimental terms T_i and predicted terms $P_i(\tau)$ at score threshold τ, both propagated to their ancestors, the protein-centric precision and recall are

$$\mathrm{pr}(\tau) = \frac{1}{m(\tau)} \sum_{i} \frac{|P_i(\tau) \cap T_i|}{|P_i(\tau)|}, \qquad \mathrm{rc}(\tau) = \frac{1}{n} \sum_{i=1}^{n} \frac{|P_i(\tau) \cap T_i|}{|T_i|},$$

where precision is averaged over the $m(\tau)$ proteins with at least one prediction and recall over all n proteins, and

$$F_{\max} = \max_{\tau} \frac{2\,\mathrm{pr}(\tau)\,\mathrm{rc}(\tau)}{\mathrm{pr}(\tau) + \mathrm{rc}(\tau)}.$$

$S_{\min}$ weights each term t by its **information content**, derived from its probability given its parents in the annotated corpus, so that specific, rare terms count more than general ones. The *remaining uncertainty* $ru(\tau)$ sums the information of true terms that were missed, the *misinformation* $mi(\tau)$ that of wrongly predicted terms, and $S_{\min} = \min_{\tau} \sqrt{ru(\tau)^2 + mi(\tau)^2}$, where lower is better (Clark and Radivojac 2013). Both measures depend on how proteins without predictions are handled, on whether averages are taken over proteins or over terms, and on the ontology release and evidence codes used.

10.7.3 Why function prediction is hard to evaluate

- **Incomplete annotations.** A protein's experimental annotations are never complete. A prediction that is not (yet) annotated is counted as a false positive, even if it is correct. This is the *open-world* problem. Measured precision is therefore usually an underestimate, and methods that predict plausible but not yet tested functions are penalised. Evaluation measures should be interpreted with this in mind; none fully corrects for it.
- **Multifunctionality and context.** Many proteins have several functions, some only in particular cell types, conditions or complexes (Section 10.2). Annotations usually record the context that was studied, so a predictor can appear wrong only because the database lacks the annotation for another context.

- **No negative data.** Databases record what proteins do, rarely what they do not do, so true negatives are hardly ever known.
- **Biased annotations.** Experimental annotations come mostly from a few organisms and a few high-throughput experiments, which favour general terms and particular functions (Schnoes et al. 2013). Evaluation on such data rewards methods that predict the common terms.
- **Changing ontology and circularity.** GO and the annotations change over time, and predictions that were deposited in databases can later be used, directly or indirectly, as evidence for new annotations.
- **The definition problem.** Since function has several meanings (Section 10.2), different evaluations measure different things, and a high score on GO terms does not guarantee that a prediction is useful to an experimentalist.

These problems explain why progress in function prediction looks modest compared with structure prediction, which has a single, well-defined and experimentally measurable answer. They also illustrate general lessons for evaluating predictors that are discussed in Chapter 12.

10.8 Key concepts

A checklist for revision.

- **What is function?** Biochemical activity, process, location, phenotype; context dependence; moonlighting and promiscuity
- **Gene Ontology:** molecular function, biological process and cellular component as separate annotation dimensions; the DAG and the true path rule (propagation over *is a* and *part of*); specificity of terms; evidence codes (experimental, phylogenetic, IEA); how few proteins have experimental annotations; what different kinds of evidence (assay, phenotype, interaction, expression, computation) show; annotation bias
- **GO annotations as statements:** relations (enables, involved in, located in); evidence and reference; the NOT qualifier and why it does not propagate upwards; annotation extensions; the open-world assumption; versions; GO-CAM causal models
- **EC numbers:** the four levels and seven classes; EC classifies reactions, not proteins; analogous enzymes; BRENDA and Rhea
- **Experimental determination of function:** forward vs. reverse genetics; mapping causal mutations by sequencing; the barcoded yeast deletion collection and pooled growth; IMPC; RNAi (knockdown, seed-mediated off-target effects) vs. CRISPR knockout, CRISPRi and CRISPRa; why knockdown and knockout phenotypes can disagree (residual protein, genetic compensation, off-targets); pooled CRISPR screens (guide counts, log fold changes, gene-level scores, MAGeCK, reference essential genes); the copy-number artefact and CERES/Chronos; core vs. context-specific essential genes; DepMap and co-essentiality; arrayed, imaging and Perturb-seq screens; redundancy, condition dependence, small effects and pleiotropy; a phenotype is not a molecular function

- **Annotation transfer by homology:** identity thresholds for enzymes as empirical tendencies, not rules; domain architecture; orthologues vs. paralogues and the ortholog conjecture (useful evidence, not a guarantee); eggNOG-mapper; error propagation and misannotation
- **Family- and domain-based annotation:** InterPro and InterPro2GO; curated annotation rules; FunFams; deep-learning family classification
- **Genomic context:** gene fusion (Rosetta stone), conserved gene neighbourhood, phylogenetic profiles; predicting links rather than functions
- **Networks:** guilt by association; propagation over networks
- **Structure-based prediction:** active-site templates; structural similarity; graph neural networks; proteome-wide annotation with predicted structures
- **Functional sites:** motifs (PROSITE), conservation and specificity-determining positions, pocket detection, catalytic-site templates; PTM site prediction (NetPhos, kinase-specific predictors, NetNGlyc/NetOGlyc and the N-X-S/T sequon, lipidation); a motif is not a modified site, and a modified site is not necessarily functional; MS data as training data and its biases
- **Disorder and short linear motifs:** functions not carried by domains; why they are hard to annotate
- **Combining evidence:** likelihood ratios and the independence assumption; pseudo-replication of copied annotations; the specificity of a claim (superfamily vs. EC class vs. substrate); rule-based annotation (UniRule, ARBA, InterPro2GO)
- **Machine learning:** DeepGOPlus; embedding-based annotation transfer; contrastive learning for EC numbers; homology between training and test sets
- **Localisation:** the signal hypothesis; signal peptides and their regions; transit peptides, NLS, PTS1, KDEL, GPI anchors; SignalP and the transmembrane-helix confusion; PSORT, TargetP, DeepLoc; multiple locations; the five SignalP 6 signal types (Sec/SPI–III, Tat/SPI–II); sequence-, cleavage-site- and residue-level evaluation; homology-aware splits
- **Variant effect prediction:** constraint vs. molecular effect vs. pathogenicity; conservation (SIFT), structure (PolyPhen-2), genome-wide scores (CADD); circularity of supervised methods; unsupervised family models (EVmutation, DeepSequence, EVE); protein language models (ESM-1v, ESM-1b); AlphaMissense; deep mutational scanning; gene constraint; clinical guidelines; loss vs. gain of function; CAGI
- **Benchmarking:** CAFA's prospective design; baselines; $F_{\max}$ (protein-centric precision and recall) and $S_{\min}$ (information content, remaining uncertainty and misinformation); propagation over the GO graph; information content; incomplete annotations and the open-world problem; multifunctionality and context; missing negatives; annotation bias; why function is harder to evaluate than structure

10.9 Recommended reading

These papers are recommended for reading in full:

- Ashburner et al. (2000) — the Gene Ontology; how function was turned into a computable vocabulary.
- Whisstock and Lesk (2003) — prediction of protein function from sequence and structure; the classical review.
- Marcotte, Pellegrini, Ng, et al. (1999) — the Rosetta stone method; predicting function from genome context rather than homology.
- Teufel et al. (2022) — SignalP 6.0; signal peptides of all types predicted with a protein language model.
- Cheng et al. (2023) — AlphaMissense; proteome-wide prediction of missense variant effects.
- Zhou et al. (2019) — CAFA3; how function prediction is evaluated, and what the results show.

Titles, abstracts, links and the full texts are in Section A.10; a longer list of further papers is in Section B.10.

10.10 Background reading (open access)

- **Protein function prediction (Wikipedia)** — Protein function prediction methods are techniques that bioinformatics researchers use to assign biological or biochemical roles to proteins. These proteins are usually ones that are poorly studied or predicted based on genomic sequence data.
  https://en.wikipedia.org/wiki/Protein_function_prediction
- **Gene Ontology (Wikipedia)** — The Gene Ontology (GO) is a major bioinformatics initiative to unify the representation of gene and gene product attributes across all species.
  https://en.wikipedia.org/wiki/Gene_Ontology
- **Enzyme Commission number (Wikipedia)** — The Enzyme Commission number is a numerical classification scheme for enzymes, based on the chemical reactions they catalyze. As a system of enzyme nomenclature, every EC number is associated with a recommended name for the corresponding enzyme-catalyzed reaction.
  https://en.wikipedia.org/wiki/Enzyme_Commission_number
- **Phylogenetic profiling (Wikipedia)** — Phylogenetic profiling is a bioinformatics technique in which the joint presence or joint absence of two traits across large numbers of species is used to infer a meaningful biological connection, such as involvement of two different proteins in the same biological pathway.
  https://en.wikipedia.org/wiki/Phylogenetic_profiling
- **Signal peptide (Wikipedia)** — A signal peptide is a short peptide present at the N-terminus of most newly synthesized proteins that are destined toward the secretory pathway. These proteins include those that reside either inside certain organelles, secreted from the cell, or inserted into most cellular membranes.
  https://en.wikipedia.org/wiki/Signal_peptide
- **Protein subcellular localization prediction (Wikipedia)** — Protein subcellular localization prediction involves the prediction of where a protein resides in a cell, its subcellular localization.
  https://en.wikipedia.org/wiki/Protein_subcellular_localization_prediction
- **Multiplexed Assays of Variant Effect (Wikipedia)** — Multiplexed Assays of Variant Effect (MAVE) is a method used to determine sequence-function relationships, identify variants that alter protein structure, stability, or activity, and characterize regulatory elements.
  https://en.wikipedia.org/wiki/Multiplexed_Assays_of_Variant_Effect

10.11 Student recommendations

Recommended by students preparing for the exam: papers, reviews, online lectures, tutorials and short explanations. To suggest something, use the suggestion form (SU login).

No recommendations yet.

10.12 Review problems

These problems are adapted from Matteo Tadiello, *Modern Bioinformatics: From Foundations to Frontiers* (CC BY 4.0), used with permission. For a longer treatment of this topic, see the chapters “Protein

Function and Annotation" and "Protein Signals, Membranes, and Localization" of that book. In the HTML version, click a box to show the extensions, solution outline and common errors.

10.12.1 Decomposing protein function

A deletion strain grows poorly during oxidative stress, the encoded protein binds NADPH in vitro, and its transcript increases after peroxide treatment. Formulate the distinct functional claims supported by these observations. Which mechanistic claims remain unresolved?

Extensions, solution outline and common errors

Extensions:

- Distinguish molecular activity from biological process, localisation, phenotype and context.
- How could multifunctionality, isoforms, modifications or complex formation change the interpretation?
- Propose one experiment that connects NADPH binding to the stress phenotype.

Solution outline:

1. The deletion supports involvement of the gene in fitness under the tested condition (a mutant phenotype, IMP), subject to genetic background and indirect effects.
2. Induction of the transcript shows condition-dependent regulation (IEP), not protein activity.
3. NADPH binding supports a molecular interaction under the assay conditions (IDA), but not catalysis, physiological affinity or cellular relevance.
4. To connect them: test a chemically defined reaction and identify its products, compare the wild type with a folded variant that has lost the binding or catalytic site, and test whether the wild-type but not the variant rescues the deletion.
5. Represent function as separate assertions, each with its context and evidence, rather than as one name.

Common errors:

- Treating expression as mechanism.
- Inferring catalysis from binding.
- Assigning a pathway from a growth phenotype alone.
- Treating missing annotations as evidence of absence.

Connections: Section 10.2; ontologies and evidence codes in Section 2.6; expression in Chapter 7; interactions in Chapter 11.

10.12.2 Interpreting a domain match

A curated profile identifies a protein-kinase-like domain between residues 410 and 690 of a 1,200-residue protein. State the strongest defensible annotation and design the next computational and experimental steps.

Extensions, solution outline and common errors

Extensions:

- Define domain, motif, site, repeat and family.
- Discuss coverage, domain boundaries, pseudokinases, transmembrane segments, disorder and regulatory regions.
- Why may hits in several databases not be independent evidence?

Solution outline:

1. The match supports membership of residues 410–690 in the modelled domain family, given the score, coverage and sequence quality. It does not determine the function of the full-length protein.
2. Map the other domains, targeting signals, transmembrane segments and disordered regions, and check whether the catalytic residues required for kinase activity are present (pseudokinases lack them).
3. Inspect a confidence-filtered structural model and place the domain in a phylogeny of the family; trace the evidence for characterised relatives.
4. Kinase activity requires an assay with a suitable substrate and product readout, controls without enzyme and with an inactive variant, and evidence that the construct is folded.

Common errors:

- Naming the whole protein from a local hit.
- Using a short motif as proof of catalysis.
- Neglecting errors in the gene model.
- Counting matches to related signature databases (for example several InterPro member databases) as replication.

Connections: Section 10.4; profile searches and domains in Section 1.6 and Section 1.9; gene models in Section 5.6; predicted structures in Section 9.8.

10.12.3 Sequence identity and family membership

Two proteins share 45% identity over 220 aligned residues, but one is 780 residues long and the other 260. What can be concluded about ancestry, family membership and functional equivalence?

Extensions, solution outline and common errors

Extensions:

- Reconsider the case at 80% identity.
- Define a protein family at an explicit evolutionary depth.
- What evidence is required to transfer an exact enzyme specificity?
- How do low-complexity regions or biased composition affect the conclusion?

Solution outline:

1. Identity is a property of an alignment, not a biological classification. The aligned region is very probably homologous.

2. Incomplete coverage of the longer protein and different domain architectures rule out automatic transfer of the full-length family or function.
3. Family membership should be defined by common ancestry at a stated level, and supported by profiles or phylogeny.
4. Exact specificity also requires an experimentally characterised source, a compatible subfamily history, conserved catalytic and specificity-determining residues, and preferably biochemical evidence. Even high identity does not guarantee the same EC number, and no fixed percentage supplies these conditions (Rost 2002).

Common errors:

- Describing proteins as "45% homologous".
- Defining ancestry by a global identity cutoff.
- Ignoring the length over which identity is computed.
- Reading an E-value as the probability of equal function.

Connections: Section 10.4; homology in Section 3.3; alignment statistics in 1; domain evolution in Section 3.5.

10.12.4 Orthology and functional conservation

A human and a mouse protein are inferred to be one-to-one orthologues. Which functional properties can be transferred, and how would you test conservation?

Extensions, solution outline and common errors

Extensions:

- Why does orthology raise the prior probability of conserved function without guaranteeing it (the ortholog conjecture)?
- Consider isoforms, lineage-specific partners, expression, localisation and gene duplication.
- How does taxon sampling change an orthology call?

Solution outline:

1. Orthology means descent through speciation; it supports, but does not prove, conservation of function.
2. Evaluate a domain-aware alignment and gene tree reconciled with the species tree, synteny where informative, correspondence of isoforms, catalytic and regulatory residues, expression, localisation and interaction partners.
3. A biochemical activity shown in one species transfers more readily than tissue-specific regulation or a phenotype.
4. Each transferred assertion should keep its source and evidence code. Cross-species complementation supports conservation if expression, localisation and dosage are controlled.

Common errors:

- Inferring orthology only from a best reciprocal hit.
- Treating one-to-one status as independent of taxon sampling.
- Equating conserved chemistry with a conserved organismal phenotype.
- Counting several orthology resources built from the same data as independent.

Connections: Section 10.4; orthologues and paralogues in Section 3.4; gene-tree reconciliation in Section 4.4; expression in Chapter 7.

10.12.5 Reading a GO assertion

A record states that a protein *enables* protein kinase activity, with evidence code IEA. Interpret the assertion, and list the additional fields and versions needed to use it reproducibly.

Extensions, solution outline and common errors

Extensions:

- Contrast IEA, EXP, ND and an explicit NOT annotation.
- Explain propagation over the ontology (the true path rule) and the open-world assumption.
- Why does annotation to a broad ancestor not imply a specific descendant?

Solution outline:

1. IEA marks an automatically generated assertion that no curator has reviewed individually; it is not necessarily wrong.
2. Interpretation requires the gene product (and isoform), the relation, the GO identifier and ontology release, the reference, any qualifier or extension, the annotating group, the date and the pipeline.
3. Positive annotations propagate to ancestors only through relations such as *is a* and *part of*.
4. NOT is an evidence-based negation; ND records that curators found no biological data for that aspect. A missing annotation is unknown, not a negative (The Gene Ontology Consortium et al. 2023).

Common errors:

- Ranking evidence codes as universal truth scores.
- Ignoring the relation.
- Treating inherited ancestor terms as independent observations.
- Using unannotated proteins as negatives for machine learning.

Connections: Section 10.2; GO as a resource in Section 2.6; hierarchical evaluation in Section 10.7.

10.12.6 Structure-based functional inference

A predicted structure gives a high-scoring Foldseek match to a biochemically characterised enzyme, although sequence searches are inconclusive. Formulate a calibrated annotation strategy.

Extensions, solution outline and common errors

Extensions:

- Distinguish global fold similarity, remote homology, similarity of local sites and equivalence of mechanism.
- Discuss model confidence, uncertain side chains, oligomerisation, ligands and convergent geometry.
- Specify a discriminating biochemical assay.

Solution outline:

1. Structure search generates a candidate relationship (van Kempen et al. 2023). Restrict the comparison to confidently predicted domains and inspect the alignment extent and topology.
2. Add profile and phylogenetic evidence, and compare the equivalence of catalytic residues, pocket geometry, cofactors and metals, and quaternary structure.
3. A common fold supports a structural class but does not by itself establish ancestry or function; the narrowest provisional claim may be a fold or reaction class.
4. Exact function requires a substrate panel, kinetic measurements and identification of products, with controls for folding and contamination.

Common errors:

- Treating a predicted model as an experimental structure.
- Trusting uncertain side-chain positions.
- Reading global similarity as equivalence of the pocket.
- Using one docking pose as validation.

Connections: Section 10.4; structure comparison in Section 9.6; model confidence and docking in Section 9.8 and Section 9.11.

10.12.7 Network evidence and biological context

An uncharacterised protein is strongly connected to a DNA-repair module in a functional association network. What does the network support, and how would you validate it?

Extensions, solution outline and common errors

Extensions:

- Distinguish physical interaction from functional association.
- Explain hub effects, mixed conditions, dependence on text mining, and study bias.
- Describe an evaluation of network-based prediction that avoids leakage.

Solution outline:

1. The network supports association with the module under the meaning of its edges; it does not establish direct binding, molecular activity or a repair mechanism.
2. Separate the evidence channels (experiments, co-expression, genomic neighbourhood, text mining, pathways, orthology) and trace shared sources.
3. Guilt by association assumes that connected nodes share functions, an assumption weakened by hubs, multifunctional proteins and mixed conditions.
4. Validate by perturbing the protein under DNA damage, measuring repair-specific molecular and phenotypic outcomes, testing rescue, and using orthogonal interaction or localisation assays.
5. Evaluate predictions by holding out whole proteins or later annotations, not random edges.

Common errors:

- Equating a STRING edge with physical contact.
- Multiplying dependent scores.
- Ignoring compartment and condition.
- Validating only with generic stress sensitivity.

Connections: Section 10.4; functional association networks in Section 11.3; physical interactions in Section 11.2; leakage in 4.

10.12.8 Annotation propagation and audit

The same specific enzyme name occurs on thousands of bacterial homologues in several databases. Design an audit and a conservative replacement pipeline.

Extensions, solution outline and common errors

Extensions:

- Explain pseudo-replication across databases, paralogy and errors in domain boundaries.
- What should a family-specific annotation rule contain?
- How should corrected descendant annotations be handled?

Solution outline:

1. Trace each displayed name to its earliest evidential source; copied descendants are one line of evidence, not many.
2. Reconstruct gene models, domain architectures, subfamilies, duplication history, required residues, taxonomic range and known exceptions.
3. A replacement rule can require profile matches, coverage, architecture, specificity-determining residues and allowed taxa, with explicit exclusions. Its output must not be more specific than the experimental evidence across the matched set.
4. Report separate confidence for family, reaction class, substrate, process and location, with provenance.
5. Evaluate on experimentally characterised proteins with homology- or time-separated splits; misannotation is common in automatically annotated superfamilies (Schnoes et al. 2009).

Common errors:

- Voting across dependent databases.
- Training and testing on near-identical homologues.
- Correcting one record while leaving its descendants unchanged.
- Treating terms missing from a benchmark as experimentally disproved.

Connections: Section 10.4 (error propagation, combining evidence); database provenance in Section 2.2; evaluation in Section 10.7 and 4.

10.12.9 Calibrating protein-function inference

An uncharacterised bacterial protein is weakly similar to a known antibiotic-resistance enzyme. Construct an evidence chain for family membership, molecular activity and resistance of the organism, and say where the conclusions must remain provisional.

Extensions, solution outline and common errors

Extensions:

- How do domain architecture and alignment coverage change the interpretation?

- Which experiments distinguish biochemical activity from physiological relevance?

Solution outline:

1. Verify the sequence and gene model, then examine local similarity, profile evidence, domain architecture, conserved residues, phylogenetic placement, genomic context, predicted localisation and structure.
2. Treat homology as shared ancestry, not identical function: a match confined to a generic domain supports a narrower conclusion than full-length, family-specific evidence.
3. Check whether the reference annotations come from direct assays or computational transfer (evidence codes).
4. Test molecular activity with purified protein, substrates, negative controls and mutation of catalytic residues. Test resistance by deletion, complementation and susceptibility measurements.
5. Report a predicted family or activity until the evidence supports a stronger statement.

Common errors:

- Treating structural resemblance as proof of the same reaction.
- Ignoring paralogy.
- Inferring an organismal phenotype from an in vitro assay alone.

Connections: Section 10.4 and Section 10.2; homology in Section 3.3; sequence search and domains in 1 and Section 1.9.

10.12.10 Interpreting a pooled CRISPR screen

A genome-wide CRISPR knockout screen with four guides per gene is run in a cancer cell line for three weeks. Gene A has all four guides strongly depleted; gene B has one guide strongly depleted and three unchanged; a cluster of ten neighbouring genes on an amplified region of chromosome 8 all appear depleted; gene C, a paralogue of gene D, shows no depletion. Which genes would you call dependencies, and what further analyses or experiments would you do?

Extensions, solution outline and common errors

Extensions:

- How would you decide whether gene A is a core essential gene or a dependency specific to this cell line?
- What would a CRISPRi screen add, and why might an RNAi screen of the same genes disagree?

Solution outline:

1. Normalise guide counts for sequencing depth, compute log fold changes against the starting population, and combine guides into gene-level scores with a robust method (for example MAGeCK's rank aggregation), controlling the false discovery rate. Check the screen's quality by how well it separates reference essential and non-essential genes.
2. Gene A: consistent depletion of independent guides is strong evidence of a fitness dependency.
3. Gene B: one depleted guide is more likely an off-target or guide-specific effect; it should not be called a hit without additional guides.

4. The amplified cluster: depletion of every gene in an amplified region is the copy-number artefact of Cas9 cutting at many sites. Correct with CERES or Chronos, or test with CRISPRi, which does not cut.
5. Gene C: no depletion does not mean no function. Paralogue redundancy with D is likely; test a double knockout for synthetic lethality, and other conditions.
6. Compare with DepMap: a gene essential in all lines is core essential; one essential only in lines with a particular mutation is a candidate selective target. Validate with independent guides and rescue by a guide-resistant cDNA.

Common errors:

- Calling hits from single guides.
- Ignoring copy number.
- Interpreting absence of depletion as absence of function.
- Equating a fitness phenotype with a molecular function.

Connections: Section 10.3; count statistics in Section 7.4; cancer genomics in Section 7.7; genetic interactions in Section 11.2.

11 Protein–protein interactions

> **From the exam description**
>
> Experimental and computational methods to analyse which proteins interact and how.

11.1 Overview

Proteins rarely act alone. The word *interaction*, however, is used for relationships of very different kinds, which are not interchangeable: direct **physical binding** between two proteins; **co-complex membership**, in which two proteins belong to the same complex without necessarily touching; **genetic interactions**, in which mutations in two genes have a combined effect on the phenotype; **regulatory influence**, in which one gene product changes the expression or activity of another; and **functional association**, in which two proteins take part in the same process. Each experimental and computational method detects one or a few of these. This chapter is broad: it covers physical interactions between proteins, functional associations, regulatory networks and the network view of the cell, as well as the prediction of interactions and of the structures of complexes:

- experimental methods: yeast two-hybrid, AP-MS and other methods, binding affinity and live-cell proximity, their errors and biases, hu.MAP, genetic interactions, and gene regulatory networks inferred from perturbations (Section 11.2);
- networks: interactome maps, network concepts and their critics, functional association networks and Bayesian integration, pathway and network enrichment analysis, disease networks, systems biology and flux balance analysis, and dynamic models of regulatory networks (feedback, switches, oscillators, robustness and parameter estimation) (Section 11.3);
- prediction methods: interfaces, genomic context, coevolution, docking and deep learning with AlphaFold, and how predictions are evaluated (Section 11.4).

The interaction databases are described in Section 2.7, the mass spectrometry methods in Section 8.5, and the structure prediction methods on which complex prediction builds in Chapter 9.

11.2 Experimental methods

Most proteins carry out their function together with others: in stable complexes such as the ribosome, in transient signalling interactions, or as enzymes acting on protein substrates. Mapping which proteins interact, and how, is a way to understand cellular machinery and to annotate unknown proteins (Section 10.4). The word *interaction* covers very different relationships, and each experimental method measures a different one. This section describes the main methods for physical interactions, the resulting maps and their errors, and the inference of regulatory networks from perturbations.

11.2.1 Binary interactions: yeast two-hybrid

The **yeast two-hybrid** (Y2H) system, invented by Stanley Fields in 1989 (Fields and Song 1989), exploits the modular structure of transcription factors. The DNA-binding domain of the yeast factor Gal4 is fused to one protein (the *bait*) and its activation domain to another (the *prey*). Only if bait and prey bind each other is a functional transcription factor reconstituted, which switches on a reporter gene that allows the yeast to grow on selective medium. Y2H tests one pair at a time and therefore enriches for **binary**, often direct, interactions, and can be run as large matrix screens of thousands of baits against thousands of preys. A positive result does not prove direct contact in the native cellular context, however: an endogenous yeast protein can bridge bait and prey, the fusion proteins are expressed outside their normal location and at unnatural levels, and the reporter can be activated without binding. The fusions can also misfold or hide the binding site, which causes false negatives.

The first proteome-scale screens were done in yeast (Uetz et al. 2000; Ito et al. 2001), and later for human proteins (Rual et al. 2005). The results were noisy: the two yeast screens overlapped little, and there was a widespread belief that Y2H data were unreliable. Marc Vidal's group showed that careful screening, retesting and an empirical framework for estimating precision and sensitivity gave high-quality data, and that the low overlap mostly reflected low *sensitivity*, since each screen samples only a fraction of all interactions (Yu et al. 2008; Braun et al. 2008; Venkatesan et al. 2008). The human reference interactome **HuRI** screened about 17,500 proteins against each other, and reported about 53,000 binary interactions (Rolland et al. 2014; Luck et al. 2020).

Y2H has its own biases. Interactions are tested in the yeast nucleus, so membrane proteins, interactions that require post-translational modifications or other partners, and proteins that activate transcription by themselves are problematic. Variants such as split-ubiquitin systems handle membrane proteins, and the **protein-fragment complementation assay** (PCA), in which two halves of a reporter enzyme are fused to the proteins and reassemble when they meet, tests interactions in their normal cellular location (Tarassov et al. 2008).

11.2.2 Co-complex interactions: affinity purification–mass spectrometry

In **affinity purification–mass spectrometry** (AP-MS), a tagged bait is purified from cells together with the proteins bound to it, which are identified by mass spectrometry (Section 8.5). The tandem affinity purification (TAP) tag, with two successive purification steps, made it possible to isolate complexes under near-native conditions (Rigaut et al. 1999), and was used for the first proteome-scale maps of yeast complexes (Gavin et al. 2002; Ho et al. 2002; Krogan et al. 2006). In human cells, the BioPlex project has purified more than 10,000 baits in two cell lines (Huttlin et al. 2015, 2021).

AP-MS reports **co-complex membership**: a prey can bind the bait directly or through other proteins. This is the key contrast with Y2H, which tests pairs and enriches for direct binary contacts, whereas AP-MS finds the proteins that co-purify with the bait in a cell, without telling which of them touch each other. A purified complex with n components can be represented in two ways, which give very different numbers of "interactions": the *spoke* model connects the bait to every prey ($n-1$ edges), while the *matrix* model connects all pairs ($n(n-1)/2$ edges), most of which are not direct contacts. Contaminants and abundant sticky proteins are removed with statistical scoring against control purifications (Section 8.5). Complementary MS methods, co-fractionation of native complexes, proximity labelling and cross-linking MS (O'Reilly and Rappsilber 2018), are also described in Section 8.5. They too measure different things: co-fractionation finds proteins that elute together, and proximity labelling finds proteins that were *near* the bait, within roughly 10–20 nm, not necessarily bound to it. **Cross-linking MS** is a bridge between interaction mapping and structure: it covalently links residues that are close in space, so each identified cross-link shows not only that two proteins are near each other but also which of their residues

are, typically within about 30 Å. These distance restraints can be used to dock or model the complex (Section 11.4), and can be collected in intact cells.

hu.MAP integrates thousands of AP-MS, co-fractionation and proximity labelling experiments with machine learning to predict human complexes (Drew et al. 2017, 2021; Fischer et al. 2025). How the map is built is described in Section 8.5. For network analysis, hu.MAP provides a set of complexes with confidence levels that complements the binary map of HuRI and the pull-downs of BioPlex.

11.2.3 Binding affinity, live-cell proximity and validation

Large-scale screens show whether two proteins associate, not how strongly, for how long or where. For a reversible 1:1 interaction $A + B \rightleftharpoons AB$, the dissociation constant is $K_d = [A][B]/[AB] = k_{\text{off}}/k_{\text{on}}$ (Section 9.3). If B is in excess and A has a single binding site, the fraction of A that is bound is

$$f_{\text{bound}} = \frac{[B]}{K_d + [B]},$$

so half of A is bound when the free concentration of B equals K_d. Whether an interaction occurs in a cell therefore depends on local concentrations as much as on affinity, and two interactions with the same K_d can have very different lifetimes ($1/k_{\text{off}}$). The simple equation assumes one independent site at equilibrium; cooperativity, multivalency (avidity) and competition between partners break it.

Affinity and kinetics are measured with purified proteins. **Surface plasmon resonance** and **biolayer interferometry** immobilise one partner and follow binding of the other in real time, which gives k_{on} and k_{off}; **isothermal titration calorimetry** measures the heat of binding, which gives K_d, the stoichiometry and the enthalpy. Such assays show direct binding under the assay conditions, but not that it happens in the cell.

In living cells, proximity can be measured with fluorescent tags. In **Förster resonance energy transfer** (FRET), an excited donor fluorophore transfers energy to a nearby acceptor with efficiency

$$E = \frac{1}{1 + (r/R_0)^6},$$

where r is the donor–acceptor distance and R_0, the Förster distance at which $E = 0.5$, is a few nanometres for common pairs (Stryer and Haugland 1967). The steep sixth-power dependence makes FRET sensitive only within a narrow range of distances. **BRET** uses a luciferase as donor, which avoids exciting the sample with light. A positive signal shows that the tags were close, which overexpression and molecular crowding can also cause, and a negative signal can reflect unfavourable tag geometry. Donor-only controls, non-binding mutants and titration of expression levels help to tell these apart. **Proximity labelling** (Section 8.5) records which proteins were near a bait during a labelling window rather than which bind it: hours for BioID (Roux et al. 2012), about ten minutes for TurboID (Branon et al. 2018), and about a minute for the peroxidase APEX, which requires hydrogen peroxide (Rhee et al. 2013).

Confidence grows when methods with *different failure modes* agree. Repeating Y2H with another complementation assay adds little, because both share the artefacts of fusion proteins; co-IP and AP-MS share the artefacts of cell lysis; and two databases may report the same original paper. A strong chain of evidence might combine discovery by AP-MS, reciprocal co-immunoprecipitation of the endogenous proteins, binding of the purified proteins, mutations of interface residues that abolish binding without unfolding either protein, and a functional defect that is rescued by the wild-type but not by the mutant protein. A single negative result rarely rules out an interaction, since every method has blind spots.

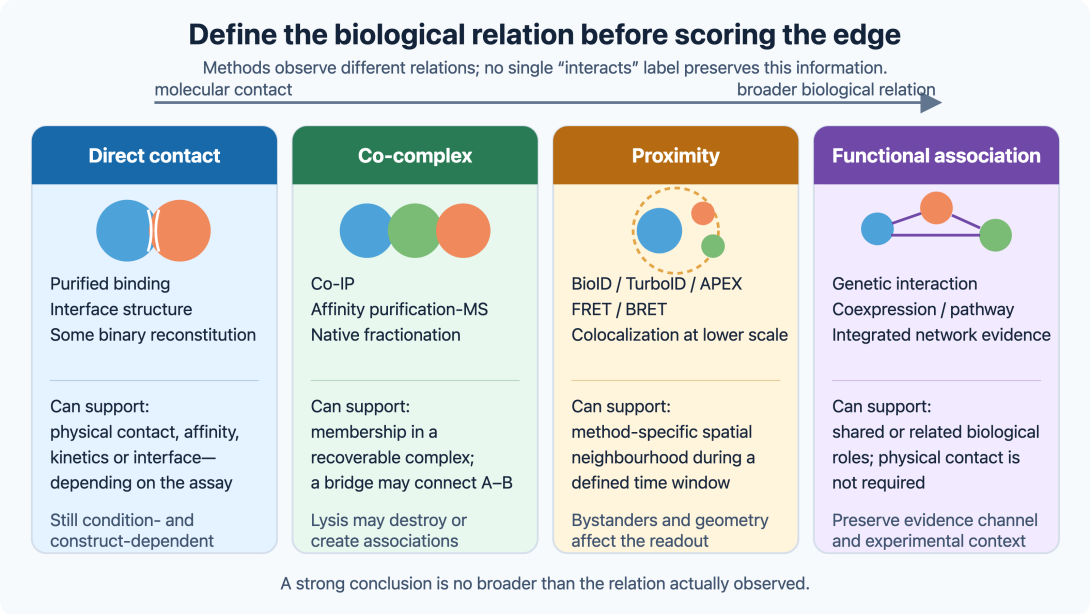

Figure 11.1: What different kinds of interaction evidence can support. Direct-contact methods (purified binding, interface structures) can show physical contact, affinity and kinetics; co-complex methods (co-IP, AP-MS, native fractionation) show membership in a recoverable complex, possibly bridged by other proteins; proximity methods (BioID, TurboID, APEX, FRET, BRET) show that proteins were near each other during a time window; and functional association (genetic interactions, co-expression, integrated networks) does not require contact at all. Figure: Matteo Tadiello, *Modern Bioinformatics: From Foundations to Frontiers* (CC BY 4.0).

11.2.4 Errors, biases and coverage

Early comparisons of yeast interaction data sets found that they overlapped surprisingly little and estimated high rates of false positives and false negatives (Mering et al. 2002). Several lessons have emerged since then:

- **Different methods measure different things.** Binary Y2H interactions and co-complex AP-MS associations are not expected to agree, and both differ from functional associations in networks such as STRING (Section 11.3).
- **Low overlap often means low sensitivity, not low precision.** Each screen detects only part of the interactome, so two good screens can overlap little (Venkatesan et al. 2008).
- **Literature-curated data are biased.** Well-studied proteins, such as cancer genes, have many reported interactions simply because many experiments were done on them, which creates artificial hubs. Systematic screens, in which every pair is tested equally, avoid this *study bias* (Rolland et al. 2014; Luck et al. 2020).
- **Interactions depend on context.** Two proteins can only interact if they are expressed in the same cell, at the same time and in the same compartment, and many interactions depend on the isoform, on post-translational modifications or on a stimulus. There is therefore no single, fixed human interactome: each cell type and condition uses a different subset. A static network such as HuRI or BioPlex is a union of interactions observed or possible across many contexts, and many of its edges may never occur in a given cell.
- **Interactions are not binary.** Databases and networks record an interaction as present or absent, but biological interactions differ enormously in strength and dynamics. Dissociation constants (K_d) range from picomolar or tighter for stable complexes to micromolar or weaker for transient signalling interactions, residence times range from milliseconds to the lifetime of the protein,

and complexes have defined stoichiometries (for example two copies of one subunit and one of another). Whether an interaction occurs in the cell depends on K_d and on the concentrations of the partners, and which interactions an assay detects depends on its sensitivity to weak and transient binding.

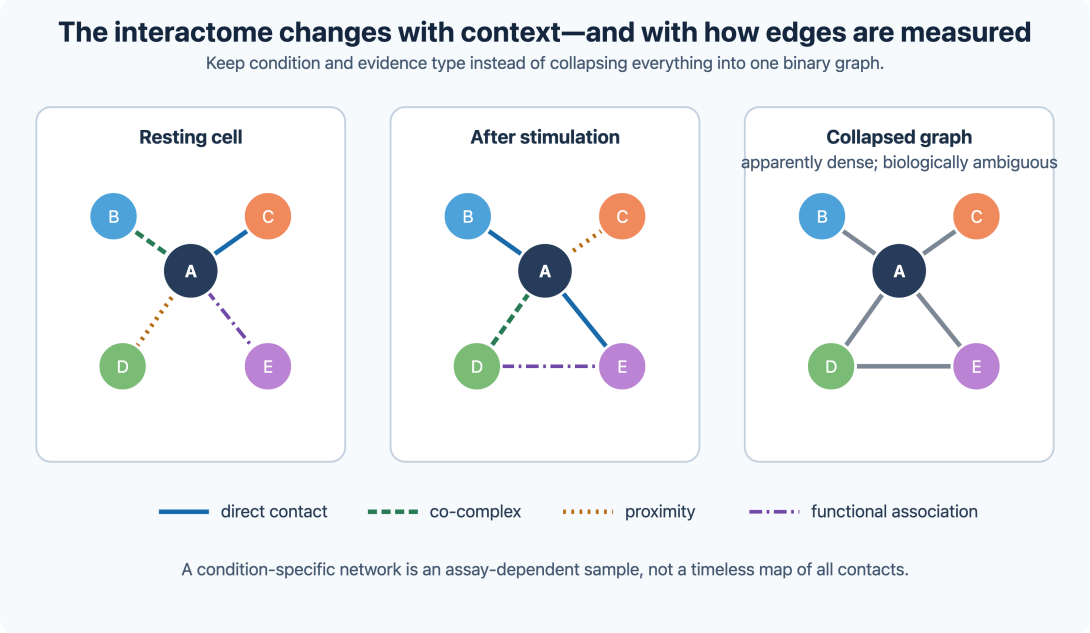

Figure 11.2: The same five proteins in a resting cell, after stimulation, and with all edges collapsed into one graph. Edges differ in kind (direct contact, co-complex, proximity or functional association) and in the condition in which they were seen; the collapsed graph looks denser and better connected than either real state. Figure: Matteo Tadiello, *Modern Bioinformatics: From Foundations to Frontiers* (CC BY 4.0).

11.2.5 Genetic interactions

A **genetic interaction** occurs when the combined effect of mutations in two genes differs from what is expected from their individual effects. In *synthetic lethality*, two mutations that are harmless alone kill the cell together. Genetic interactions do not imply physical contact, but they reveal functional relationships: genes with similar profiles of genetic interactions tend to work in the same pathway or complex. A map of almost all pairwise genetic interactions in yeast showed a hierarchy of functional modules (Costanzo et al. 2016). Synthetic lethality is also a strategy for cancer therapy, targeting a gene whose partner is mutated in the tumour.

Quantitatively, a genetic interaction is a deviation from a null model. If w_A, w_B and w_{AB} are the fitness of the single and double mutants relative to the wild type, the usual multiplicative model expects $w_{AB} = w_A w_B$, and the interaction score is $\varepsilon_{AB} = w_{AB} - w_A w_B$. Negative scores (*aggravating* interactions, with synthetic lethality as the extreme case) often connect genes in parallel, buffering pathways; positive scores (*alleviating* interactions) often connect genes in the same pathway or complex, where losing one already disables the whole. An additive or logarithmic null model gives different scores, so which pairs "interact" depends on the model chosen.

11.2.6 Gene regulatory networks and inference from perturbations

A **gene regulatory network** (GRN) describes which transcription factors regulate which genes. Its edges are directed and signed (activation or repression), unlike the undirected edges of protein interaction networks. Regulatory interactions can be measured directly, for example by ChIP-seq of transcription factors, but they are often *inferred* from expression data.

- **Correlation and information-based methods** connect genes whose expression co-varies across many samples. ARACNE uses mutual information and removes indirect links with the data-processing inequality (Margolin et al. 2006). GENIE3 predicts the expression of each gene from all others with random forests and ranks the regulators by importance (Huynh-Thu et al. 2010).
- **Perturbation-based methods** use experiments in which genes are knocked down, knocked out or overexpressed. Since a perturbation is a cause, these data can reveal the direction of regulation, which correlations cannot. Early methods fitted linear dynamical models to the responses to known perturbations (Gardner et al. 2003; Tegnér et al. 2003), and the idea that perturbation data reveal the network structure goes back to the systematic perturbation of the yeast galactose pathway (Ideker et al. 2001).
- **Single-cell perturbation screens**, such as Perturb-seq, combine pooled CRISPR perturbations with single-cell RNA-seq, so that the transcriptional effect of each perturbation is read out in the same cells (Dixit et al. 2016). Genome-scale Perturb-seq has measured the effect of perturbing essentially every expressed gene in human cells (Replogle et al. 2022).

Network inference is notoriously difficult. The DREAM challenges compared dozens of methods on simulated and real data, and found that no single method was best, that performance on real data was modest, and that a consensus of several methods ("the wisdom of crowds") was most robust (Marbach et al. 2012). Benchmarks on single-cell data reached similar conclusions (Pratapa et al. 2020). Inferred networks should therefore be treated as hypotheses, and their accuracy depends strongly on how much of the network was actually perturbed.

11.3 Networks

Interactions together form networks, and network science provides the concepts and tools to study them (Barabási and Oltvai 2004). This section describes the large interactome maps, the main properties of biological networks, functional association networks that integrate many kinds of evidence, and two applications: network medicine and metabolic modelling.

11.3.1 Interactome maps and databases

Three large, systematic maps of human protein interactions are the references for network analysis today:

- **HuRI**, the binary interactome from systematic yeast two-hybrid screens (Luck et al. 2020);
- **BioPlex**, the co-complex network from AP-MS in two cell lines (Huttlin et al. 2021);
- **hu.MAP**, protein complexes integrated from many MS experiments (Fischer et al. 2025).

These are complemented by curated databases of interactions reported in the literature, such as IntAct and BioGRID, and by functional association networks, such as STRING and FunCoup, which are described as resources in Section 2.7.

11.3.2 Network concepts

A network (graph) consists of **nodes** (proteins or genes) and **edges** (interactions). Edges may be undirected (physical binding), directed (regulation, signalling) or weighted (confidence). The main descriptive properties are:

- The **degree** k of a node is its number of edges, and the **degree distribution** $P(k)$ the fraction of nodes with degree k. In a random (Erdős–Rényi) graph, degrees follow a Poisson distribution around the mean.
- **Scale-free networks** have a power-law degree distribution, $P(k) \propto k^{-\gamma}$, so that most nodes have few links and a few **hubs** have very many. Barabási and Albert showed that such networks arise from *preferential attachment*: new nodes link preferentially to nodes that already have many links (Barabási and Albert 1999). In the early 2000s, metabolic and protein interaction networks were reported to be scale-free (Jeong et al. 2000), and gene duplication, in which a copied gene inherits the interactions of its parent, was proposed as a biological mechanism for preferential attachment. These claims are now regarded as controversial (see below).
- The **clustering coefficient** of a node is the fraction of pairs of its neighbours that are themselves connected: for a node i with k_i neighbours and e_i edges among them, $C_i = 2e_i / [k_i(k_i - 1)]$. Biological networks have high clustering and short paths between most nodes, the **small-world** property (Watts and Strogatz 1998).
- **Centrality** measures how important a node is for the network, for example by its degree or by the number of shortest paths passing through it. The *betweenness* of node i is $C_B(i) = \sum_{s \neq i \neq t} \sigma_{st}(i) / \sigma_{st}$, where σ_{st} is the number of shortest paths between nodes s and t and $\sigma_{st}(i)$ the number of those that pass through i. Centrality describes a position in one particular graph; it is not a measure of biological importance.
- **Modules** or **communities** are groups of nodes more densely connected to each other than to the rest, often corresponding to complexes or pathways. They are found with clustering algorithms such as Girvan–Newman edge removal (Girvan and Newman 2002) and the Markov cluster algorithm (Enright 2002). Many methods maximise the *modularity* $Q = \frac{1}{2m} \sum_{ij} \left(A_{ij} - \frac{k_i k_j}{2m} \right) \delta(c_i, c_j)$, where A is the adjacency matrix, m the number of edges and $\delta(c_i, c_j) = 1$ if nodes i and j are in the same module: the number of edges within modules minus the number expected in a random network with the same degrees. A module found in this way is a hypothesis, not necessarily a complex. Metabolic networks show a hierarchical organisation of modules (Ravasz et al. 2002).
- **Network motifs** are small subgraphs, such as the feed-forward loop in transcriptional networks, that occur much more often than in randomised networks with the same degrees (Milo et al. 2002).

Early studies linked network position to biology. In yeast, hubs were found to be more often essential than other proteins, a correlation that became known as the *centrality–lethality rule* (Jeong et al. 2001).

Hubs were divided into *party hubs*, which interact with their partners at the same time, inside complexes, and *date hubs*, which bind different partners at different times (Han et al. 2004), and they differ in sequence and domain properties (Ekman et al. 2006). Interactions between hubs were found to be rarer than expected (Maslov and Sneppen 2002).

Many of these conclusions have been questioned. Interaction maps are incomplete and biased, so the observed network is a sample of the true one, and sampling can create or hide apparent power laws (Hakes et al. 2008; Lima-Mendez and Helden 2009). A heavy-tailed degree distribution is not necessarily a power law: other distributions, such as the log-normal or a power law with an exponential cut-off, often fit the data as well or better. A systematic analysis of nearly a thousand networks from many fields found that strongly scale-free networks are rare (Broido and Clauset 2019). Hubs in literature-curated networks partly reflect study bias (Section 11.2).

The same biases confound the centrality–lethality correlation. Essential proteins are studied more, and therefore accumulate more reported interactions. When AP-MS data are represented with the matrix model, every member of a large complex becomes a hub, and many large complexes are essential. The strength of the correlation depends on the data set and the detection method, and it does not show that a protein is essential *because* it has many partners (He and Zhang 2006). Network properties are therefore best treated as descriptions of a particular data set, and compared with appropriate randomised networks, rather than as universal laws.

11.3.3 Functional association networks

Physical interactions are only one kind of evidence that two proteins work together. Others are co-expression, genetic interactions, shared genomic context (Section 10.4), co-occurrence in the literature, shared domains and interactions of orthologues in other species. **Functional association networks** integrate all of these into a single network in which each edge has a confidence score (Guala et al. 2019).

The integration is usually **Bayesian**. For each evidence type i, a *likelihood ratio* is estimated from a gold standard of known positive pairs (for example proteins in the same complex or pathway) and negative pairs:

$$\mathrm{LR}_i = \frac{P(e_i \mid \text{linked})}{P(e_i \mid \text{not linked})}.$$

If the evidence types are assumed to be independent (*naive Bayes*), the posterior odds that two proteins are linked are the prior odds multiplied by the likelihood ratios of all the evidence, so a link supported by several independent weak signals can become confident. This approach was introduced for yeast (Jansen et al. 2003; Lee et al. 2004). **FunCoup**, developed by Erik Sonnhammer's group in Stockholm, applies it across many species and evidence types, and transfers evidence between species by orthology (Alexeyenko and Sonnhammer 2009; Buzzao, Persson, et al. 2024). **STRING** uses a similar scheme, with scores for each evidence channel combined into an overall confidence (Szklarczyk et al. 2024). If the channel scores s_i are treated as independent probabilities, the combined score is $1 - \prod_i (1 - s_i)$, the probability that at least one channel is right, computed after the prior probability that two random proteins are linked has been removed from each channel. The assumption of independence is not exact, for example because co-expression and shared pathway membership are correlated, and the networks reflect the biases of their gold standards.

An edge in such a network means that two proteins probably **work together**, not that they bind each other. Functional association networks are used to predict function by guilt by association (Section 10.4), to interpret gene lists from expression or genetic screens, and to prioritise disease genes.

11.3.4 Pathways, gene sets and network enrichment

Gene lists from expression, proteomics or genetic screens are usually interpreted with **gene sets**: GO terms and pathways from KEGG and Reactome (Section 2.6). Over-representation analysis with the hypergeometric test, gene set enrichment analysis (GSEA), and the choice of background and threshold are described in Section 7.5. Several further problems arise from the structure of the annotations and from the use of networks.

- **Dependence in the GO graph.** Annotations propagate to all ancestors of a term (Section 10.2), so a term and its parents share most of their genes. If a specific term is enriched, its ancestors usually are too, even when they carry no additional signal, and the result is a long, redundant list. The *elim* and *weight* algorithms of topGO remove or down-weight the genes of significant descendant terms before their parents are tested (Alexa et al. 2006), and *parent–child* analysis tests a term against the genes annotated to its parents rather than against the whole background (Grossmann et al. 2007). Long lists can also be summarised by clustering terms by semantic similarity, for example with REVIGO (Supek et al. 2011).
- **Multiple testing.** Thousands of overlapping sets are tested, so p-values must be corrected, usually by controlling the false discovery rate (Section 7.4). Because the tests are strongly dependent, the number of significant sets says little about the number of independent findings. Results also change with the database, its release and the identifier mapping, which should be reported (Wijesooriya et al. 2022; Chicco and Agapito 2022).
- **Annotation bias and circularity.** Well-studied and multifunctional genes belong to many sets and can drive both enrichment and guilt by association results on their own (Gillis and Pavlidis 2011). A network calibrated with pathway databases, as STRING partly is, cannot provide independent evidence for the same pathways.

Over-representation analysis and GSEA treat a pathway as an unordered set of genes. **Topology-based pathway analysis** also uses the directed, signed edges of a signalling pathway. SPIA, for example, combines the usual enrichment p-value with a perturbation score that propagates the measured changes along the pathway, so that a change in an upstream receptor counts for more than a change in a peripheral gene (Tarca et al. 2008).

Network enrichment analysis goes further. It asks whether the genes in a list have more links to the genes of a pathway, in a functional association network such as FunCoup, than expected by chance. A pathway can then be detected even if few of the query genes are annotated to it, which helps when annotations are incomplete. The null model is essential: hubs link to everything, and large pathways receive many links by chance, so the expected number of links is estimated from randomised networks that preserve the degree of each node (Alexeyenko et al. 2012), or with a binomial model of link counts, as in BinoX (Ogris et al. 2016). ANUBIX samples random gene sets against the intact pathway rather than treating pathways as random gene sets, which removes a bias towards particular pathways (Castresana-Aguirre and Sonnhammer 2020), and is available with other methods in the PathBIX web server (Castresana-Aguirre et al. 2021). In a benchmark that used related KEGG pathways as a gold standard for 82 disease expression data sets, network enrichment methods performed best, and most methods gave skewed p-values on randomised data (Buzzao, Castresana-Aguirre, et al. 2024); the benchmark came from the group that developed several of these methods. The same idea is used to prioritise genes: MaxLink ranks candidate genes by how many links they have to a seed set of known disease genes, compared with what their degree would predict (Guala et al. 2014).

Overlap-based and network-based methods answer different questions and can legitimately disagree. Network methods inherit the incompleteness and study bias of the network (Section 11.2), and are not automatically better.

11.3.5 Disease networks and network medicine

Genes associated with the same disease tend to interact with each other or lie close together in the network. A network of human diseases, connected when they share associated genes, showed that disease genes form clusters (Goh et al. 2007). **Network medicine** uses this to find new disease genes, to relate diseases to each other and to find drug targets (Barabási et al. 2010). Diseases correspond to network neighbourhoods (*disease modules*), and diseases whose modules overlap tend to share clinical features and comorbidities (Menche et al. 2015). Candidate genes from genetic studies are prioritised by their network proximity to known disease genes, for example with **random walks** or **network propagation**, in which signal diffuses from known genes through the network and nodes that receive much of it are ranked highly (Köhler et al. 2008; Vanunu et al. 2010). In a random walk with restart, a probability vector over the nodes is updated as $\mathbf{p}_{t+1} = (1-r)W\mathbf{p}_t + r\mathbf{p}_0$, where W is the column-normalised adjacency matrix, $\mathbf{p}_0$ puts all probability on the known (seed) genes and r is the probability of jumping back to them; the steady-state $\mathbf{p}$ ranks the candidates. Such methods are evaluated by hiding some of the known genes and testing whether they are ranked highly, which is only fair if the network was not itself built from the same disease annotations. A related idea is to look for *active subnetworks*, connected regions of the network in which many genes change in an experiment (Ideker et al. 2002). A network of genes in *C. elegans* could predict the phenotypes of perturbations (Lee et al. 2008).

11.3.6 Systems biology and metabolic modelling

Systems biology aims to understand how the behaviour of a system emerges from its components and their interactions, by combining large-scale measurements, perturbations and quantitative models (Kitano 2002; Ideker et al. 2001). Models range from qualitative networks to systems of ordinary differential equations describing the kinetics of each reaction, which require parameters that are rarely known.

Metabolism is the best-mapped network in the cell. You should know its outline: **glycolysis** breaks glucose down to pyruvate, the **citric acid cycle** oxidises acetyl-CoA to CO_2 and produces reduced electron carriers (NADH, $FADH_2$), and **oxidative phosphorylation** in mitochondria uses them to pump protons across the inner membrane and drive ATP synthase. **ATP** is the energy currency that couples energy-releasing to energy-consuming reactions. Biosynthetic pathways branch from these central routes. Pathways are described in databases such as KEGG and Reactome (Section 2.6), and can be reconstructed for any sequenced genome by orthology.

For metabolism, **constraint-based modelling** avoids the need for kinetic parameters. A **genome-scale metabolic model** lists all reactions encoded in a genome, with their stoichiometry, collected in a matrix S (metabolites × reactions) (Thiele and Palsson 2010). **Flux balance analysis** (FBA) assumes a steady state, in which each metabolite is produced and consumed at equal rates, $S\mathbf{v} = 0$, where $\mathbf{v}$ is the vector of reaction fluxes. Fluxes are bounded by enzyme capacities and nutrient uptake, $\mathbf{v}_{\min} \le \mathbf{v} \le \mathbf{v}_{\max}$, and among all feasible flux distributions, linear programming finds the one that maximises an objective, usually the production of biomass (growth) (Orth et al. 2010). FBA predicted the growth of *E. coli* on different substrates and the effects of gene deletions (Edwards and Palsson 2000), and *E. coli* evolved in the laboratory towards the optimal growth rates predicted by FBA (Ibarra et al. 2002). Human metabolic models, such as Recon3D (Brunk et al. 2018) and Human-GEM from Chalmers in Gothenburg (Robinson et al. 2020), are used to study metabolic diseases and cancer metabolism, often after tailoring the model to a cell type with expression data.

11.3.7 Dynamic models of regulatory and signalling networks

Flux balance analysis describes a steady state and needs no kinetic parameters, but it cannot say how a system changes in time, or why it switches, oscillates or adapts. **Kinetic models** describe the concentration of each species with ordinary differential equations (ODEs). Under **mass action**, the rate of a reaction is proportional to the product of the concentrations of the reactants: for $A + B \rightarrow C$ with rate constant k, $d[C]/dt = k[A][B]$. For an enzyme-catalysed reaction in which the enzyme is much less abundant than the substrate, **Michaelis–Menten** kinetics gives the rate $v = V_{\max}[S]/(K_M + [S])$, which is linear at low substrate concentration and saturates at high concentration. Cooperative binding, as in gene regulation by multimeric transcription factors, is often described by a Hill function, $[X]^n/(K^n + [X]^n)$, which becomes switch-like as n increases.

The behaviour of such models depends on the structure of the network more than on the exact parameters:

- **Network motifs.** The *feed-forward loop*, in which X regulates Y and both regulate Z, is over-represented in the transcriptional networks of *E. coli* and yeast (Shen-Orr et al. 2002; Milo et al. 2002). In its coherent form, with an AND gate at Z, it responds only to a persistent signal in X and filters out brief fluctuations; in its incoherent form it can produce a pulse and speed up responses (Mangan and Alon 2003; Alon 2007).
- **Negative feedback** stabilises a level and speeds up the response, but with a delay, or several steps around the loop, it produces **oscillations**. The *repressilator*, three repressors that repress each other in a cycle, was built in *E. coli* and oscillated (Elowitz and Leibler 2000).
- **Positive feedback**, or two mutual repressors, can create **bistability**: two stable states, with the system staying in one until a large enough signal flips it, which gives memory and all-or-none cell fate decisions. A synthetic *toggle switch* demonstrated this (Gardner et al. 2000). Such small circuits have been classified by the behaviours they can produce (Tyson et al. 2003).

Biological networks are also **robust**: some properties are insensitive to large changes in parameters. In bacterial chemotaxis, precise adaptation to a constant stimulus follows from the structure of the network, not from fine-tuned rate constants (Barkai and Leibler 1997; Alon et al. 1999). Robustness arises from feedback, from **redundancy** (as in the buffering genetic interactions of Section 11.2) and from **modularity**, the organisation of the cell into semi-independent functional units (Hartwell et al. 1999; Kitano 2004). It has a cost: a system robust to common perturbations can be fragile to rare ones.

The practical difficulty is **parameter estimation**. Most rate constants are unknown and are fitted to time-course data, typically by minimising the squared difference between simulated and measured concentrations. A parameter is *structurally non-identifiable* when different values give exactly the same output for the observed species, and *practically non-identifiable* when the data are too few or too noisy to pin it down (Raue et al. 2009). Typical models are "sloppy": predictions depend on a few combinations of parameters, while most individual parameters are poorly determined (Gutenkunst et al. 2007). Useful predictions can still be made, but fitted values should not be read as measurements, and models with many parameters relative to the data should be treated with caution, as in any fitting problem (4).

ODEs describe average concentrations and are **deterministic**. When molecules are few, as for a gene present in one or two copies and its mRNA, random timing of individual reactions matters: genetically identical cells in the same environment differ in expression (Elowitz et al. 2002). **Stochastic models** are simulated with the Gillespie algorithm, which draws the time and identity of the next reaction from their exact probabilities (Gillespie 1977). Noise can also be useful, for example to make some cells in a population switch state.

Models are exchanged in the **Systems Biology Markup Language** (SBML), an XML format that describes species, reactions, rate laws and parameters, so that a model can be simulated by different software (Hucka et al. 2003). **BioModels** collects published models in SBML, many curated so that they

reproduce the results in the original paper (Malik-Sheriff et al. 2019). Compared with constraint-based models, kinetic models are much smaller (usually tens of species rather than thousands of reactions), but they describe dynamics, regulation and responses to signals that a steady-state flux analysis cannot.

11.4 Prediction methods

Computational methods address two related questions: **which** proteins interact, and **how**, that is, the structure of the complex. Until recently these were separate fields, using genomic and evolutionary signals for the first question and docking for the second. Deep learning has merged them: methods such as AlphaFold now predict whether two proteins interact by predicting the structure of their complex.

11.4.1 Interfaces

Protein–protein interfaces were characterised from the first structures of complexes (Chothia and Janin 1975; Jones and Thornton 1996). Stable interfaces typically bury 1,200–2,000 Å² of surface, are more hydrophobic than the rest of the surface, and are closely packed. Transient interfaces are smaller and more polar. The binding energy is not spread evenly: a few **hot-spot** residues, often tryptophan, arginine and tyrosine at the centre of the interface, contribute most of it, as shown by alanine scanning (Bogan and Thorn 1998). Interface residues are more conserved than the rest of the surface, although less than the core, and this conservation is one signal used to predict interfaces.

Not all association happens through a single, well-defined interface. **Biomolecular condensates**, such as nucleoli and stress granules, are membrane-less compartments that form by phase separation, driven by many weak, *multivalent* interactions, for example between intrinsically disordered regions or between repeated domains and the short motifs they bind. Such collective assemblies are not well described by a set of binary edges in a network or by one predicted complex structure (Banani et al. 2017).

11.4.2 Genomic context

The genomic-context methods of Section 10.4, gene fusion, conserved gene neighbourhood and phylogenetic profiles, predict **functional links**, which are often, but not always, physical interactions. They are cheap, work best in prokaryotes, and are a main source of evidence in STRING (Section 11.3).

11.4.3 Coevolution between proteins

The coevolution methods used for structure prediction (Section 9.8) can also be applied to two proteins. If residues in one protein contact residues in another, mutations at the interface should be correlated across species. This requires a **paired** (concatenated) multiple sequence alignment, in which each row contains the sequences of the two proteins from the same species, and in which the two sequences actually interact. Pairing is easy for proteins encoded next to each other in bacterial operons, but hard when there are several paralogues in each genome, since it is not known which copy interacts with which.

- Correlated mutations between interacting proteins were exploited with Bayesian methods to pair interaction partners among paralogues (Burger and Nimwegen 2008). Pairing can be inferred iteratively, by choosing the pairing that maximises coevolution (Bitbol et al. 2016).
- Direct-coupling analysis of paired alignments predicted residue contacts across interfaces accurately enough to model complexes, in bacteria (Ovchinnikov et al. 2014; Hopf et al. 2014).
- Proteome-wide coevolution screens identified new interactions in bacteria (Cong et al. 2019; Green et al. 2021) and, combined with deep learning, structures of core eukaryotic complexes in yeast (Humphreys et al. 2021).

Coevolution signals are weak for interactions that are not conserved over long evolutionary distances, such as those between host and pathogen proteins and between antibodies and antigens, and for eukaryotic proteins with few homologues.

11.4.4 Docking

Protein–protein docking predicts the structure of a complex from the structures of its components. Rigid-body docking searches all relative rotations and translations of the two proteins and scores surface complementarity. The fast Fourier transform made an exhaustive search of translations efficient (Katchalski-Katzir et al. 1992), and is used by programs such as ZDOCK (Pierce et al. 2014) and ClusPro (Kozakov et al. 2017). The top-scoring poses are then refined, for example with RosettaDock, which optimises the rigid-body position and side chains together (Gray et al. 2003). HADDOCK uses experimental information, such as mutagenesis, NMR or cross-linking data, as restraints to guide docking (Dominguez et al. 2003).

Docking has been assessed in the blind **CAPRI** experiment since 2001 (Janin et al. 2003), with models scored by the fraction of native contacts and the interface and ligand RMSD, combined in the DockQ score (Basu and Wallner 2016) (Section 9.2). Rigid docking works when the unbound structures are similar to the bound ones, but fails when binding involves large conformational changes, and scoring functions struggle to pick the correct pose among many decoys.

11.4.5 Deep learning: AlphaFold for complexes

Soon after AlphaFold2 was released, it turned out that it could predict complexes when two sequences were joined with a linker, using paired alignments. Two developments followed in 2021–2022:

- **AlphaFold-Multimer** was trained specifically on complexes. Its confidence score for interfaces, **ipTM**, measures how reliable the predicted relative positions of the chains are (Evans et al. 2021).
- **FoldDock** evaluated AlphaFold2 on heterodimers, and introduced **pDockQ**, a score based on the number of interface contacts and their pLDDT, which predicts the DockQ of a model and separates interacting from non-interacting pairs (Bryant, Pozzati, and Elofsson 2022). Combining folding and docking in one step was shown to outperform docking of separately predicted structures (Pozzati et al. 2021).

Since then, confidence scores of predicted complexes have been used to **screen for interactions at proteome scale**: more than eight million pairs of yeast proteins were screened with coevolution and deep learning (Humphreys et al. 2021), tens of thousands of human pairs from interaction databases were modelled (Burke et al. 2023), and proteins of human pathogens have been screened in the same way (Humphreys et al. 2024). Large complexes that are too big to predict at once can be assembled from predicted subcomplexes, for example with Monte Carlo tree search (Bryant, Pozzati, Zhu, et al. 2022). AlphaFold3 and the open co-folding models extend this to complexes with nucleic acids and ligands (Section 9.8).

11.4.6 Evaluation and limitations

Evaluating predicted interactions is difficult, because negative examples (pairs known *not* to interact) are rarely available. That an interaction was not detected does not make a pair a true negative, unless the assay was able to detect that pair under the relevant conditions: the proteins may not have been expressed, may have been in the wrong compartment, or the interaction may be too weak or transient for the method. Random protein pairs are therefore used as a proxy, but they are unrealistically easy negatives, since they often come from different compartments or processes, and they inflate the apparent performance (Park and Marcotte 2012). Performance is also inflated when the same proteins, or close homologues of them, occur in both training and test pairs, because a method can then learn which proteins interact often rather than which pairs interact; see 4 for this kind of data leakage and how to split data to avoid it (Bernett et al. 2024).

Since only a small fraction of all possible pairs interact, even a method with a low false-positive rate gives many false positives in a proteome-wide screen, so precision at the top of the ranking matters more than overall accuracy. A high-confidence predicted interface is not proof of a biological interaction either. Co-folding methods can produce plausible, confident interfaces for proteins that never meet in the cell, for example because they are expressed in different cell types or compartments, or for paralogues of the true partner. Predicted interactions should therefore be evaluated with appropriate negatives and controls, and interpreted together with biological context such as expression and localisation. AlphaFold-based methods work well for stable, obligate complexes with coevolution between the partners, and much less well for antibody–antigen and other non-conserved interactions, for transient interactions mediated by short linear motifs in disordered regions, and for large flexible assemblies (Zhu et al. 2023). Predicted interactions remain hypotheses, but with a structural model and a confidence score they are much easier to test than earlier predictions.

11.5 Key concepts

A checklist for revision.

- **Kinds of interaction:** physical binding, co-complex membership, genetic interaction, regulatory influence and functional association are not interchangeable

- **Yeast two-hybrid:** principle; binary interactions (enriched for direct contacts, but not proof of them); proteome-scale screens in yeast and human; HuRI; precision vs. sensitivity; biases (nucleus, membrane proteins, auto-activation); split-ubiquitin and PCA
- **AP-MS:** TAP tags; co-complex membership (vs. binary Y2H); spoke vs. matrix models; contaminants; BioPlex; co-fractionation, proximity labelling and cross-linking MS (residue-level distance restraints); hu.MAP
- **Binding and validation:** $K_d = k_{\text{off}}/k_{\text{on}}$ and fraction bound; SPR, BLI and ITC; FRET ($E = 1/(1 + (r/R_0)^6)$) and BRET; proximity labelling windows (BioID, TurboID, APEX); orthogonal validation with different failure modes; interface mutants and rescue
- **Quality of interaction data:** low overlap and what it means; literature and study bias; context dependence (no single fixed interactome); affinity (K_d), kinetics and stoichiometry hidden by binary edges
- **Genetic interactions:** synthetic lethality; the multiplicative null model and $\varepsilon_{AB} = w_{AB} - w_A w_B$; aggravating vs. alleviating interactions; genetic interaction profiles; the yeast genetic interaction map
- **Gene regulatory networks:** directed, signed edges; correlation and mutual information (ARACNE); GENIE3; inference from perturbations; Perturb-seq; DREAM and the wisdom of crowds
- **Network concepts:** degree distribution; random vs. scale-free networks and preferential attachment; small worlds and clustering coefficient ($C_i = 2e_i/[k_i(k_i - 1)]$); betweenness centrality; modularity; modules and community detection (Girvan–Newman, MCL); motifs
- **Hubs:** centrality–lethality; party and date hubs; degree correlations; critiques (sampling, study bias, alternative heavy-tailed distributions, "scale-free networks are rare"); correlation, not causation
- **Functional association networks:** types of evidence; gold standards; likelihood ratios and naive Bayesian integration; FunCoup and STRING; combining channel scores ($1 - \prod_i (1 - s_i)$); links mean "work together"
- **Pathway and network enrichment:** gene sets from GO, KEGG and Reactome; ORA and GSEA (Section 7.5); dependence in the GO graph (topGO elim/weight, parent–child); multiple testing of overlapping sets; annotation bias and circularity; topology-based pathway analysis (SPIA); network enrichment and crosstalk (NEA, BinoX, ANUBIX, PathBIX) with degree-aware null models; MaxLink
- **Network medicine:** the human disease network; disease modules; random walks with restart and network propagation for gene prioritisation, and how to evaluate them; active subnetworks
- **Systems biology:** metabolism in outline (glycolysis, citric acid cycle, oxidative phosphorylation, ATP); kinetic vs. constraint-based models; genome-scale metabolic models; flux balance analysis ($S\mathbf{v} = 0$, bounds, linear programming, biomass objective); Recon3D and Human-GEM
- **Dynamic models:** ODE models with mass action, Michaelis–Menten ($v = V_{\max}[S]/(K_M + [S])$) and Hill kinetics; coherent and incoherent feed-forward loops (persistence detection, pulses); negative feedback and oscillations (the repressilator); positive feedback and bistability (the toggle switch); robustness (chemotaxis adaptation), redundancy and modularity; parameter fitting, structural vs. practical identifiability and sloppiness; deterministic vs. stochastic models and the Gillespie algorithm; SBML and BioModels; kinetic vs. constraint-based models
- **Interfaces:** size, composition and hot spots; condensates and multivalent association
- **Coevolution between proteins:** paired alignments and the pairing problem; DCA across interfaces; proteome-wide screens
- **Docking:** FFT-based rigid-body search; refinement; restraint-driven docking (HADDOCK); CAPRI and DockQ; conformational change
- **Deep learning:** AlphaFold-Multimer and ipTM; FoldDock and pDockQ; proteome-scale screening; assembling large complexes; limitations (antibodies, transient and motif-mediated interactions); a confident interface is not proof of interaction; evaluation without true negatives (undetected ≠

negative; random pairs are easy negatives; shared proteins and homologues between training and test)

11.7 Background reading (open access)

- **Protein–protein interaction (Wikipedia)** — Protein–protein interactions (PPIs) are physical contacts of high specificity established between two or more protein molecules as a result of biochemical events steered by interactions that include electrostatic forces, hydrogen bonding and the hydrophobic effect.
  https://en.wikipedia.org/wiki/Protein%E2%80%93protein_interaction
- **Two-hybrid screening (Wikipedia)** — Two-hybrid screening is a molecular biology technique used to discover protein–protein interactions (PPIs) and protein–DNA interactions by testing for physical interactions between two proteins or a single protein and a DNA molecule, respectively.
  https://en.wikipedia.org/wiki/Two-hybrid_screening
- **Interactome (Wikipedia)** — In molecular biology, an interactome is the whole set of molecular interactions in a particular cell. The term specifically refers to physical interactions among molecules but can also describe sets of indirect interactions among genes.
  https://en.wikipedia.org/wiki/Interactome
- **Biological network (Wikipedia)** — A biological network is a method of representing systems as complex sets of binary interactions or relations between various biological entities. In general, networks or graphs are used to capture relationships between entities or objects.
  https://en.wikipedia.org/wiki/Biological_network
- **Clustering coefficient (Wikipedia)** — In graph theory, a clustering coefficient is a measure of the degree to which nodes in a graph tend to cluster together.
  https://en.wikipedia.org/wiki/Clustering_coefficient
- **Scale-free network (Wikipedia)** — A scale-free network is a network whose degree distribution follows a power law, at least asymptotically. That is, the fraction P(k) of nodes in the network having k connections to other nodes goes for large values of k as
  https://en.wikipedia.org/wiki/Scale-free_network
- **Gene regulatory network (Wikipedia)** — A gene regulatory network (GRN) is a collection of molecular regulators that interact with each other and with other substances in the cell to govern the gene expression levels of mRNA and proteins which, in turn, determine the function of the

cell.
https://en.wikipedia.org/wiki/Gene_regulatory_network

- **Network medicine (Wikipedia)** — Network medicine is the application of network science towards identifying, preventing, and treating diseases. This field focuses on using network topology and network dynamics towards identifying diseases and developing medical drugs.
https://en.wikipedia.org/wiki/Network_medicine
- **Systems biology (Wikipedia)** — Systems biology is the computational and mathematical analysis and modeling of complex biological systems. It is a biology-based interdisciplinary field of study that focuses on complex interactions within biological systems, using a holistic approach to biological research.
https://en.wikipedia.org/wiki/Systems_biology
- **Flux balance analysis (Wikipedia)** — In biochemistry and systems biology, flux balance analysis (FBA) is a mathematical method for simulating the metabolism of cells or entire unicellular organisms, such as E. coli or yeast, using genome-scale reconstructions of metabolic networks.

11.8 Student recommendations

Recommended by students preparing for the exam: papers, reviews, online lectures, tutorials and short explanations. To suggest something, use the suggestion form (SU login).

No recommendations yet.

11.9 Review problems

These problems are adapted from Matteo Tadiello, *Modern Bioinformatics: From Foundations to Frontiers* (CC BY 4.0), used with permission. For a longer treatment of this topic, see the chapters "Molecular Interactions: Experiments, Structures, and Networks" and "Networks, Pathways, and Enrichment" of that book. In the HTML version, click a box to show the extensions, solution outline and common errors.

11.9.1 Define the biological relation

An interaction database contains an edge between proteins A and B. What can and cannot be inferred from this edge before the underlying publication is consulted?

Extensions, solution outline and common errors

Extensions:

1. Distinguish direct contact, co-complex membership, spatial proximity, genetic interaction and functional association.
2. Which metadata are needed to interpret the edge?
3. How would the conclusion change if A and B were specific isoforms or modified forms?

Solution outline:

1. The edge alone establishes only that the database records some relation between two

identifiers.
2. Recover the molecular forms, organism, cell type, compartment, perturbation, time, detection method, confidence and publication. Curated databases such as IntAct record these in the PSI-MI standard (Section 2.7).
3. Direct binding requires evidence that excludes an unobserved bridging protein; co-complex evidence (AP-MS) allows one. Proximity records presence within an assay-specific distance and time window. A genetic interaction is a deviation of a double-mutant phenotype from a null model, and functional association may come from co-expression, pathway membership, genomic neighbourhood or the literature.
4. Several databases may repeat the same source, and are then not independent evidence.

Common errors:

- Treating every edge as direct physical binding.
- Interpreting colocalisation as molecular contact.
- Ignoring isoforms, modifications, compartment and the experimental host.
- Treating the absence of an edge as evidence of non-interaction.

Connections: Section 11.2 and Figure 11.1; interaction databases in Section 2.7; functional association networks in Section 11.3.

11.9.2 Evaluate a yeast two-hybrid result

Design a yeast two-hybrid experiment for proteins A and B, and state the strongest conclusion supported by a positive reporter signal.

Extensions, solution outline and common errors

Extensions:

1. Explain bait auto-activation and the effects of fusion orientation.
2. Identify important causes of false negatives.
3. Propose an orthogonal validation strategy.

Solution outline:

1. Fuse A to the DNA-binding domain and B to the activation domain of a transcription factor; association of the fusions reconstitutes reporter transcription, as in the original Gal4 system (Fields and Song 1989).
2. Controls: empty vectors, unrelated proteins, auto-activation tests, expression measurements, sequencing of constructs, several reporters, reciprocal orientations and independent transformants.
3. A positive result supports association of the two fusion proteins in the yeast nucleus. It does not establish direct binding in the native context: a yeast protein may bridge them, and the fusion geometry, location or expression level may create the signal.
4. Negative results can come from misfolding, toxicity, missing modifications, membrane topology or a hidden binding site.
5. Validate with a method based on a different physical principle, for example co-immunoprecipitation of the endogenous proteins and, if direct binding is the claim, binding of the purified proteins.

Common errors:

- Describing Y2H as an in vitro assay.
- Omitting auto-activation and expression controls.
- Equating a negative result with biological absence.
- Calling a closely related complementation assay an orthogonal validation.

Connections: Section 11.2; sensitivity, precision and missing data in 4.

11.9.3 Infer co-complex membership from AP-MS

Protein B is identified by mass spectrometry after affinity purification of protein A. Formulate a statistical and experimental analysis that distinguishes bait-specific enrichment from background.

Extensions, solution outline and common errors

Extensions:

1. Define suitable biological and process controls.
2. What does a SAINT score represent?
3. Does reciprocal co-immunoprecipitation prove direct contact?

Solution outline:

1. The observation makes B a candidate co-complex member.
2. Compare normalised prey abundance with matched controls (untagged cells, tag only, an irrelevant bait or a knockout) across independent biological preparations, and record bait recovery, tag position, buffer and batch.
3. SAINT estimates the probability of a true interaction from the abundance distributions in bait and control purifications (Choi et al. 2010); the CRAPome lists recurrent contaminants but cannot replace matched controls (Mellacheruvu et al. 2013).
4. Lysis may destroy weak associations or let proteins from different compartments meet.
5. Reciprocal capture strengthens the evidence for co-complex membership, but a third protein may still bridge A and B.

Common errors:

- Accepting one peptide or one purification as sufficient evidence.
- Treating repeated injections as biological replicates.
- Using controls made with different tags, buffers or cells without qualification.
- Expanding every bait–prey result into all prey–prey contacts (the matrix model).

Connections: Section 11.2; interaction proteomics and scoring in Section 8.5; peptide identification in Section 8.3.

11.9.4 Interpret proximity labelling

Compare TurboID, APEX and AP-MS for identifying the proteins associated with a membrane receptor after stimulation.

Extensions, solution outline and common errors

Extensions:

1. How do the labelling window and the orientation of the enzyme affect the result?
2. Design controls that separate receptor-specific proximity from compartmental background.
3. Propose validation for a low-abundance candidate.

Solution outline:

1. TurboID (a biotin ligase) and APEX (a peroxidase) label proteins covalently in living cells before lysis, so weak, transient, insoluble or membrane-proximal neighbours can be recovered after stringent extraction (Branon et al. 2018; Rhee et al. 2013). AP-MS recovers only complexes that survive lysis.
2. The result is a proximity proteome integrated over the labelling window (minutes for TurboID and APEX, hours for BioID), not a list of binders (Roux et al. 2012). Labelling depends on accessible residues, enzyme orientation, residence time and abundance.
3. Controls: the enzyme alone targeted to the same compartment, omission of substrate or peroxide, unstimulated cells, and tests that the fusion keeps the receptor's localisation and function.
4. Validate candidates with an orthogonal live-cell or endogenous capture method and, for direct binding, with purified proteins or interface mutations.

Common errors:

- Assuming one universal labelling radius.
- Calling every enriched protein a direct interactor.
- Ignoring abundant bystanders in the same compartment and global changes in abundance.

Connections: Section 11.2; proximity labelling and quantitative proteomics in Section 8.5; localisation in 3.

11.9.5 Distinguish proximity from binding with FRET

A FRET signal increases after ligand stimulation. Give the relevant relationship, and state the biological interpretations compatible with the observation.

Extensions, solution outline and common errors

Extensions:

1. What are the roles of donor–acceptor orientation and the Förster distance?
2. Compare FRET with BRET.
3. Design controls for crowding, expression level and conformational change.

Solution outline:

1. The efficiency is $E = 1/[1 + (r/R_0)^6]$, where r is the donor–acceptor distance and R_0 the distance at which $E = 0.5$ (Stryer and Haugland 1967).
2. The increase shows a change in the proximity or orientation of the fluorophores, or in the populations of states. It does not distinguish direct binding from crowding, recruitment to a larger complex, or a conformational change within one protein.

3. BRET uses a luciferase as donor, avoiding excitation light and autofluorescence.
4. Controls: donor-only and acceptor-only samples, spectral correction or lifetime measurements, titration of expression and acceptor saturation, non-binding proteins in the same compartment, tag swaps, and interface mutants that remain folded.

Common errors:

- Treating FRET as an exact distance measurement.
- Concluding that the absence of FRET excludes binding.
- Using a single overexpression level without testing for saturation.

Connections: Section 11.2; conformational ensembles in Section 9.11.

11.9.6 Use cross-linking MS as a structural restraint

Explain how cross-linking mass spectrometry constrains the structure of a protein complex, and why the cross-linker is not an exact molecular ruler.

Extensions, solution outline and common errors

Extensions:

1. Why is the identification of cross-linked peptide pairs harder than ordinary peptide identification?
2. How can cross-links be combined with docking or integrative modelling?

Solution outline:

1. A chemical cross-linker covalently connects reactive side chains that are close in the sample; after digestion and tandem MS, linked peptide pairs are identified and mapped to residues (O'Reilly and Rappsilber 2018).
2. With n candidate peptides there are of the order of n^2 possible pairs, so the search space is much larger and false discoveries must be controlled carefully.
3. A cross-link is compatible with a range of distances (up to about 30 Å between Cα atoms for common reagents), depending on spacer length, side chains, flexibility and conformational state.
4. Consistent cross-links can filter docking poses or act as restraints in docking (HADDOCK, Section 11.4) and integrative modelling (Section 9.4), but alternative stoichiometries and conformations must be tested.
5. A missing cross-link is weak negative evidence, since reactive residues and detectable peptides are unevenly distributed.

Common errors:

- Using the nominal spacer length as an exact distance cutoff.
- Ignoring aggregation and mixtures of states.
- Choosing one structural model without testing alternatives.

Connections: Section 11.2 and Section 11.4; XL-MS in Section 8.5; integrative structures in Section 9.4.

11.9.7 Evaluate a predicted complex

An AlphaFold-class model predicts a high-confidence interface between A and B. Design an evaluation that separates structural plausibility from evidence that the proteins associate in the cell.

Extensions, solution outline and common errors

Extensions:

1. Which confidence and physical-quality measures should be inspected?
2. Design biologically realistic negative controls.
3. How would you benchmark a learned interaction predictor without homology leakage?

Solution outline:

1. The model is a structural hypothesis conditional on having submitted both partners. Inspect ipTM, inter-chain PAE, interface pLDDT or pDockQ, clashes, buried chemistry, conservation, repeated seeds and alternative stoichiometries.
2. Compare with non-partners matched for localisation and size, competing paralogues, and known positive and tested negative pairs. A co-folding score is not a dissociation constant.
3. Coevolution between the chains supports a contact only if orthologues and paralogues are paired correctly and the alignment is deep enough.
4. Benchmarks should separate homologous families, complexes or time periods between training and test sets; random splits of pairs leak information through shared proteins. Unreported pairs are unknown, not verified negatives (Park and Marcotte 2012; Bernett et al. 2024).

Common errors:

- Reading confidence as interaction probability or affinity.
- Evaluating only on known positive complexes.
- Ignoring incompatible compartments and competing partners.

Connections: Section 11.4; AlphaFold in Section 9.8; leakage and calibration in 4.

11.9.8 Analyse physical and genetic networks without mixing their meaning

A protein has the highest degree in an integrated interaction network, and a pair of genes shows a strongly negative genetic interaction. What do these observations imply, and how should they be validated?

Extensions, solution outline and common errors

Extensions:

1. Define degree, betweenness, modularity and the multiplicative genetic-interaction score.
2. Explain study bias, spoke and matrix expansion, and unequal detectability.
3. Design an analysis comparing the network before and after stimulation.

Solution outline:

1. Degree $k_i = \sum_j A_{ij}$ is observed connectivity in one graph; betweenness counts shortest paths

through a node; modularity compares edges within modules with a degree-preserving null. These describe the graph, not binding, causal control or essentiality.
2. Abundant, easily studied and well-known proteins are tested more often; matrix expansion of AP-MS data adds prey–prey edges that need not be contacts. Both inflate degree.
3. For fitness values, $\varepsilon_{AB} = w_{AB} - w_A w_B$; a negative value means a double-mutant phenotype more severe than the multiplicative expectation, often for genes in parallel pathways, not protein binding (Costanzo et al. 2016).
4. Comparisons between conditions should model quantitative evidence and account for bait and prey abundance, batch and missing values, rather than subtract thresholded edge lists.
5. Validate genetic interactions by reconstructing the double mutant; physical mechanisms need independent molecular measurements.

Common errors:

- Mixing direct, co-complex, proximity, genetic and functional edges without labels.
- Treating centrality as indispensability (the centrality–lethality debate).
- Interpreting a network module as a biochemical complex without validation.

Connections: Section 11.3 and Section 11.2; graph null models in 4.

11.9.9 When is a network a biological model?

Compare the meaning of a co-expression network, a protein interaction network, a pathway graph and a metabolic network. When does each support mechanistic inference, and how does pathway enrichment differ from a model?

Extensions, solution outline and common errors

Extensions:

- What does an edge mean in each network?
- Why can hub genes be artefacts?
- How does network enrichment analysis differ from over-representation analysis, and why does it need a degree-preserving null model?
- Explain flux balance analysis.

Solution outline:

1. For each network, define the nodes, the meaning of the edges, their direction, confidence, context and provenance: statistical dependence, physical evidence, curated reactions, or stoichiometric participation.
2. Well-studied genes receive more annotations and edges, which creates hubs and biases enrichment.
3. Over-representation analysis tests the overlap of a gene list with a gene set against a background; network enrichment tests whether the list has more links to the set than expected in randomised networks with the same degrees, which prevents hubs and large pathways from appearing significant by chance.
4. Enrichment summarises a list against prior knowledge; a model predicts states or fluxes. Flux balance analysis maximises an objective $\mathbf{c}^T\mathbf{v}$ subject to $S\mathbf{v} = 0$ and flux bounds; the objective and the reconstruction are assumptions.
5. Validate network conclusions with degree-preserving null models, sensitivity to the database and release, and experiments appropriate to the claim.

Common errors:

- Calling a correlation a physical interaction or regulation.
- Assuming that pathway boundaries are unique or complete.
- Saying that FBA measures fluxes or proves that cells maximise growth.
- Testing against a random graph that does not preserve degrees.

Connections: Section 11.3 (network concepts, pathway and network enrichment, metabolic modelling); over-representation analysis and GSEA in Section 7.5; graph neural networks in Section 12.4.

11.9.10 Building a kinetic model of a feedback loop

A transcription factor X represses its own gene. A time course after induction shows that X rises, overshoots and then settles at a steady level. Write a simple ODE model, explain which feature produces the overshoot, and discuss how you would fit and test it.

Extensions, solution outline and common errors

Extensions:

- How would the behaviour change if X activated its own gene instead?
- Which parameters do you expect to be identifiable from measurements of X alone?

Solution outline:

1. A minimal model: $dm/dt = \alpha/(1 + (X/K)^n) - \delta_m m$ for the mRNA and $dX/dt = \beta m - \delta_X X$ for the protein, with a Hill function for repression.
2. Negative autoregulation speeds up the approach to steady state and reduces its variability. The overshoot arises from the delay between transcription and the accumulation of protein: the repression acts on mRNA that is already made. A steep Hill function (large n) and long delays push the system towards damped or sustained oscillations.
3. Fit the parameters by least squares to the time course, ideally with several perturbations (induction strengths, mutants). Examine identifiability with profile likelihoods: with only protein measurements, the synthesis rates and K may be confounded, so only combinations of them are determined.
4. Test the model on a prediction it was not fitted to, such as the response of a mutant with a weakened binding site.
5. Positive autoregulation with a steep Hill function can instead give bistability: two stable levels and memory of past induction.
6. If X is present in few molecules, a stochastic simulation (Gillespie) shows cell-to-cell variation that the ODE averages away.

Common errors:

- Interpreting fitted parameters as measured rate constants.
- Concluding from a good fit that the model structure is correct.
- Forgetting that the deterministic model describes a population average.

Connections: Section 11.3 (dynamic models, systems biology); gene regulatory networks in Section 11.2; model fitting and overfitting in 4.

12 Machine learning

> **From the exam description**
>
> Fundamental knowledge about machine learning. How machine learning is used in bioinformatics. Recent progress in machine learning methodologies.

12.1 Overview

Machine learning is now part of almost every area of bioinformatics, and recent progress in deep learning has changed several of them completely. This chapter cannot include everything. It covers the minimum that every bioinformatician should understand, which corresponds roughly to the course *Machine learning for bioinformatics* (KB8029), and points to the applications described in the other chapters:

- the basics: kinds of learning, linear models and regularisation, generalisation and overfitting, the pitfalls of biological data, and how to evaluate predictors (4);
- the history: the perceptron, neural networks and backpropagation, hidden Markov models, support vector machines and random forests (Section 12.3);
- deep learning: convolutional, recurrent, transformer and graph networks, language models for proteins and DNA, interpretability and reporting standards (Section 12.4);
- generative models: autoregressive models, autoencoders, GANs and diffusion (Section 12.5);
- foundation models and how to evaluate them (Section 12.6);
- AI in research practice: what large language models are, what they have achieved in biology, and how to use AI tools responsibly (Section 12.7);
- integrating data: multi-omics integration, latent factors and networks, and what integration can and cannot show about causes (Section 12.8).

Applications are found throughout the book: profile HMMs and protein language models in Chapter 1, gene finding in Chapter 5, single-cell analysis in Chapter 7, de novo peptide sequencing in Chapter 8, structure prediction and design in Chapter 9, function and variant effect prediction in Chapter 10, and image analysis and virtual cell models in Chapter 13.

12.2 Basics

Machine learning (ML) is a set of methods that learn patterns from data instead of having them programmed explicitly. Bioinformatics has used ML since the early 1980s, and it is now part of almost every area covered in this book (Tarca et al. 2007; Greener et al. 2021; Sapoval et al. 2022). This section introduces the basic concepts, and the pitfalls that are specific to biological data. It is not possible to cover the whole field here; the aim is the minimum that a bioinformatician must understand to use and evaluate ML methods.

Terminology: AI, ML, deep learning, foundation models

The terms overlap but are not synonyms.

- **Artificial intelligence (AI)** is the broad goal of machines performing tasks that are thought to require intelligence. It includes rule-based systems that do not learn from data.
- **Machine learning (ML)** is the part of AI in which a model learns its parameters from data. It includes linear and logistic regression, HMMs, SVMs and random forests.
- **Deep learning** is the part of ML that uses neural networks with many layers, which learn their own features from raw input (Section 12.4).
- **Generative AI** refers to models that generate new data, such as text, images, sequences or structures (Section 12.5). Not all generative models are deep.
- A **foundation model** is a model, usually deep and pre-trained with self-supervision on broad data, that is used for many downstream tasks (Section 12.6). The term describes how a model is used, not its size. **Large language models** (LLMs) are foundation models for text.

12.2.1 Kinds of learning

- In **supervised learning**, a model is trained on labelled examples, pairs of inputs $\mathbf{x}$ and outputs y, to predict y for new inputs. If y is a category (signal peptide or not; cell type), the task is **classification**; if it is a number (binding affinity; expression level), it is **regression**.
- In **unsupervised learning**, there are no labels. The model finds structure in the data, for example clusters or low-dimensional representations (PCA, t-SNE, UMAP; Section 7.4).
- In **self-supervised learning**, the model creates its own labels from the data, for example by hiding some residues of a protein sequence and predicting them from the rest. This makes it possible to train on hundreds of millions of unlabelled sequences, and it is the basis of language and foundation models (Section 12.6).

In all cases, a model is a function $f(\mathbf{x}; \theta)$ with parameters θ (weights), and **training** means choosing θ to minimise a **loss function** on the training data, such as the squared error for regression or the cross-entropy for classification. For most models this is done with **gradient descent**: the parameters are moved a small step against the gradient of the loss, $\theta \leftarrow \theta - \eta \nabla L$, where η is the *learning rate*, usually computed on small random batches of data (*stochastic* gradient descent) and improved with momentum-based optimisers such as Adam.

12.2.2 Linear models and regularisation

The simplest supervised models are linear, and they should be the first baseline for most problems. **Linear regression** models the outcome as a weighted sum of the features, $y = \beta_0 + \mathbf{x}^T\beta + \epsilon$, and ordinary least squares chooses the weights that minimise the squared error. **Logistic regression** models a binary outcome through its log odds,

$$\log \frac{p}{1-p} = \beta_0 + \mathbf{x}^T\beta, \qquad p = P(y = 1 \mid \mathbf{x}),$$

and is fitted by maximum likelihood, which is the same as minimising the cross-entropy loss. A coefficient β_j describes how the prediction changes with x_j when the other features in the model are held fixed; in logistic regression, e^{β_j} is an odds ratio. These are conditional associations, not causal effects, and they change if correlated features are added or removed. Linear and logistic regression are special

cases of *generalised linear models*, which also include the negative binomial models used for read counts (Section 7.4).

With many more features than examples, which is the normal situation in omics (20,000 genes and perhaps 100 patients), an unpenalised linear model fits the training data perfectly and generalises poorly. **Regularisation** adds a penalty on the size of the weights to the loss, $L(\beta) + \lambda P(\beta)$, and the strength λ is a hyperparameter:

- **L2** (*ridge*) regression uses $P = \sum_j \beta_j^2$. It shrinks all weights smoothly towards zero but rarely sets any to exactly zero, and it stabilises the fit when features are correlated by spreading the weight over them (Hoerl and Kennard 1970).
- **L1** (the *lasso*) uses $P = \sum_j |\beta_j|$. Because the penalty has corners on the axes, many weights become exactly zero, so the lasso also *selects* features and gives a sparse model (Tibshirani 1996).
- The **elastic net** combines the two penalties. It selects features like the lasso, but tends to keep or drop groups of correlated features together (Zou and Hastie 2005).

A common mistake is to reverse L1 and L2: it is L1 that gives sparse models. The penalties act on the size of the weights, so features must be put on comparable scales, for example standardised, before fitting, and λ must be chosen inside the training data, by (nested) cross-validation (below). A sparse "signature" of genes selected by the lasso is a predictive model, not a list of causal genes. When genes are correlated, as genes in the same pathway usually are, the lasso picks one of them more or less arbitrarily, and a different sample of patients can give a different signature with the same performance. The stability of the selection should therefore be checked by resampling.

12.2.3 Generalisation and overfitting

The goal of a model is not to fit the training data but to make correct predictions on new data, to **generalise**. A flexible model with many parameters can memorise its training set, including its noise, and then perform poorly on new data. This is **overfitting**. A model that is too simple cannot capture the pattern at all (*underfitting*). The balance is described by the *bias–variance trade-off* (Lever et al. 2016; Hastie et al. 2009).

Overfitting is controlled by:

- **Separate data sets.** Data are split into a **training set**, used to fit the parameters, a **validation set**, used to choose hyperparameters and compare models, and a **test set**, used once at the end to estimate performance. If the test set is used for any modelling decision (choosing features, hyperparameters, architectures or which of several models to report), it has in effect become a validation set and its estimate is optimistic. A new, untouched test set is then needed.
- **Cross-validation.** With little data, the data are divided into k parts; each part is used once for evaluation while the model is trained on the rest, and the results are averaged. If hyperparameters are also chosen by cross-validation, the error of the best setting is optimistic, because it was selected on the same data. **Nested cross-validation** avoids this: an inner loop, run only on the training part of each outer fold, selects the hyperparameters, and the outer loop estimates the performance of the whole procedure, selection included. This matters most for small data sets, where the optimism of selection can be large (Varma and Simon 2006; Hastie et al. 2009).
- **Regularisation.** Penalising large weights (L2 or *weight decay*; L1, which also drives weights to zero), stopping training when the validation error starts to increase (*early stopping*), or randomly switching off units during training (*dropout*) (Srivastava et al. 2014).
- **More data**, or data augmentation.

The same idea appears in structural biology: the free R-factor of crystallography is a held-out test set (Section 9.4).

12.2.4 Pitfalls specific to bioinformatics

Biological data violate the assumption, made by most ML methods, that examples are independent. The most important consequence is that a **random split** into training and test sets is rarely appropriate. Related examples, such as homologous proteins, samples from the same patient, cells from the same donor or experiment, or genomic windows from the same chromosome, end up on both sides of a random split, and the measured performance can be grossly overestimated. Data should instead be split by **group** (all examples from one cluster, patient, donor or chromosome go to the same subset), by **time**, or by both, so that the test set resembles the new data the method will actually be used on.

- **Homology between training and test sets.** Proteins and genes are related by evolution. If a test protein has a close homologue in the training set, the model can predict it by remembering the homologue, and the measured performance says little about new families. Data sets must therefore be **redundancy-reduced**, and split so that no test example is too similar to any training example. Hobohm and colleagues introduced algorithms for selecting representative, non-redundant protein sets (Hobohm et al. 1992), and today sequences are clustered with tools such as CD-HIT or MMseqs2 (Li and Godzik 2006; Steinegger and Söding 2018), with all members of a cluster placed in the same subset. Simple clustering can leave close homologues in different subsets, and partitioning algorithms such as GraphPart construct splits in which no test sequence is above a chosen similarity to any training sequence, while keeping the classes balanced (Teufel et al. 2023). For structure, splits by fold or by date (training on structures released before a cutoff, testing on later ones) are stricter.
- **Data leakage.** Information about the test set can leak into training in less obvious ways: through features computed from the whole data set, through normalisation, through the same patient or experiment appearing in both sets, or through benchmark data that have been used to develop earlier versions of the method. Every step that learns from the data, including normalisation, imputation, feature selection, batch correction, oversampling of the rare class and calibration, is part of the model and must be fitted on the training part of each split only. A classic example is selecting the genes most correlated with the outcome on the whole data set and then cross-validating a classifier on those genes: the estimated error can be close to zero even when the labels are random (Ambroise and McLachlan 2002). A survey of many fields found that leakage of this kind was widespread in machine-learning-based science, and that correcting it often removed the claimed advantage of complex models (Kapoor and Narayanan 2023).
- **Class imbalance.** Most biological prediction problems are imbalanced: few residues are in binding sites, few variants are pathogenic, few protein pairs interact. A classifier that always predicts the majority class can have high accuracy and be useless.
- **Biased and noisy labels.** Labels come from databases with their own biases (Section 10.7), and the negatives are often not true negatives.
- **Distribution shift.** A model can perform well on held-out data from the same source and fail when the data change: a new species, protein family, hospital, sequencing technology or laboratory protocol. Performance should therefore be reported for the kind of data the model will be applied to, and a test set from a different source (*external validation*) is the best check.
- **Prediction is not causation.** A predictor may exploit any correlation in the data, including confounders such as batch, sequencing depth or ancestry, without capturing the underlying mechanism. A gene whose expression predicts a disease need not cause it, and a feature that is important for a model is not necessarily important biologically. Establishing causes requires perturbation experiments or methods designed for causal inference, such as Mendelian randomisation. Explaining and predicting are different goals, and a model that is best for one is often not best for the other (Shmueli 2010) (Section 12.8).

12.2.5 Evaluation

For a binary classifier, predictions are summarised in a **confusion matrix** of true positives (TP), false positives (FP), true negatives (TN) and false negatives (FN). Common measures are:

Table 12.1: Measures computed from the confusion matrix.

Measure	Definition	Question it answers
Accuracy	$(TP+TN)/(TP+FP+TN+FN)$	What fraction is correct?
Sensitivity (recall)	$TP/(TP+FN)$	What fraction of the positives is found?
Specificity	$TN/(TN+FP)$	What fraction of the negatives is correctly rejected?
Precision	$TP/(TP+FP)$	What fraction of the predicted positives is correct?
F1 score	$2\cdot\text{precision}\cdot\text{recall}/(\text{precision}+\text{recall})$	Harmonic mean of precision and recall

These measures are not interchangeable. The false-positive rate ($FP/(FP+TN) = 1-$ specificity) is computed over the negatives, whereas the false discovery rate ($FP/(TP+FP) = 1-$ precision) is computed over the predictions; with many negatives, a low false-positive rate can coexist with a high false discovery rate. **Accuracy** is often misleading for biological problems, because the classes are imbalanced: if 1% of residues are in binding sites, predicting "no" everywhere is 99% accurate. Sensitivity, specificity, precision and MCC, reported together, are the core measures.

The **Matthews correlation coefficient**,

$$\text{MCC} = \frac{TP\cdot TN - FP\cdot FN}{\sqrt{(TP+FP)(TP+FN)(TN+FP)(TN+FN)}},$$

is the correlation between predicted and true labels. It ranges from -1 to 1, is 0 for random predictions, and is high only if the classifier does well on both classes, so it is more informative than accuracy or F1 for imbalanced data (Chicco and Jurman 2020). MCC was used early for secondary structure prediction.

Most classifiers output a score, and the measures above depend on the threshold. Two curves describe performance over all thresholds:

- The **ROC curve** plots sensitivity against the false-positive rate ($1 - $ specificity). The area under it (**AUC** or AUROC) is the probability that a random positive is scored higher than a random negative: 0.5 for random and 1 for perfect. The ROC curve does not depend on the proportion of positives, which is why it can look excellent when positives are rare while precision is poor.
- The **precision–recall curve** plots precision against recall, and the area under it (AUPRC or PR-AUC, close to the average precision) summarises it. A random classifier has a precision equal to the fraction of positives, not 0.5. For imbalanced problems, where the interesting question is how many of the top predictions are correct, it is more informative than the ROC curve, since a small false-positive *rate* can still mean many false positives (Saito and Rehmsmeier 2015). For example, with 100 true binding residues among 10,000, a false-positive rate of 1% gives about 100 false positives, so even if every true site is found, half of the predictions are wrong.

In practice a method is used at one threshold, so performance should also be reported at the **operating point** that will be used, for example the precision at a given recall or the sensitivity at 1% false-positive rate.

Ranking and calibration. AUC measures only how well a method *ranks* examples. It says nothing about whether the scores are probabilities. A model is **calibrated** if, among all examples given a score of 0.9, about 90% are positive. Many models are not: an output of 0.9 from a neural network or a random forest is a score, not a 90% probability, unless calibration has been checked. Calibration is assessed with a **reliability diagram** (calibration curve), which plots the observed fraction of positives against the predicted probability in bins, and can be corrected afterwards on held-out data, for example by Platt scaling (fitting a logistic function to the scores) or isotonic regression. Calibration also depends on the proportion of positives: a model calibrated on a balanced training set will overestimate probabilities when positives are rare in practice. Calibrated probabilities are needed when scores are combined with costs to choose a threshold, or interpreted as confidence for a single prediction. The quality of probabilities can be summarised with a *proper scoring rule*, which is optimised only by the true probabilities: the **Brier score**, $\frac{1}{n}\sum_i (p_i - y_i)^2$, the mean squared difference between the predicted probability and the outcome (0 or 1), or the log loss, which penalises confident errors heavily.

Discrimination, calibration and the choice of threshold answer three different questions: can the model rank positives above negatives, do its probabilities mean what they say, and which errors matter when it is used? The threshold is a decision, not a property of the model. It should be chosen from the costs of the two kinds of error, a missed pathogenic variant is usually worse than one more variant to check, using validation data rather than the test set.

Two kinds of uncertainty are often distinguished. **Aleatoric** uncertainty is noise in the data themselves, such as measurement error or genuinely variable outcomes, and does not decrease with more data. **Epistemic** uncertainty is the model's lack of knowledge, which is large for inputs unlike the training data (for example a protein from an unseen family) and can be reduced with more data. Ensembles of models that disagree on an input are a common indicator of epistemic uncertainty.

For regression, performance is measured with the correlation (Pearson or Spearman) or the mean squared error between predicted and true values.

Benchmark design. How the test data are chosen matters as much as the measure. In a **retrospective** benchmark, methods are tested on data that already exist, often data the developers could have seen; it is easy to run but prone to leakage and repeated tuning. Stricter designs are:

- a **family or cluster split**, in which test examples have no close homologue (or other related example) in the training set, which estimates performance on new families;
- a **temporal split**, in which the method is trained on data available before a cutoff date and tested on data that appeared later, which mimics real use;
- **external validation** on an independent data set, from another laboratory, technology or population, which tests robustness to distribution shift;
- a **prospective** or **blind** benchmark, in which predictions are made before the answers are known and are assessed by others.

Blind benchmarks are the most reliable way to compare methods, because the test data do not exist when the methods are developed. Bioinformatics has a strong tradition of such community experiments: CASP for structure (Section 9.2), CAFA for function (Section 10.7), CAGI for variants (Section 10.6), CAMI for metagenomics (Section 5.7) and DREAM for networks (Section 11.2). Every new method should also be compared with a **simple baseline**, such as nearest-neighbour transfer by BLAST, logistic regression or the most frequent class. Surprisingly often, sophisticated methods do not beat them by much.

12.3 A short history of machine learning in bioinformatics

Machine learning and bioinformatics grew up together. Many methods that are now standard were first applied to biological sequences in the 1980s and 1990s, and the history explains why some ideas keep returning.

12.3.1 The perceptron

In 1958 Frank Rosenblatt described the **perceptron**, a model of a neuron that computes a weighted sum of its inputs and outputs 1 if the sum exceeds a threshold (Rosenblatt 1958):

$$y = \begin{cases} 1 & \text{if } \mathbf{w} \cdot \mathbf{x} + b > 0 \\ 0 & \text{otherwise.} \end{cases}$$

The perceptron learning rule adjusts the weights after each mistake, and converges if the two classes can be separated by a hyperplane. A position weight matrix used to score a sequence motif (Section 1.6) is exactly such a weighted sum. In one of the first applications of ML in molecular biology, Gary Stormo and colleagues used the perceptron in 1982 to recognise translation initiation sites in *E. coli* (Stormo et al. 1982).

In 1969 Marvin Minsky and Seymour Papert showed that a single perceptron cannot learn functions that are not linearly separable, the classic example being exclusive or (XOR) (Minsky and Papert 1969). Their book contributed to a decline of neural network research for more than a decade. In biology, XOR-like patterns correspond to interactions between positions (*epistasis*), where the effect of a residue depends on another.

12.3.2 Neural networks and backpropagation

Networks with **hidden layers** of units with non-linear activation functions can represent any function, including XOR, but for a long time there was no efficient way to train them. **Backpropagation**, popularised by Rumelhart, Hinton and Williams in 1986 (Rumelhart et al. 1986), computes the gradient of the loss with respect to every weight by applying the chain rule backwards through the network, so that all weights can be trained by gradient descent (Krogh 2008).

Neural networks were applied to protein secondary structure almost immediately. Qian and Sejnowski in 1988 (Qian and Sejnowski 1988) and Holley and Karplus in 1989 (Holley and Karplus 1989) trained networks on windows of sequence, reaching about 64% accuracy. The decisive improvement came from the input, not the network: **PHD** fed evolutionary profiles from multiple alignments into a two-layer network and reached more than 70% (Rost and Sander 1993) (Section 9.8). This was an early example of a lesson that has been learned many times since: the **representation** of the data matters as much as

the model. Neural networks were also used for signal peptides (SignalP, 3) and many other sequence features in the 1990s, often by Danish groups around Søren Brunak and Anders Krogh.

12.3.3 Hidden Markov models

Hidden Markov models (HMMs) describe a sequence as generated by a series of hidden states, each emitting symbols with its own probabilities (Rabiner 1989; Eddy 2004a). They were developed for speech recognition, and introduced to biology by Churchill for DNA segmentation (Churchill 1989) and by Krogh, Haussler and colleagues for protein families (Krogh et al. 1994). Three algorithms, all based on dynamic programming, make HMMs practical:

- the **Viterbi algorithm** finds the most probable path of hidden states for a sequence (Viterbi 1967);
- the **forward–backward algorithm** computes the total probability of the sequence and the posterior probability of each state at each position;
- the **Baum–Welch algorithm**, a form of expectation–maximisation, trains the parameters from unlabelled sequences (Baum et al. 1970).

HMMs became one of the most successful ML methods in bioinformatics: profile HMMs for protein families (HMMER and Pfam, Section 1.6), gene finders (GeneMark, GENSCAN, Section 5.6) and membrane protein topology (TMHMM, Section 9.10) (Durbin et al. 1998). Their strengths are a clear probabilistic interpretation, a grammar of states that encodes biological knowledge, and the ability to handle sequences of variable length. Their weakness is that each position depends only on the current state, so long-range dependencies cannot be modelled.

HMMs differ from the neural networks and SVMs in this section. They are probabilistic **generative** models of sequences (Section 12.5), whose structure is usually designed by hand, and they are often regarded as statistics rather than machine learning. They belong in this history because their parameters are learned from data, by counting in labelled sequences or by Baum–Welch in unlabelled ones, and because they became some of the most widely used learned models in bioinformatics.

12.3.4 Support vector machines, trees and ensembles

In the 1990s and 2000s, other methods became popular for classification with hand-crafted features:

- **Support vector machines** (SVMs) find the hyperplane that separates two classes with the largest *margin* (Cortes and Vapnik 1995; Noble 2006). Through the **kernel trick**, they implicitly map data to high-dimensional spaces in which non-linear problems become linearly separable, and kernels can be defined directly on sequences or structures. SVMs were used for remote homology detection, function prediction and many other problems, and are the basis of the semi-supervised rescoring in proteomics (Section 8.4).
- **Decision trees** split the data by asking a series of questions about the features. A single tree overfits easily, but **random forests** average many trees, each trained on a bootstrap sample of the data and a random subset of the features (Breiman 2001). **Gradient boosting** builds trees sequentially, each correcting the errors of the previous ones (Friedman 2001); XGBoost is a widely used implementation (Chen and Guestrin 2016).

For small, tabular data sets with well-chosen features, random forests and gradient boosting are still often as good as deep learning, are faster to train and are easier to interpret. They should be among the first baselines tried for a new problem.

12.4 Deep learning

Deep learning uses neural networks with many layers that learn their own features from raw input, rather than relying on features designed by hand (LeCun et al. 2015). It became dominant after 2012, when a deep convolutional network won the ImageNet image recognition competition by a large margin (Krizhevsky et al. 2017), made possible by large data sets, graphics processors (GPUs) and better training methods. In biology it has driven some of the largest advances of the last decade, most notably AlphaFold (Ching et al. 2018; Eraslan et al. 2019; Sapoval et al. 2022).

12.4.1 Training deep networks

Deep networks are trained with backpropagation and stochastic gradient descent, like the networks of the 1980s, but several innovations made depth possible. Activation functions such as the rectified linear unit (ReLU, $\max(0, x)$) avoid the *vanishing gradients* of deep networks with sigmoid units. Careful initialisation, normalisation layers and adaptive optimisers such as Adam stabilise training. **Residual connections**, which add the input of a block to its output, allow networks with hundreds of layers to be trained (He et al. 2016). Overfitting is controlled with dropout, weight decay, early stopping and data augmentation (4).

The reason is the chain rule. The gradient for an early layer is a product of one factor per later layer, and with saturating activations such as the sigmoid or tanh most of these factors are small, so the product vanishes. The gradient of ReLU is 1 for positive inputs, and a residual connection, $\mathbf{h}_{\ell+1} = \mathbf{h}_\ell + F(\mathbf{h}_\ell)$, gives the gradient a direct path past each block (Figure 12.1).

12.4.2 Architectures

Different architectures build different assumptions about the data into the network.

- **Convolutional neural networks** (CNNs) apply the same small filters at every position of an image or sequence (Lecun et al. 1998). Weight sharing means far fewer parameters than a fully connected network, and the filters learn local patterns, such as edges in images or motifs in DNA. Stacking layers with pooling lets later layers see larger regions. In genomics, CNNs learned the binding specificities of DNA- and RNA-binding proteins (DeepBind) (Alipanahi et al. 2015), predicted chromatin features and the effects of non-coding variants from sequence (DeepSEA, Basset) (Zhou and Troyanskaya 2015; Kelley et al. 2016), and, applied to coevolution matrices as images, predicted protein contact maps (Section 9.8).
- **Recurrent neural networks** (RNNs) process a sequence one element at a time, carrying a hidden state that summarises what has been seen. The **long short-term memory** (LSTM) unit uses gates to keep information over long distances (Hochreiter and Schmidhuber 1997). Bidirectional LSTMs read sequences in both directions, and were used in DeepLoc and early protein language models. RNNs are slow to train, because they must process positions in order.

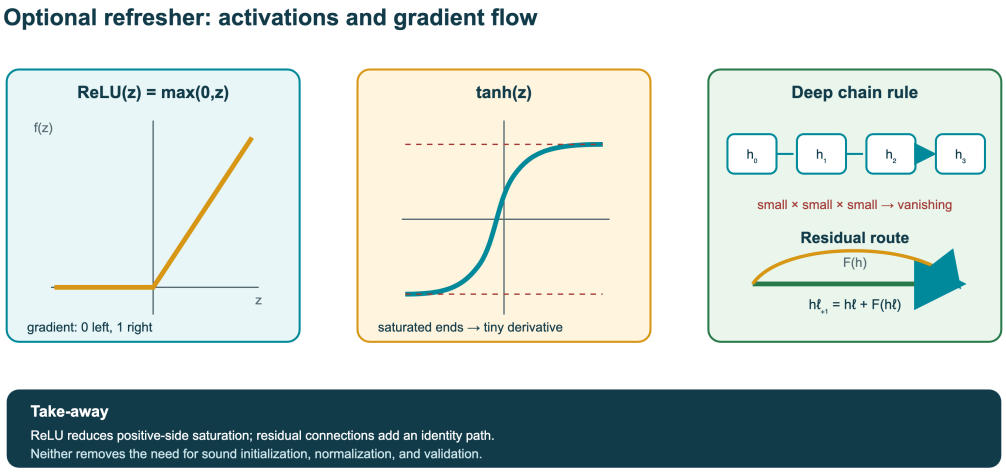

Figure 12.1: Why deep networks became trainable. Sigmoid-like activations such as tanh saturate, so their derivatives are close to zero for large inputs, and the product of many small factors in the chain rule makes the gradient vanish. ReLU has a gradient of 1 for positive inputs, and a residual connection adds an identity path around each block. Figure: Matteo Tadiello, *Modern Bioinformatics: From Foundations to Frontiers* (CC BY 4.0).

- **Attention and transformers.** *Attention* lets each position look directly at every other position, with weights computed from the content of the positions. The **transformer** architecture is built from layers of self-attention and feed-forward networks, with residual connections and normalisation (Vaswani et al. 2017). Since every pair of positions can exchange information directly in every layer, transformers can model dependencies between distant positions, such as residues that are far apart in sequence but in contact in the structure. How well they do so in practice depends on the context length (the cost of attention grows with the square of the sequence length), the training data and the architecture. Transformers can also be trained in parallel on very large data sets. Transformers are the basis of large language models, protein language models and AlphaFold.
- **Graph neural networks** (GNNs) operate on graphs, passing *messages* between connected nodes. They are natural for molecules, protein structures (residues connected by spatial proximity) and interaction networks, and are used, for example, in structure-based function prediction and in ProteinMPNN (Section 10.4, Section 9.12). Architectures that respect the symmetries of three-dimensional space, such as AlphaFold's invariant point attention, are related.
- **Generative models**, including autoencoders, GANs and diffusion models, learn to generate new data and are described in Section 12.5.

In self-attention, each token (a residue, a base or an image patch) is represented by a vector, and three learned linear maps turn the matrix of token vectors X into *queries* Q, *keys* K and *values* V. The output is

$$\text{Attention}(Q, K, V) = \text{softmax}\left(\frac{QK^T}{\sqrt{d_k}}\right)V,$$

where d_k is the dimension of the keys. Each row of the softmax gives the weights with which one token collects information from all the others (Figure 12.2). *Multi-head* attention runs several such operations in parallel with different projections. Attention by itself ignores the order of the tokens, so information about their positions must be added to the input. The $L \times L$ matrix of weights for a sequence of length L

is the source of the quadratic cost mentioned above, which matters for whole chromosomes, long reads and large sets of cells.

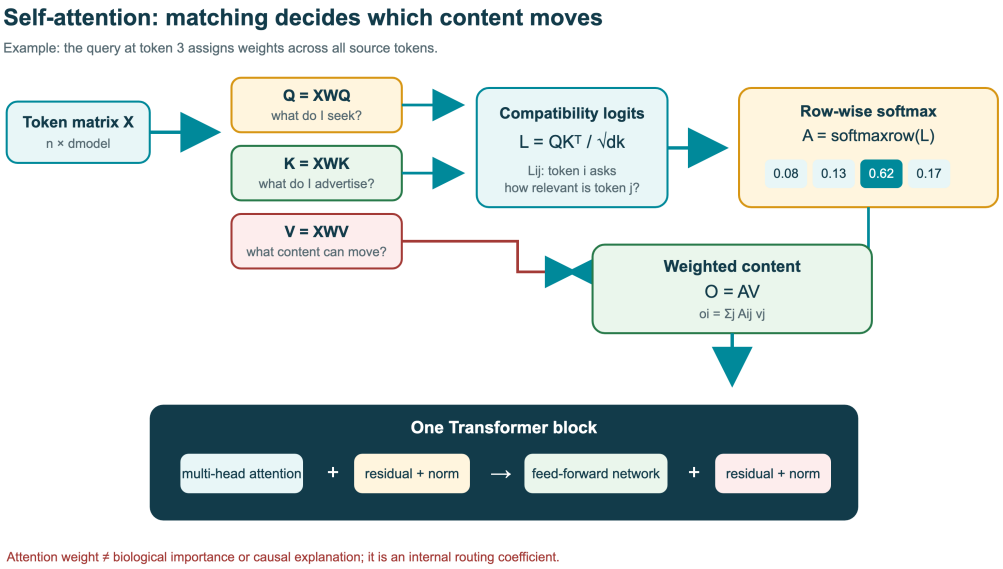

Figure 12.2: Self-attention in a transformer. The token matrix is projected to queries, keys and values; the scaled products of queries and keys, normalised row by row with a softmax, give the weights with which each token mixes the values of all tokens. A transformer block adds residual connections, normalisation and a feed-forward network. The attention weights are internal coefficients of the computation, not by themselves explanations. Figure: Matteo Tadiello, *Modern Bioinformatics: From Foundations to Frontiers* (CC BY 4.0).

12.4.3 Language models for proteins and DNA

Language models are trained, self-supervised, to predict missing or next tokens in sequences. For proteins, the tokens are amino acids. Two training objectives dominate:

- **masked-token prediction** (as in BERT): a fraction of the tokens, about 15%, is hidden and predicted from the context on both sides. ESM-2, ProtBert, DNABERT and the Nucleotide Transformer are trained this way (Lin et al. 2023; Elnaggar et al. 2022; Ji et al. 2021; Dalla-Torre et al. 2024). Such models are mainly used to produce embeddings and to score mutations;
- **next-token prediction** (autoregressive, as in GPT): each token is predicted from the tokens before it. ProGen, ProtGPT2 and Evo are trained this way (Madani et al. 2023; Ferruz et al. 2022; Nguyen et al. 2024), and can generate new sequences one token at a time (Section 12.5).

In both cases, the labels come from the sequences themselves, which is what makes it possible to train on all known sequences. Models such as ESM (Rives et al. 2021; Lin et al. 2023) and ProtTrans (Elnaggar et al. 2022), trained on hundreds of millions of sequences from UniProt and metagenomes, learn **embeddings**, vector representations of each residue and each protein, that capture structure, function and evolutionary constraints without ever being shown them. Their history and architecture are described in Section 1.10, and their use for structure prediction in Section 9.9.

The embeddings enable **transfer learning**: a large model is pre-trained once on unlabelled sequences, and its representations are then used as input for many downstream tasks with little labelled data, such as localisation (DeepLoc 2, SignalP 6; 3), variant effects (Section 10.6) or function (Section 10.4). A small

model on top of the embeddings, or *fine-tuning* of the whole model, often matches or beats specialised methods.

For **DNA**, language models face longer sequences and a sparser signal, since most of the genome is not under strong constraint (Section 6.9). DNABERT (Ji et al. 2021) and the Nucleotide Transformer (Dalla-Torre et al. 2024) adapted the transformer to DNA, and Evo and Evo 2, trained on genomes from all domains of life, model sequences of up to a million bases and can generate new genomic sequences (Nguyen et al. 2024; Brixi et al. 2025). A complementary approach trains supervised models to predict experimental measurements, such as gene expression, chromatin accessibility and splicing, directly from long DNA sequences: Enformer (Avsec et al. 2021) and AlphaGenome (Avsec et al. 2026) use this to predict the effects of non-coding variants.

12.4.4 Interpretability and reporting standards

Deep networks are often described as *black boxes*. Several methods try to explain what they have learned (Novakovsky et al. 2022): **attribution** methods, such as saliency maps and *in silico* mutagenesis, ask which input positions influence a prediction most, and can reveal the motifs a genomics model has learned; attention weights can be inspected, for example showing that protein language models attend to residues in contact (Rao et al. 2020); and models can be probed with designed inputs. Attention weights are not by themselves explanations: a position that receives high attention need not be the one that changes the prediction, and showing that an input causes an output requires further analysis, such as perturbing the input and measuring the effect. Explanations are useful for finding errors and generating hypotheses, but they are themselves approximations and should not be over-interpreted.

As ML spread through biology, the quality of studies varied widely. Common problems were inadequate test sets, data leakage, missing baselines and code or data that were not available. Recommendations have been proposed to improve this (Jones 2019). The **DOME** recommendations, from the ELIXIR machine learning focus group, ask authors to report four aspects of a supervised ML study: **D**ata (sources, size, splits, redundancy between them), **O**ptimisation (algorithm, hyperparameters, how overfitting was prevented), **M**odel (availability, interpretability) and **E**valuation (metrics, comparison with baselines and other methods, confidence) (Walsh et al. 2021). They are a useful checklist both for designing studies and for reading them critically, which is what the exam expects.

12.4.5 Feature importance and attribution

The same caution applies to the importance measures used for any model, including linear models and random forests.

- **Coefficients** of a linear model depend on the scaling of the features and on which other features are included (4).
- **Impurity-based importance** in random forests favours features with many possible split points, such as continuous features.
- **Permutation importance** measures how much the performance drops when one feature is shuffled. When two features are correlated, the model can use either, and shuffling one of them may change little, so both can appear unimportant.
- **SHAP values** distribute a single prediction among the features, using Shapley values from game theory, relative to a chosen *background* set of examples. **Integrated gradients** sum the gradients of the output along a path from a reference input (for example an all-zero or shuffled sequence) to the actual input.

All of these describe how a particular model makes its predictions. The result depends on the reference or background, on how the features are represented and on how they are correlated, and should be checked for stability across resamples. None of them estimates the effect of changing the feature in a real cell or patient. If a model of drug response gives the largest SHAP value to an immune gene, this is a hypothesis about the gene, to be tested in independent data and by perturbation, not evidence that the gene causes the response. An explanation that agrees with known biology may still reflect a confounder, such as the hospital or batch.

12.5 Generative models

Most of the models above are **discriminative**: they predict a label y for an input $\mathbf{x}$, that is, they model $P(y \mid \mathbf{x})$. **Generative models** instead learn an approximation of the distribution of the data themselves, $P(\mathbf{x})$, so that they can generate new examples, such as new protein sequences, structures or cells. Profile HMMs are an old example: they are generative models of protein families (Section 12.3). Modern generative models use deep networks and come in several families.

- **Autoregressive models** generate a sequence one token at a time, each conditioned on the previous ones, $P(\mathbf{x}) = \prod_i P(x_i \mid x_1, \dots, x_{i-1})$, as in GPT-style language models. Protein language models of this kind, such as ProGen and ProtGPT2, generate new sequences that resemble natural families, and some generated enzymes were active in the laboratory (Madani et al. 2023; Ferruz et al. 2022).
- **Variational autoencoders** (VAEs) compress each example into a low-dimensional *latent* vector with an encoder and reconstruct it with a decoder, trained so that the latent space follows a simple distribution (Kingma and Welling 2014). New examples are generated by sampling the latent space. VAEs of protein families predict the effects of mutations (DeepSequence and EVE, Section 10.6), and scVI models single-cell data (Section 7.6).
- **Generative adversarial networks** (GANs) train a generator to produce examples that a discriminator cannot distinguish from real ones (Goodfellow et al. 2020). They produce sharp images, but are difficult to train and have been less important in biology.
- **Diffusion models** learn to reverse a process that gradually adds noise to the data. Training teaches a network to remove a small amount of noise at each step; generation starts from pure noise and applies the network repeatedly until a clean example emerges (Ho et al. 2020). Diffusion models generate images of very high quality, and in structural biology they generate protein backbones (RFdiffusion, Chroma) and all-atom structures of complexes (AlphaFold3) (Section 9.8, Section 9.12) (Watson et al. 2023; Ingraham et al. 2023; Abramson et al. 2024). *Flow matching* is a closely related, increasingly used approach.

Generative models can be **conditioned** on desired properties: a structure model can be asked for a binder to a given target, a sequence model for a protein with a given function, and multimodal models

such as ESM3 can be prompted with any combination of sequence, structure and function (Hayes et al. 2025). This turns them into design tools.

Evaluating generative models is harder than evaluating predictors, because there is no single correct answer. Generated proteins are assessed for *plausibility* (do they look like natural proteins?), *novelty* (are they different from the training set?), *diversity*, and *designability* (does a structure predictor fold the sequence into the intended structure?). These are all computational proxies. A model that assigns high likelihood to natural sequences, or generates samples that look realistic, has not necessarily learned the true biological distribution, and a plausible sequence is not necessarily a folded, stable or functional protein. In the end, only laboratory experiments show whether a generated protein works, and experimental success rates are the most meaningful measure. Generative models also raise biosecurity questions, since the same tools that design useful proteins could in principle be misused, which has led to discussions of responsible development and screening of DNA synthesis orders.

See also: further explanation in Section D.12.4; related Wikipedia articles in Section E.12.4.

12.6 Foundation models

A **foundation model** is a large model trained on broad data, usually with self-supervision, that can be adapted to many downstream tasks (Bommasani et al. 2021). The term was coined for large language models such as GPT, but the idea, *pre-train once, reuse everywhere*, is now applied to most kinds of biological data. Size and breadth of pre-training alone do not make a model a foundation model. The claim is an operational one, and it should be tested by showing that the model is useful for many tasks it was not trained for, through one of three forms of adaptation:

- **probing**: a simple model, often linear, is trained on frozen embeddings to see what information they contain;
- **fine-tuning**: some or all of the weights are trained further on labelled data for the new task;
- **zero-shot use**: the pre-trained model is used directly, for example by comparing the likelihoods of a wild-type and a mutant sequence to predict the effect of a mutation (Meier et al. 2021).

The self-supervised objectives of Section 12.4, masked-token and next-token prediction, are the usual pre-training tasks. Examples include:

- **proteins**: ESM-2, ESM C and ESM3, ProtTrans and similar language models (Section 9.9);
- **DNA**: the Nucleotide Transformer, Evo and Evo 2 (Dalla-Torre et al. 2024; Brixi et al. 2025);
- **single cells**: Geneformer and scGPT, trained on tens of millions of transcriptomes (Section 7.6) (Theodoris et al. 2023; Cui et al. 2024);
- **structures and complexes**: AlphaFold3 and the co-folding models are sometimes described as foundation models for biomolecular interactions (Section 9.8).

In language, performance improves predictably with model size, data and compute, following **scaling laws** (Kaplan et al. 2020), which motivated ever larger models. In biology the picture is more mixed. Protein language models improve with size up to a point, but gains for many downstream tasks level off, and the amount of truly independent data is limited by evolution: hundreds of millions of sequences represent far fewer independent families.

Foundation models must be evaluated with particular care:

- **Baselines.** Several systematic evaluations have found that foundation models do not beat simple baselines. Single-cell foundation models without fine-tuning were often no better than highly variable genes and PCA (Kedzierska et al. 2025), and deep models did not outperform simple linear models at predicting the effects of genetic perturbations (Ahlmann-Eltze et al. 2025). A

re-evaluation of the single-cell model scBERT found that logistic regression performed as well or better at cell-type annotation, and that removing the pre-training made little difference (Boiarsky et al. 2024), and a benchmark of DNA foundation models found that performance varied between tasks and that specialised models were still better for some, such as predicting gene expression (Feng et al. 2025). A fair comparison gives the baselines the same data and the same effort of tuning, and uses *ablations* (the same architecture without pre-training, or at a smaller scale) to show which part of the model gives the benefit.

- **Benchmark contamination.** Pre-training data are so broad, often all of UniProt, the PDB or large genome collections, that the test sequences or structures of downstream benchmarks, or close homologues of them, have usually been seen during pre-training, although without the labels. This is not ordinary supervised leakage, but it can still invalidate claims that a model generalises to new proteins: the model may only recognise sequences it has seen. Claims of generalisation therefore require test sets that are filtered against the pre-training data as well as the fine-tuning data, or that were created after it (4).
- **Benchmarks.** Standardised benchmarks, such as ProteinGym for the effects of mutations on protein fitness, built from many deep mutational scanning experiments (Notin et al. 2023), make comparisons fairer, but every benchmark can be overfitted by repeated use.
- **Openness and cost.** Training the largest models requires compute available to few groups, and some of the most capable models are closed, so they can be judged only by what their developers report (Section 9.8). Results that cannot be reproduced without such resources are hard to verify. The energy used in training and, for widely used models, in inference has an environmental cost, and the gap in access to compute between large companies, well-funded laboratories and others raises questions of fairness. Smaller models, or distilled versions of large ones, are often sufficient and should be compared.

Learned models usually complement databases and search rather than replace them. AlphaFold2 takes as input a multiple sequence alignment and structural templates found by database searches (Jumper, Evans, Pritzel, Green, Figurnov, Ronneberger, Tunyasuvunakool, Bates, Žídek, Potapenko, Bridgland, Meyer, Kohl, Ballard, Cowie, Romera-Paredes, Nikolov, Jain, Adler, Back, Petersen, Reiman, Clancy, Zielinski, Steinegger, Pacholska, Berghammer, Bodenstein, et al. 2021), and ColabFold made this practical by replacing the slow searches with MMseqs2 (Mirdita et al. 2022). Many predictors combine embeddings with homology transfer by BLAST, and general LLMs are increasingly connected to literature or sequence databases from which they retrieve information before answering (*retrieval-augmented generation*). Such hybrid systems are often more accurate, and easier to update, than a model that must store all knowledge in its weights.

Foundation models are nevertheless changing how bioinformatics is done. Embeddings from a pre-trained model are now a standard starting point for a new predictor, and general-purpose large language models are increasingly used to write code, search the literature and run analyses. They are powerful tools, but, like every method in this book, they must be used with an understanding of what they were trained on, how they were evaluated, and when they fail.

12.7 AI in research practice

Artificial intelligence now affects not only the methods of bioinformatics, described in the rest of this chapter, but also the way research is carried out. This section summarises what every researcher is expected to understand, whatever their own topic.

- **Terminology.** *Artificial intelligence* is the broad goal of machines performing tasks that require intelligence. *Machine learning* is the dominant approach: learning from data rather than following explicit rules. *Deep learning* uses neural networks with many layers. *Generative AI* refers to models that produce text, images, sequences or structures, including **large language models** (LLMs) such as those behind ChatGPT, Claude or Gemini. See the terminology box in

    4.

- **How LLMs work, in outline.** They are transformers (Vaswani et al. 2017) trained to predict the next token on very large text collections, and then adapted with instruction tuning and human feedback. You should be able to explain this at the level of Section 1.10, where the same ideas are applied to proteins.
- **Major achievements in biology.** AlphaFold and its successors (Jumper, Evans, Pritzel, Green, Figurnov, Ronneberger, Tunyasuvunakool, Bates, Žídek, Potapenko, Bridgland, Meyer, Kohl, Ballard, Cowie, Romera-Paredes, Nikolov, Jain, Adler, Back, Petersen, Reiman, Clancy, Zielinski, Steinegger, Pacholska, Berghammer, Bodenstein, et al. 2021; Abramson et al. 2024), which were recognised by the 2024 Nobel Prize in Chemistry; protein language models; and generative protein design (Chapter 9). Be ready to discuss what these advances do and do not solve.
- **Using AI tools in research.** LLMs are useful for writing and debugging code, summarising literature and improving language, but they can produce fluent text that is wrong. The main risks are: *invented references* that look real but do not exist or do not support the claim; *fabricated or incorrect facts*, stated with the same confidence as correct ones; *code* that runs but computes the wrong thing, or that is insecure, for example by exposing passwords or installing packages that do not exist or are malicious; *loss of confidentiality* when data are sent to an external service; and *irreproducibility*, since hosted models are updated or withdrawn without notice and the same prompt can give different answers. Check every reference and every claim, test and read generated code, and record the tool, model version, date and prompts used for anything that enters your results. You remain responsible for all output. AI tools cannot be authors of scientific papers (Thorp 2023), and their use should be disclosed according to journal and university policies.
- **Rules and ethics.** Follow Stockholm University's and your department's guidelines on the use of AI tools in courses, examinations and theses. Do not upload unpublished data, confidential information or personal data to external AI services. Be aware of the wider issues: biases inherited from training data, the energy cost of training and using large models, and dual-use concerns, for example in protein design.

12.8 Integrating data

No single kind of measurement describes a cell or an organism. DNA sequence constrains what can happen; chromatin, RNA, proteins and metabolites each reflect different processes, with different time scales, noise and missing values. **Multi-omics integration** combines such layers in the hope of answering questions that no single layer can answer (Hasin et al. 2017). Machine learning provides most of the methods, but the main difficulties are about design and interpretation: what is being combined, what question the combination answers, and what it can show. This section draws together ideas from the rest of the chapter and from Section 7.6 and Section 11.3.

12.8.1 What is being integrated?

Before choosing a method, four things must be clear: which **units** were measured (the same cell, the same tissue sample, the same patient, or only comparable cohorts), which **features** the data sets share, what the **goal** is (exploration, finding subtypes, prediction or the effect of an intervention), and to which new data the result should **apply** (another hospital, species or technology). Three regimes are usually distinguished (Figure 12.3):

- **horizontal** integration combines data sets with the same features measured on different units, such as RNA-seq cohorts from several hospitals; the main problem is batch effects;
- **vertical** integration combines different layers measured on the same units, such as RNA and chromatin accessibility in the same cells (Section 7.6), or the genome, transcriptome and proteome of the same tumours (Section 7.7);
- **diagonal** (or *mosaic*) integration combines data sets that share neither all units nor all features, so that the correspondence between them must be inferred, from anchors, prior knowledge or a model.

Paired data, with all layers measured on the same unit, allow the relationship between the layers to be estimated directly. With *unpaired* data the relationship is assumed rather than observed. Mapping identifiers between layers (transcripts to genes, peptides to proteins, metabolite names to database entries; Chapter 2) is a frequent and underestimated source of errors, and collapsing one-to-many mappings can create agreement between layers that is not there.

12.8.2 Early, intermediate and late integration

Methods are often classified by the stage at which the layers are combined.

- **Early integration** concatenates the (normalised) features of all layers into one table and trains a single model. It is simple and works with any method, but a layer with many features or large values can dominate, so scaling and regularisation (4) are essential.
- **Intermediate integration** learns a joint representation, such as shared latent factors, a joint embedding or a fused network, and then uses it for the analysis. It can separate variation shared between layers from variation specific to one, but the latent dimensions are not uniquely defined, and they are harder to interpret than the original features.
- **Late integration** trains one model per layer and combines their predictions, for example by averaging or by a second model (*stacking*). It copes naturally with samples in which a layer is missing, but cannot find interactions between features of different layers. In stacking, the second model must be trained on predictions made for samples that the first-level models were not trained on.

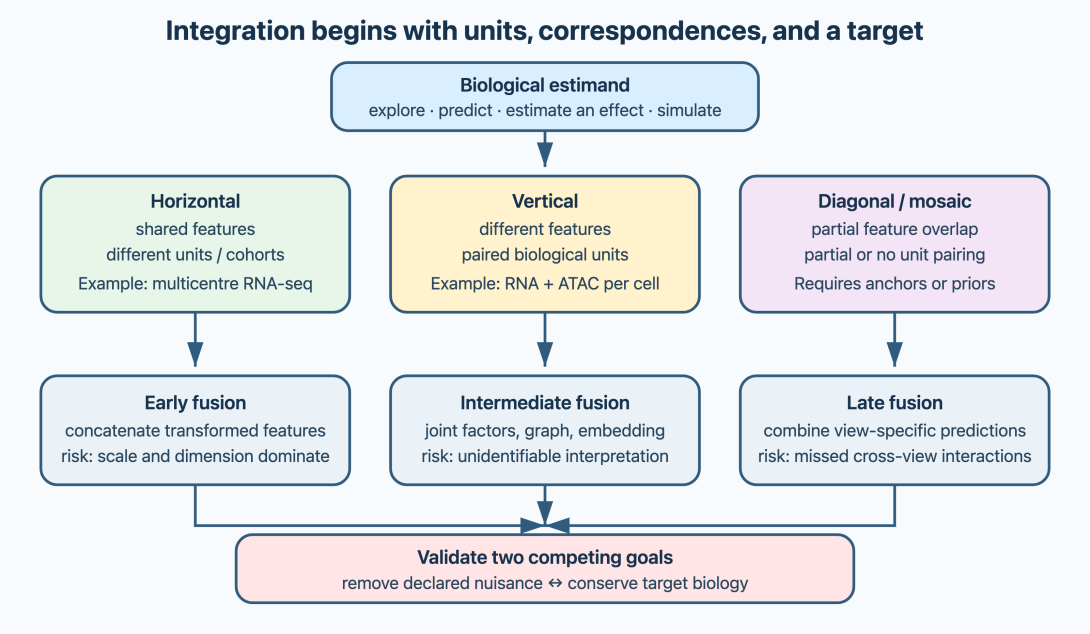

Figure 12.3: Integration starts from the question and from how the data sets correspond. Horizontal integration combines data sets with the same features measured on different units, vertical integration combines different layers measured on the same units, and diagonal integration must infer both correspondences. Early, intermediate and late integration make different assumptions, and every integration must be judged both by how well it removes unwanted variation and by how well it keeps the biology of interest. Figure: Matteo Tadiello, *Modern Bioinformatics: From Foundations to Frontiers* (CC BY 4.0).

The choice depends on the question and on the data that will be available when the model is used: a predictor that needs proteomics is of little use in a clinic where proteomics is rarely measured. Whatever the method, the gain from integration must be shown by comparison with models of each layer alone and with simple concatenation, evaluated in the same way, with all preprocessing inside the training folds and with splits by patient or site (4). Without these comparisons, an analysis cannot show that integration added anything.

12.8.3 Latent factors and networks

Many integration methods are extensions of the dimensionality reduction used for one data type (Section 7.4).

- **Multi-Omics Factor Analysis** (MOFA, MOFA+) is a multi-layer generalisation of PCA (Argelaguet et al. 2018, 2020). Each layer m is modelled as $X^{(m)} = ZW^{(m)T} + E^{(m)}$: a matrix Z of factor values for each sample, shared by all layers, times a matrix of loadings $W^{(m)}$ specific to each layer, plus noise with a likelihood suited to the layer (Gaussian, count or binary). Priors make the loadings sparse and switch off factors in layers where they are not needed, so that the result shows which sources of variation are shared and which belong to a single layer, and how much variance each factor explains in each layer.
- **Canonical correlation analysis** (CCA) finds combinations of the features of two layers that are maximally correlated with each other; sparse versions are needed when there are more features than samples.
- **Supervised** methods, such as DIABLO, find components that are both correlated between layers and discriminate between known groups of samples (Singh et al. 2019). They are useful for finding

multi-layer biomarker panels, but since the labels shape the components, the result is not an unbiased picture of the data, and the selection must be inside the cross-validation.

- **Similarity network fusion** builds a network of samples for each layer, connecting samples with similar profiles, and fuses them into a single network by repeatedly exchanging neighbourhood information between the layers; clusters of the fused network define, for example, cancer subtypes (B. Wang et al. 2014).
- **Knowledge networks**, such as protein interaction, pathway and functional association networks (Section 11.3), can be combined with measurements, for example by network propagation from the genes that change in an experiment. The meaning of an edge differs between networks (physical binding, regulation, co-expression, shared pathway membership), and well-studied genes have more edges, so results must be compared with randomised networks that keep the degree of each node.

A latent factor is a mathematical summary of covariation, not a biological programme. A factor that is shared by all layers may reflect batch, the hospital, tumour purity or the time a sample spent before freezing as easily as biology, and a factor specific to one layer is not necessarily noise: post-translational regulation, for example, is not expected to be visible in RNA. Factors are interpreted by their loadings, by their association with measured technical and biological variables, by their stability when the data, the number of factors or the preprocessing change, and by whether their association with a phenotype is reproduced in samples that were not used to find them.

Integration across batches and cohorts has the same trade-off as single-cell integration (Section 7.6): removing technical variation can also remove biology, and benchmarks therefore measure both batch removal and the conservation of biological variation (Luecken et al. 2021). If all cases were measured in one batch and all controls in another, disease and batch are completely confounded, and no algorithm can separate them. This can only be prevented by the design of the experiment.

12.8.4 What integration can and cannot show

Integration does not change the basic distinction between **prediction** and **causation** (4). A model that predicts drug response from several omics layers estimates $P(y \mid \mathbf{x})$, the probability of the outcome given the measurements. A causal question asks what would happen to y if a gene, protein or treatment were changed, and correlations in observational data can arise from common causes (*confounders*), from the outcome affecting the measurements, or from how the samples were selected. Agreement between layers strengthens a hypothesis, for example a copy-number gain, higher RNA and protein levels of a receptor, and phosphorylation of its downstream kinase in resistant tumours, but does not show that the receptor causes the resistance: the amplified region may contain other genes, and the phosphorylation may have another cause.

Causal reasoning requires explicit assumptions about how the variables affect each other, often drawn as a *directed acyclic graph*. The graph shows which variables must be adjusted for. Adjusting for a confounder removes bias; adjusting for a *mediator*, a variable on the causal path such as a transcript downstream of a genetic variant, changes the question from the total to the direct effect; and adjusting for a *collider*, a variable affected by both the exposure and the outcome, such as a quality-control measure that depends on both disease and sample quality, creates an association that was not there. Adding every available omics feature as a covariate is therefore not a safe default.

Several designs give stronger causal evidence:

- **Perturbations**, such as CRISPR knockouts or drugs, randomise the change and break confounding. Perturb-seq combines pooled CRISPR screens with single-cell RNA-seq, so that the effect of each perturbation on the whole transcriptome is measured (Dixit et al. 2016) (Section 11.2). Even then,

guide efficiency, off-target effects and the selection of cells matter, and an effect shown in one cell line applies to that context.

- **Mendelian randomisation** uses genetic variants, which are assigned at conception, as natural experiments to estimate the effect of an exposure, such as the level of a protein, on a disease (Davey Smith and Ebrahim 2003). It assumes that the variants affect the disease only through the exposure, an assumption that pleiotropy, linkage disequilibrium and population structure (Section 6.6) can violate.
- **Time courses** and **independent cohorts** help, but temporal order alone does not exclude confounding.

The strength of the evidence must match the strength of the claim (Figure 12.4). That a representation contains information, that a model performs well on a benchmark, and that it works in a new hospital are claims about the model's capability. That a gene mediates a phenotype is a claim about biology, and requires perturbation and independent lines of evidence. A careful conclusion states the narrowest claim that the evidence supports, and the experiment that would test the next step.

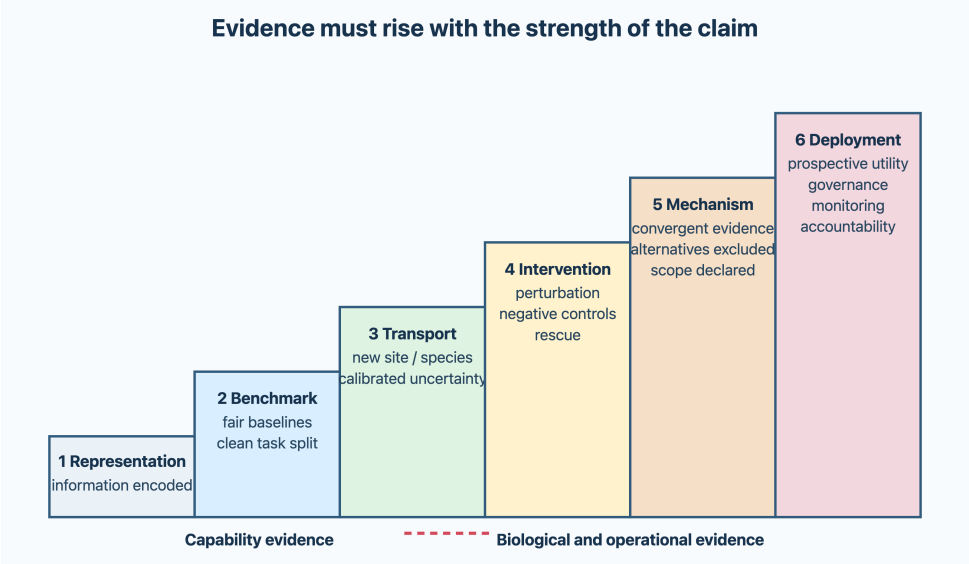

Figure 12.4: The evidence must rise with the strength of the claim. A model's representation, its benchmark performance and its performance on new sites or species are evidence of capability. Claims about interventions and mechanisms require perturbations, negative controls and convergent evidence, and use in practice requires prospective evaluation and monitoring. Figure: Matteo Tadiello, *Modern Bioinformatics: From Foundations to Frontiers* (CC BY 4.0).

12.9 Key concepts

A checklist for revision.

- **Terminology:** AI, ML, deep learning, generative AI and foundation models overlap but are not synonyms
- **Kinds of learning:** supervised, unsupervised and self-supervised; classification vs. regression; loss functions; gradient descent, learning rate, stochastic gradient descent and Adam
- **Linear models:** linear and logistic regression; coefficients as conditional associations; odds ratios; L2 (ridge) shrinks, L1 (lasso) sets weights to zero and selects features, elastic net; feature scaling; unstable selection of correlated features
- **Generalisation:** overfitting and underfitting; bias–variance trade-off; training, validation and test sets (a test set used for decisions becomes a validation set); cross-validation and nested cross-validation for hyperparameter selection; regularisation (L1, L2, early stopping, dropout)
- **Pitfalls of biological data:** non-independent examples and why random splits overestimate performance; homology between training and test sets; redundancy reduction and grouped splits by clusters, folds, patients, donors, chromosomes or dates; data leakage, including preprocessing and feature selection outside the training folds; homology-aware partitioning (GraphPart); class imbalance; biased labels and missing negatives; distribution shift; prediction vs. causation
- **Evaluation:** confusion matrix; accuracy (and why it misleads for imbalanced data), sensitivity, specificity, precision, F1; false-positive rate vs. false discovery rate; MCC; ROC and AUC; precision–recall curves and their baseline; operating points; ranking vs. calibration, reliability diagrams; Brier score and log loss; choosing a threshold from the costs of errors; aleatoric vs. epistemic uncertainty; correlation for regression; benchmark design (retrospective, cluster and temporal splits, external validation, prospective/blind); blind benchmarks (CASP, CAFA, CAGI, CAMI, DREAM); simple baselines
- **History:** the perceptron and its limits (XOR); backpropagation; neural networks for secondary structure and the importance of representation (PHD); HMMs (generative models, and why they belong in this history) and the Viterbi, forward–backward and Baum–Welch algorithms; applications of HMMs; SVMs and kernels; decision trees, random forests and gradient boosting
- **Deep learning:** why depth became possible (data, GPUs, ReLU, residual connections); CNNs and their use for DNA motifs and contact maps; RNNs and LSTMs; attention and transformers (and the limits of long-range modelling); graph neural networks; vanishing gradients; queries, keys and values in self-attention, positional information and the quadratic cost
- **Language models:** self-supervised pre-training; masked-token vs. next-token prediction; embeddings; transfer learning and fine-tuning; protein language models; DNA language models (DNABERT, Nucleotide Transformer, Evo); sequence-to-function models (Enformer, AlphaGenome)
- **Interpretability and reporting:** attribution, in silico mutagenesis, attention maps (and why attention is not explanation); coefficients, permutation importance, SHAP and integrated gradients describe the model, not causal effects; the DOME recommendations (data, optimisation, model, evaluation)
- **Generative models:** discriminative vs. generative; autoregressive models (ProGen, ProtGPT2); VAEs; GANs; diffusion models; conditioning; evaluating generated proteins (plausibility is not function); biosecurity
- **AI in research practice:** AI, ML, deep learning and generative AI; how LLMs are trained; AlphaFold and the 2024 Nobel Prize; using AI tools responsibly (invented references, fabricated facts, code security, data confidentiality, model versions and reproducibility, authorship, disclosure); bias, energy use and dual use
- **Foundation models:** operational definition; probing, fine-tuning and zero-shot use; examples for proteins, DNA, single cells and structures; scaling laws and their limits in biology; evaluation against baselines with equal tuning and ablations, benchmark contamination by pre-training data, benchmarks (ProteinGym); models combined with MSAs, templates and database search; open vs. closed models, compute, energy and access
- **Integrating data:** units, features, goal and transport; horizontal, vertical and diagonal integration;

paired vs. unpaired data; identifier mapping; early, intermediate and late integration and the need for single-layer baselines; MOFA, CCA, DIABLO, similarity network fusion, network propagation; latent factors are not programmes; batch vs. biology and complete confounding; prediction vs. causation; confounders, mediators and colliders; perturbations, Perturb-seq and Mendelian randomisation; matching the evidence to the claim

12.10 Recommended reading

These papers are recommended for reading in full:

- LeCun et al. (2015) — deep learning, by three of its founders.
- Krogh (2008) — what artificial neural networks are, in three pages.
- Walsh et al. (2021) — DOME; what a supervised machine learning study in biology should report.
- Chicco and Jurman (2020) — why the Matthews correlation coefficient is better than F1 and accuracy.

Titles, abstracts, links and the full texts are in Section A.12; a longer list of further papers is in Section B.12.

12.11 Background reading (open access)

- **Machine learning (Wikipedia)** — Machine learning (ML) is a field of study in artificial intelligence concerned with the development and study of statistical algorithms that can learn from data and generalize to unseen data, and thus perform tasks without being explicitly programmed.
  https://en.wikipedia.org/wiki/Machine_learning
- **Deep learning (Wikipedia)** — In machine learning, deep learning (DL) focuses on utilizing multilayered neural networks to perform tasks such as classification, regression, and representation learning.
  https://en.wikipedia.org/wiki/Deep_learning
- **Hidden Markov model (Wikipedia)** — In probability theory, a hidden Markov model (HMM) is a Markov model in which the observations are dependent on a latent Markov process. An HMM requires that there be an observable process whose outcomes depend on the outcomes of in a known way.
  https://en.wikipedia.org/wiki/Hidden_Markov_model
- **Artificial neural network (Wikipedia)** — In machine learning, a neural network (NN) or artificial neural network (ANN) is a computational model inspired by the structure and functions of biological neural networks.
  https://en.wikipedia.org/wiki/Neural_network_(machine_learning)
- **Backpropagation (Wikipedia)** — In machine learning, backpropagation is a gradient computation method commonly used for training a neural network in computing parameter updates.
  https://en.wikipedia.org/wiki/Backpropagation
- **Support vector machine (Wikipedia)** — In machine learning, a support vector machine (SVM) or support vector network is a supervised max-margin model with associated learning algorithms that analyze data for classification and regression analysis.
  https://en.wikipedia.org/wiki/Support_vector_machine

- **Random forest (Wikipedia)** — Random forests or random decision forests is an ensemble learning method for classification, regression and other tasks that works by creating a multitude of decision trees during training. For classification tasks, the output of the random forest is the class selected by most trees.
  https://en.wikipedia.org/wiki/Random_forest
- **Overfitting (Wikipedia)** — In mathematical modeling, overfitting is the production of an analysis that corresponds too closely or exactly to a particular set of data and may therefore fail to fit to additional data or predict future observations reliably.
  https://en.wikipedia.org/wiki/Overfitting
- **Regularization (Wikipedia)** — In mathematics, statistics, finance, and computer science, particularly in machine learning and inverse problems, regularization is a process that converts the answer to a problem to a simpler one. It is often used in solving ill-posed problems or to prevent overfitting.
  https://en.wikipedia.org/wiki/Regularization_(mathematics)
- **Cross-validation (Wikipedia)** — Cross-validation, sometimes called rotation estimation or out-of-sample testing, is any of various similar model validation techniques for assessing how the results of a statistical analysis will generalize to an independent data set.
  https://en.wikipedia.org/wiki/Cross-validation_(statistics)
- **Transformer (deep learning architecture) (Wikipedia)** — In deep learning, the transformer is a family of artificial neural network architectures based on the multi-head attention mechanism, in which input data such as text, images, or audio is converted to a sequence of numerical representations called tokens, and each token is converted into a vector through an embedding layer.
  https://en.wikipedia.org/wiki/Transformer_(deep_learning_architecture)
- **Diffusion model (Wikipedia)** — In machine learning, diffusion models, also known as diffusion-based generative models or score-based generative models, are a class of latent variable generative models. A diffusion model consists of two major components: the forward diffusion process, and the reverse sampling process.
  https://en.wikipedia.org/wiki/Diffusion_model
- **Foundation model (Wikipedia)** — In artificial intelligence, a foundation model (FM), also known as large x model, is a machine learning or deep learning model trained on vast datasets so that it can be applied across a wide range of use cases. Generative AI applications like large language models (LLMs) are common examples of foundation models.
  https://en.wikipedia.org/wiki/Foundation_model

12.12 Student recommendations

Recommended by students preparing for the exam: papers, reviews, online lectures, tutorials and short explanations. To suggest something, use the suggestion form (SU login).

No recommendations yet.

12.13 Review problems

These problems are adapted from Matteo Tadiello, *Modern Bioinformatics: From Foundations to Frontiers* (CC BY 4.0), used with permission. For a longer treatment of this topic, see the chapters "Statistics and Machine Learning for Biological Data" and "Integration, Reproducibility, and Emerging Bioinformatics"

of that book. In the HTML version, click a box to show the extensions, solution outline and common errors.

12.13.1 L1 and L2 regularisation

Compare L1, L2 and elastic-net regularisation for a classifier of patients trained on the expression levels of 20,000 genes, many of which are correlated.

Extensions, solution outline and common errors

Extensions:

- Why do L1 penalties give exactly zero weights, and L2 penalties not?
- Why must the features be scaled before fitting?
- How should the penalty strength λ be chosen?
- How stable is the set of selected genes, and what does it mean biologically?

Solution outline:

1. With a loss $L(\beta)$, L1 (lasso) minimises $L + \lambda \sum_j |\beta_j|$. The penalty has corners on the coordinate axes, so many weights become exactly zero and the model selects features.
2. L2 (ridge) minimises $L + \lambda \sum_j \beta_j^2$. It shrinks all weights smoothly towards zero but rarely sets any to zero, and stabilises the fit when features are correlated.
3. The elastic net combines both, and tends to keep or drop correlated genes together.
4. The penalties act on the size of the weights, so features must be on comparable scales.
5. λ is a hyperparameter, chosen by cross-validation inside the training data (nested cross-validation if performance is also estimated).
6. Selection should be checked by resampling. Selected genes are predictive within this model, not causal: a correlated gene could often replace a selected one with the same performance.

Common errors:

- Reversing L1 and L2.
- Choosing λ on the final test set.
- Treating a sparse signature as unique when correlated genes could replace it.
- Fitting without scaling the features.

Connections: 4 (linear models, regularisation, nested cross-validation); Section 7.4 (correlated expression and differential expression).

12.13.2 Leakage-free evaluation for protein sequences

Design a benchmark for a method that predicts enzyme function from 100,000 protein sequences with family labels.

Extensions, solution outline and common errors

Extensions:

- Compare random, homology-aware, family-held-out and clade-held-out splits.
- Where do normalisation, feature selection, hyperparameter tuning, calibration and the

choice of threshold belong in a nested design?
- What if the method uses embeddings from a protein language model pre-trained on UniProt?

Solution outline:

1. Define the intended novelty: a new member of a known family, a new family, or a new clade. The split follows from this.
2. Cluster sequences by similarity (for example with MMseqs2, or with a partitioning method such as GraphPart) and keep each cluster, and where relevant each family or clade, in one subset.
3. Fix the outer test set first. Fit every learned step and choose the model, features, hyperparameters, calibration and threshold using only the inner training and validation data.
4. Record the pre-trained model and the version of its training data, estimate how many test sequences or close homologues were seen in pre-training, and repeat with stricter filtering.
5. Compare with nearest-neighbour transfer by BLAST, profile methods and a linear model on the embeddings, with the same tuning effort.
6. Report performance both for close homologues and for new families if both claims are made.

Common errors:

- Treating different accessions as independent examples.
- Fitting normalisation or feature selection before splitting.
- Choosing the architecture by test-set performance.
- Ignoring overlap with pre-training data.
- Comparing a heavily tuned model with an untuned baseline.

Connections: 4 (pitfalls and benchmark design); Section 12.6 (benchmark contamination); Section 1.11 (benchmarks of homology search); Section 10.7 (function prediction benchmarks).

12.13.3 Evaluation under class imbalance and distribution shift

A cancer-screening model reports 98% accuracy and an AUC of 0.91 in a cohort with 1% disease prevalence. Does the evidence support clinical use?

Extensions, solution outline and common errors

Extensions:

- Compare the ROC curve with the precision–recall curve.
- Define calibration and the Brier score.
- How should the threshold be chosen?
- What do case–control sampling, external validation and subgroups change?

Solution outline:

1. At 1% prevalence, always predicting “healthy” gives 99% accuracy, so 98% accuracy says nothing on its own.
2. The AUC measures ranking of positives above negatives. Precision–recall curves focus on the positive predictions; their random baseline equals the prevalence, so they show whether the top predictions are correct.
3. Whether the scores are probabilities requires a reliability diagram and a proper score such as the Brier score or log loss.

4. The threshold is chosen on validation data from the costs of false negatives and false positives.
5. Performance needs confidence intervals and evaluation in external sites, later time periods and relevant subgroups.
6. If the prevalence in a case–control sample differs from the screening population, the probabilities must be recalibrated.

Common errors:

- Treating the AUC as sufficient because it does not depend on prevalence.
- Choosing the threshold on the final test cohort.
- Reporting subgroup results without uncertainty.
- Assuming that retrospective discrimination shows prospective usefulness.

Connections: 4 (evaluation, calibration, distribution shift); Section 10.6 (variant effect prediction).

12.13.4 Diagnosing a violated assumption

A classifier that performs very well in random cross-validation fails on samples from a new laboratory. Give at least four explanations and design diagnostics to distinguish them.

Extensions, solution outline and common errors

Extensions:

- How can a negative control feature reveal leakage?
- Which kinds of distribution shift can recalibration fix, and which need retraining or a new design?
- How can you tell whether the model used a signal correlated with the laboratory?

Solution outline:

1. Possible explanations: batch artefacts specific to the laboratory; leakage through preprocessing or identifiers; a shift in the distribution of the features; a different prevalence; a different relation between features and labels; inconsistent labelling; and biology not covered by the training data.
2. Plot features and predictions by laboratory and by biological covariates, and check missing values, controls and instrument metrics.
3. Repeat the evaluation with splits by laboratory, and with all preprocessing fitted inside the training folds.
4. Test whether the laboratory can be predicted from the features, and whether predictions remain associated with laboratory after accounting for the true label.
5. Recalibration can correct a change in prevalence or in the scale of the scores, but not missing biology or a confounded training design.

Common errors:

- Batch-correcting the whole data set before splitting.
- Treating distribution shift as a single phenomenon.
- Reporting only overall accuracy.
- Interpreting laboratory-specific features as disease biology.

Connections: 4 (data leakage, distribution shift); Section 13.6 (site signatures in pathology images); Section 7.4 (batch effects).

12.13.5 Transformers and biological foundation models

Explain how a transformer represents a biological sequence, and what evidence is needed to conclude that large-scale pre-training improves a downstream biological task.

Extensions, solution outline and common errors

Extensions:

- Write down scaled dot-product attention.
- Discuss tokens, positional information, self-supervised objectives and the quadratic cost of attention.
- Which comparisons separate the effect of pre-training from that of the architecture and the model size?

Solution outline:

1. Tokens (residues, bases or k-mers, genes) are embedded and projected to queries, keys and values; attention is $\text{softmax}(QK^T/\sqrt{d_k})V$, and several heads use different projections.
2. Attention ignores order, so positional information is added. The cost grows with the square of the sequence length.
3. Pre-training uses masked-token or next-token prediction; the embeddings reflect this objective and the training data.
4. A benefit of pre-training is shown only with leakage-aware splits, baselines with the same data and tuning, ablations (the same model without pre-training or at smaller size), external data sets, calibration and, for claims about function, experiments.
5. An attention weight is not in itself an interaction or an explanation.

Common errors:

- Treating attention as a mechanistic explanation.
- Calling any large network a foundation model.
- Assuming that a high-likelihood generated sequence folds, functions or is safe.
- Comparing a heavily optimised model with an untuned baseline.

Connections: Section 12.4 (transformers and language models); Section 12.6 (evaluating foundation models); Section 1.10 and Section 9.9 (protein language models).

12.13.6 Interpreting feature attributions

A model that predicts response to therapy from tumour expression data gives the largest SHAP value to an immune gene. What can be concluded, and what would be needed before the model is used in the clinic?

Extensions, solution outline and common errors

Extensions:

- How do correlated features and the choice of background affect SHAP values?
- How would you check that the attribution is stable?
- What evidence would make the gene a candidate therapeutic target?

Solution outline:

1. SHAP distributes this model's prediction among the features relative to a background set; it says how the model predicts, not what the gene does.
2. Correlated genes can share or exchange attribution, so stability must be checked across folds, sites, backgrounds and preprocessing choices.
3. The association might reflect a confounder, such as hospital, batch or tumour purity.
4. A causal role requires independent cohorts and perturbation experiments.
5. Clinical use requires a defined population, external or prospective validation, calibrated probabilities, analysis by site and subgroup, fixed versions of data and model, and monitoring after deployment.

Common errors:

- Turning a feature attribution directly into a drug target.
- Assuming interpretability repairs leakage or confounding.
- Treating predictive performance as causal understanding.

Connections: Section 12.4 (interpretability and feature attribution); Section 12.8 (prediction and causation); Section 7.7 (cancer genomics).

12.13.7 Designing a trustworthy method benchmark

A new method reports the highest average score across ten public data sets. How strong is this evidence, and how would you design a more informative benchmark?

Extensions, solution outline and common errors

Extensions:

- Which kinds of leakage are specific to biology?
- Why do public benchmarks lose their value over time?
- Which baselines and measures are required, and what would count as a meaningful advance?

Solution outline:

1. Restate the task, the population the method will be used on, the independent unit and what counts as new.
2. Check for overlap of patients, donors, families, homologues, sites, time periods and near-duplicates across splits.
3. Keep normalisation, imputation, feature selection and tuning inside the training data, and check pre-training data for overlap with the test sets.
4. Compare with simple, specialised and earlier methods, with ablations, using the same data and tuning effort.

5. Report results per data set with uncertainty, not only the mean rank, together with calibration, failures and compute.
6. Prefer blind or prospective tests, and an improvement larger than the variation caused by analysis choices.

Common errors:

- Selecting the best random seed or the most favourable measure.
- Calling a small, statistically detectable gain a breakthrough.
- Assuming a public test set stays uncontaminated.

Connections: 4 (benchmark design and blind benchmarks); Section 9.2 (CASP); Section 12.6 (contamination).

12.13.8 Defining multi-omics integration

Genome, RNA, protein and metabolite measurements are available for a cohort of patients. Propose an integration strategy, and state when integration would not be justified.

Extensions, solution outline and common errors

Extensions:

- Are the layers measured on the same units?
- Compare horizontal, vertical and diagonal integration.
- Compare early, intermediate and late integration.

Solution outline:

1. Define the goal: harmonisation, exploration, subtypes, prediction or mechanism.
2. Map each layer to patient, tissue sample, cell and time point; distinguish paired from unpaired data.
3. Do quality control for each layer before combining them, and keep one-to-many identifier mappings.
4. Explain early concatenation, joint latent representations and late combination of predictions, and how each handles missing layers.
5. Fit single-layer and simple concatenation baselines with the same validation design.
6. Require independent evidence before interpreting a shared factor biologically.
7. Do not integrate when a single layer already answers the question, or when complete confounding makes the question impossible to answer.

Common errors:

- Assuming more layers automatically means more information.
- Calling the largest latent factor a biological programme without checking batch.
- Analysing only complete cases and hiding why layers are missing.

Connections: Section 12.8 (integrating data); Section 7.6 (multimodal single-cell data); Chapter 2 (identifiers).

12.13.9 Interpreting a latent factor

MOFA finds a latent factor that is associated with disease and has large loadings in RNA, methylation and protein data. What can be concluded, and how would you validate it?

Extensions, solution outline and common errors

Extensions:

- Write down the factor model.
- How do shared and layer-specific factors differ?
- Is the factor uniquely defined?

Solution outline:

1. The model is $X^{(m)} = ZW^{(m)T} + E^{(m)}$, with factor values Z shared by all layers, loadings $W^{(m)}$ for each layer, and a likelihood suited to each layer.
2. The factor summarises covariation; it is not an observed mechanism.
3. Check the variance explained per layer, the stability of the loadings, association with technical variables, missing data, the number of factors, preprocessing and random seed.
4. The sign and order of factors are arbitrary; match factors between runs by their loadings.
5. Test the association with disease in held-out patients.
6. Use independent assays or perturbations to test a proposed pathway.

Common errors:

- Interpreting a two-dimensional plot without looking at the original measurements.
- Treating a layer-specific factor as noise.
- Using the same outcome to find and to validate the factor.
- Inferring causal direction from correlated loadings.

Connections: Section 12.8 (latent factors); Section 7.4 (PCA and dimensionality reduction).

12.13.10 Distinguishing prediction from causal mechanism

A multi-omics classifier predicts drug response accurately in held-out samples. Does it identify a mechanism of resistance? What design and evidence would a causal claim need?

Extensions, solution outline and common errors

Extensions:

- What is the difference between $P(y \mid \mathbf{x})$ and the effect of an intervention?
- How should a causal graph be used?
- Why might adjusting for expression introduce bias?
- What would Perturb-seq add?

Solution outline:

1. Prediction estimates performance on new cases from a population; a mechanism concerns what changes under intervention.
2. Define treatment, outcome, population, time and the effect of interest (total or direct).

3. Draw plausible confounders, mediators, colliders and selection processes before choosing covariates.
4. Adjusting for a mediator changes the question; adjusting for a collider can create bias.
5. Use genetic or pharmacological perturbations with negative controls, rescue, time courses and several genetic backgrounds.
6. Perturb-seq measures the transcriptome-wide effect of each perturbation, but guide efficiency, off-target effects and cell selection must be checked.

Common errors:

- Treating feature importance as a causal effect.
- Assuming that temporal order removes confounding.
- Adjusting for every available omics feature.
- Calling an in silico knockout an experiment.

Connections: Section 12.8 (what integration can and cannot show); Section 11.2 (Perturb-seq and perturbation screens); Section 12.4 (feature attribution).

13 Image analysis and models of cells

> **Not in the exam description**
>
> This topic is not part of the 2025 exam description. It was added in version 0.4 of this book because image-based methods, and the large projects that aim to classify cell types and build models of whole cells, have become a central part of bioinformatics. Ask your examiner whether it is included in your exam.

13.1 Overview

Images are now one of the largest sources of biological data. Automated microscopes image millions of cells in a single screen, histology slides are scanned at high resolution in hospitals, and electron tomography shows the molecules inside cells. Deep learning has made it possible to analyse such images at scale, and the results are increasingly combined with sequence, expression and structure data. This chapter builds on the machine-learning methods of Chapter 12 and covers:

- images as data: kinds of images, classical analysis, software, file formats and repositories (Section 13.2);
- deep learning for images: classification and segmentation, U-Net, Cellpose and StarDist, vision transformers, self-supervised learning and foundation models, and the pitfalls (Section 13.3);
- image-based profiling: Cell Painting, morphological profiles and the JUMP and RxRx data sets (Section 13.4);
- protein localisation from images: the subcellular atlas of the Human Protein Atlas, image-classification challenges, OpenCell and self-supervised models (Section 13.5);
- tissues: multiplexed imaging, spatial omics and computational pathology (Section 13.6);
- cell atlases and AI virtual cells: the Human Cell Atlas, HuBMAP, the virtual-cell efforts of CZI, the Arc Institute and SciLifeLab's Alpha Cell, and how well current models work (Section 13.7);
- mechanistic and structural models of whole cells, and cryo-electron tomography (Section 13.8).

The chapter connects to many others: spatial proteomics and the Human Protein Atlas in Chapter 8, sequence-based localisation prediction in Chapter 10, single-cell and spatial transcriptomics in Chapter 7, and cryo-EM and molecular dynamics in Chapter 9.

13.2 Images as data

Microscopy is the oldest way of studying cells, and for most of its history the results were judged by eye. Modern microscopes produce far more images than anyone can inspect: an automated screen can image millions of cells, and a single light-sheet experiment can produce terabytes. **Bioimage analysis** turns these images into measurements that can be analysed with the same statistical and machine-learning methods as other omics data.

13.2.1 What an image is

A digital image is an array of numbers. A fluorescence image has one *channel* for each fluorescent label, and may in addition have several focal planes (z) and time points (t), so that a single experiment is a five- dimensional array (x, y, z, channel, time). Each value is an intensity, not a count of molecules: it depends on the label, the microscope, the exposure and the detector, and images are only comparable when they were acquired in the same way. The main kinds of images in biology are:

- **Transmitted-light** (brightfield, phase contrast) images, which need no labels but show little molecular detail;
- **fluorescence** images (widefield, confocal, light-sheet and super-resolution microscopy), where proteins or structures are made visible with antibodies, dyes or fluorescent proteins;
- **electron microscopy**, which reaches molecular resolution but only for fixed or frozen samples (Section 13.8);
- **histology**, thin tissue sections stained, for example with haematoxylin and eosin (H&E), and scanned as *whole-slide images* of up to 100,000 × 100,000 pixels (Section 13.6).

13.2.2 Classical image analysis

The classical workflow, still used in many pipelines, has four steps: *preprocessing* (background and illumination correction, denoising), *segmentation* (finding the objects, usually nuclei and cells, for example by thresholding followed by a watershed transform to split touching objects), *feature extraction* (measuring size, shape, intensity and texture for each object) and *analysis* of the resulting table. Each step involves choices, and the results depend on them; this is why image analysis is often less reproducible than it appears.

13.2.3 Tools, formats and repositories

Most bioimage analysis uses open-source software. **ImageJ** and its distribution **Fiji** are the general-purpose tools of light microscopy, extended by thousands of plugins (Schindelin et al. 2012; Rueden et al. 2017). **CellProfiler** builds analysis pipelines from modules without programming and is the standard tool for high-throughput screens (Carpenter et al. 2006; Stirling et al. 2021). **ilastik** trains pixel and object classifiers interactively from a few user annotations (Berg et al. 2019). **QuPath** is designed for whole-slide pathology images (Bankhead et al. 2017), and **napari** is a multidimensional image viewer for Python, to which many deep-learning tools are added as plugins.

Images need metadata (organism, sample preparation, microscope and acquisition settings) to be reusable. The REMBI recommendations define the minimum metadata for publishing biological images (Sarkans et al. 2021), and the OME-Zarr format (OME-NGFF) stores large multidimensional images in chunks that can be read directly from the cloud (Moore et al. 2021, 2023). Published images are deposited in the **BioImage Archive** at EMBL-EBI (Hartley et al. 2022), and curated reference data sets, linked to genes, compounds and phenotypes, in the **Image Data Resource** (IDR) (Williams et al. 2017). The **Broad Bioimage Benchmark Collection** (BBBC) provides annotated image sets for testing methods (Ljosa et al. 2012), and the **Cell Tracking Challenge** has benchmarked segmentation and tracking methods for more than ten years (Maška et al. 2023). The volume of data is part of the challenge: unlike sequences, images cannot be compressed to a few bytes per measurement, and moving them is often harder than analysing them.

13.3 Deep learning for images

Image analysis is where modern deep learning started, and microscopy was one of the first scientific fields to adopt it (Moen et al. 2019). The general methods are described in Section 12.4; this section describes how they are used for biological images.

13.3.1 Tasks

Four tasks cover most applications, and it is worth keeping them apart:

- **classification** assigns a label to a whole image or to a cell (for example a cell type, a cell-cycle phase or the location of a protein);
- **segmentation** assigns each pixel to a class (*semantic segmentation*, e.g. nucleus vs. background) or to an individual object (*instance segmentation*, which separates touching cells);
- **detection and tracking** find objects, such as cells or particles, and follow them over time;
- **image-to-image** methods restore noisy images or predict one kind of image from another, for example fluorescence from brightfield.

13.3.2 Convolutional networks and U-Net

Convolutional neural networks (CNNs) learn filters that detect local patterns and combine them into increasingly abstract features. The breakthrough came in 2012, when AlexNet won the ImageNet challenge by a large margin (Krizhevsky et al. 2017), and residual connections later made networks with more than a hundred layers trainable (He et al. 2016). For biomedical images, the most influential architecture is **U-Net** (Ronneberger et al. 2015). An encoder reduces the image to coarse features, a decoder expands them back to full resolution, and *skip connections* pass fine detail from the encoder to the decoder, so that the network produces precise pixel-wise output from relatively few training images. A U-Net plugin for ImageJ made the method usable without programming (Falk et al. 2018).

13.3.3 Instance segmentation of cells

Separating touching cells is the central problem of cell segmentation. **StarDist** describes each nucleus as a *star-convex polygon*: for every pixel, a CNN predicts whether it belongs to an object and the distances to the object boundary along a fixed set of rays, and overlapping candidates are removed by non-maximum suppression (Schmidt et al. 2018). **Cellpose** predicts, for every pixel, the direction towards the centre of its cell (a *flow field*), and groups pixels whose flows end at the same point. Trained on a diverse collection of images, it segments many kinds of cells without retraining (Stringer et al. 2020), and Cellpose 2.0 adds human-in-the-loop training, so that a model can be adapted to new data from a few corrected images (Pachitariu and Stringer 2022). For tissue images, Mesmer was trained on TissueNet, more than a million manually annotated cells, and reached the accuracy of human annotators (Greenwald et al. 2021).

13.3.4 Transformers, self-supervision and foundation models

Vision transformers (ViTs) split an image into patches and treat them as a sequence of tokens, as language models do with words (Dosovitskiy et al. 2021). They need more training data than CNNs, which has made **self-supervised learning** important. In *DINO*, a student network learns to match the output of a teacher network on different views of the same image, without labels (Caron et al. 2021), and DINOv2 scaled this to general-purpose visual features (Oquab et al. 2023). *Masked autoencoders* (MAE) hide most of the patches of an image and learn to reconstruct them (He et al. 2022), the image counterpart of masked language modelling (Section 12.4). For microscopy, Cell-DINO showed that self-supervised features of fluorescence images classify protein localisation well with few labels (Moutakanni et al. 2025).

The **Segment Anything** model (SAM), trained on more than a billion masks, segments objects from a prompt such as a point or a box (Kirillov et al. 2023). It was not trained on microscopy, but versions fine-tuned for light and electron microscopy, such as µSAM (Archit et al. 2025) and CellSAM (Marks et al. 2025), are now general segmentation tools. These are examples of foundation models (Section 12.6) for images.

13.3.5 Label-free prediction

Networks can also learn to predict one kind of image from another. *In silico labelling* predicted fluorescent labels of nuclei, cell types and dead cells from transmitted-light images of unlabelled cells (Christiansen et al. 2018), and similar models from the Allen Institute predicted the three-dimensional fluorescence of several cellular structures from brightfield images (Ounkomol et al. 2018). Such predictions are useful, but they can only reproduce what is predictable from the input image, and they should not be mistaken for measurements.

13.3.6 Pitfalls

The general pitfalls of machine learning (4) all apply, and some are specific to images. Images from different plates, microscopes, days or hospitals differ systematically (*batch effects*), and a network may learn these differences rather than biology; training and test sets should therefore be split by experiment, not by image. Ground-truth annotations are produced by people, who disagree with each other. Restored or predicted images can contain plausible structures that are not in the sample. Guidelines for validating and reporting deep-learning image analysis address these problems (Laine et al. 2021), and good introductions for biologists are available (Chamier et al. 2019; Hallou et al. 2021). Notebooks such as ZeroCostDL4Mic let users train common models without installing software (Chamier et al. 2021).

13.4 Image-based profiling

A cell's appearance reflects its state. **Image-based profiling** (also called morphological profiling or *phenomics*) uses this systematically: cells are treated with chemical or genetic perturbations, imaged,

and described by thousands of measurements, so that perturbations can be compared in the same way as expression profiles (Chapter 7).

13.4.1 Cell Painting

The most widely used assay is **Cell Painting** (Gustafsdottir et al. 2013; M.-A. Bray et al. 2016). Six fluorescent dyes, imaged in five channels, label eight cellular components: the nucleus (DNA), nucleoli and cytoplasmic RNA, the endoplasmic reticulum, actin, the Golgi apparatus, the plasma membrane and mitochondria. The assay is cheap, needs no antibodies, and works in many cell types. Software such as CellProfiler segments each cell and measures its size, shape, intensity and texture in every channel, giving more than a thousand features per cell (Section 13.2). A third version of the protocol was optimised quantitatively by the JUMP consortium (Cimini et al. 2023).

13.4.2 From images to profiles

The analysis follows a standard workflow (Caicedo et al. 2017):

1. **Single-cell features** are extracted, either hand-designed features from CellProfiler or embeddings from deep networks (Section 13.3).
2. Features are **aggregated** per well, usually as the median over cells, **normalised** against negative controls on the same plate, and reduced to a smaller set of informative, uncorrelated features.
3. **Batch effects** between plates and laboratories are corrected, the same problem as in expression data (Section 7.4).
4. The profiles are compared: perturbations are tested for whether they change the cells at all, and similar profiles are matched, for example by cosine similarity, to group compounds by mechanism or to connect a gene to a compound that mimics its loss.

Profiles are used to find the mechanism of action of compounds, to identify toxicity, to group genes into pathways, and to find disease phenotypes that a drug reverses.

13.4.3 Large public data sets

The **JUMP Cell Painting Consortium**, a collaboration of the Broad Institute and pharmaceutical companies, has released Cell Painting images of more than 100,000 chemical and genetic perturbations. A pilot data set, CPJUMP1, contains about three million images of cells treated with matched chemical and genetic perturbations of the same genes, designed as a benchmark for methods (Chandrasekaran et al. 2024). A morphological map of the over- and underexpression of more than 15,000 genes in human cells followed (Chandrasekaran et al. 2025). The company Recursion has released RxRx3, images and embeddings of more than 17,000 gene knockouts and 1,674 compounds, with some identities hidden (Fay et al. 2023). These data sets are large enough to train foundation models of cell morphology, and to test whether such models can predict the effects of perturbations that were not measured (Section 13.7).

13.5 Protein localisation from images

Where a protein is in the cell is part of its function. 3 describes how localisation is predicted from sequence; this section describes how it is measured and classified from images, which also provides the training data for the sequence-based predictors.

13.5.1 The subcellular atlas of the Human Protein Atlas

The subcellular section of the Human Protein Atlas (Section 8.6) is based on immunofluorescence: each protein is stained with antibodies in cell lines, together with markers for the nucleus, microtubules and the endoplasmic reticulum, and imaged by confocal microscopy. The first version mapped 12,003 proteins to 30 subcellular structures and showed that about half of all proteins are found in more than one location (Thul et al. 2017). Many proteins also vary between individual cells of the same cell line; about a fifth of the proteome shows such cell-to-cell variability, and only part of it is explained by the cell cycle (Mahdessian et al. 2021).

13.5.2 Image classification as a community challenge

Annotating localisation by eye does not scale, so the HPA organised two open Kaggle competitions. In the first, more than 2,000 teams classified images into 28 location classes, with up to six labels per image. The best models clearly outperformed the earlier automated method, but did not reach the accuracy of human experts (Ouyang et al. 2019). The second competition was *weakly supervised*: labels were given for whole images, and the models had to predict the localisation of each individual cell (Le et al. 2022). The two competitions illustrate several general issues of image classification: multi-label output, rare classes, the choice of evaluation metric (macro-F1 gives each class equal weight) and labels that are themselves uncertain.

13.5.3 Endogenous tagging and self-supervised models

Antibodies can bind other proteins than their target. An alternative is to tag the endogenous gene with a fluorescent label. **OpenCell**, at the Chan Zuckerberg Biohub, tagged more than a thousand human proteins with CRISPR, imaged them in living cells and identified their interaction partners by mass spectrometry; proteins with similar localisation patterns often interact (Cho et al. 2022). Using these images, **cytoself** learned a representation of localisation without any labels, by self-supervised learning, and grouped proteins down to the level of individual complexes (Kobayashi et al. 2022). **SubCell** applies self-supervised vision transformers to the whole HPA image collection and produces a hierarchical map of the proteome learned from images alone (Gupta et al. 2024). Such image embeddings can be combined with sequence embeddings from protein language models (Section 1.10).

13.5.4 Organisation of the whole cell

The **Allen Institute for Cell Science** has taken a complementary approach: instead of many proteins in one cell line, it tagged 25 key structures in human induced pluripotent stem cells and imaged more than 200,000 living cells in three dimensions. The data show that the organisation of the cell's interior is robust to large variation in cell shape, and provide a quantitative description of what a "normal" cell looks like (Viana et al. 2023). The images are available through the Allen Cell Explorer.

13.6 Tissues: multiplexed imaging and computational pathology

Cells in a tissue are defined not only by what they express but also by where they are and which cells they touch. Images of tissues are therefore analysed both to classify cell types and to describe how they are arranged.

13.6.1 Multiplexed imaging and spatial omics

Highly multiplexed imaging measures tens of proteins in the same tissue section (Section 8.6). In CODEX, antibodies carry DNA barcodes that are read in repeated cycles (Goltsev et al. 2018). In imaging mass cytometry (Giesen et al. 2014) and multiplexed ion beam imaging (MIBI) (Angelo et al. 2014), antibodies are labelled with metal isotopes that are read by mass spectrometry. Imaging-based spatial transcriptomics, such as MERFISH (Chen et al. 2015) and Xenium (Janesick et al. 2023), measures hundreds to thousands of RNAs in the same way (Section 7.6); an overview of the technologies is given by Park et al. (2022).

The analysis is the same for all of these methods: *segment* the cells (Section 13.3), *quantify* each marker in each cell, *assign cell types*, and analyse *spatial neighbourhoods*, for example which cell types are found next to each other more often than expected by chance. Cell types are usually assigned by clustering, as for single-cell RNA-seq, but they can also be classified directly from the images; CellSighter, a CNN trained on a few thousand labelled cells, reaches about the agreement between human annotators (Amitay et al. 2023).

13.6.2 Computational pathology

Pathologists diagnose cancer and other diseases from H&E-stained tissue sections, and digital scanners have made these slides available for machine learning. A whole-slide image is too large to process at once, so it is split into thousands of small *tiles*, each tile is embedded with a network, and the embeddings are aggregated, often with attention, to make a prediction for the slide (*multiple-instance learning*). Networks trained in this way grade tumours, predict mutations, and predict gene expression from morphology, which links histology to spatial transcriptomics (He et al. 2020).

Since 2024, several **pathology foundation models** have been trained by self-supervised learning on very large collections of slides: UNI on more than 100,000 slides (Chen et al. 2024), Virchow on about 1.5 million (Vorontsov et al. 2024) and Prov-GigaPath on more than 170,000 slides, with a model of the whole slide rather than single tiles (Xu et al. 2024). CONCH was trained on pairs of images and captions, so that slides can be searched and classified with text (Lu et al. 2024). Their embeddings are used as general features for many clinical tasks.

A warning example shows why careful evaluation is needed. In The Cancer Genome Atlas, the hospital that submitted a slide can be recognised from the image itself, from differences in staining and scanning, even after colour normalisation. Models can use these site signatures to predict outcomes, which inflates accuracy when training and test sets contain slides from the same sites (Howard et al. 2021). This is the image version of the data leakage described in 4.

13.7 Cell atlases and virtual cells

The methods of this chapter and of Section 7.6 are now being combined in very large projects. Their first aim is to catalogue all human cell types; their more ambitious aim is a model that can predict how a cell behaves.

13.7.1 Cell atlases

The **Human Cell Atlas** (HCA), launched in 2016, aims to describe every cell type in the human body by its molecular profile, location and morphology, and to make all data openly available (Regev et al. 2017). A collection of papers published in 2024 described progress from a census of cells towards three-dimensional maps of organs and foundation models trained on the atlas (Rood et al. 2024). The NIH **Human BioMolecular Atlas Program** (HuBMAP) builds three-dimensional maps of human tissues at single-cell resolution, combining imaging with omics (HuBMAP Consortium 2019; Jain et al. 2023). The Human Protein Atlas (Section 8.6) and the Allen Institute for Cell Science (Section 13.5) contribute the protein and imaging dimensions.

13.7.2 The idea of an AI virtual cell

A widely cited perspective from 2024 proposed the **AI virtual cell**: a model, learned from data, that represents molecules, cells and tissues in different states, and can *simulate* the effect of perturbations that have never been measured (Bunne et al. 2024). Unlike the mechanistic models of Section 13.8, such a model would not be built from known reactions but learned from atlases, perturbation screens and images. Its proposed uses include predicting the effects of drugs and mutations and designing experiments in silico.

Several large initiatives are working towards this goal:

- The **Chan Zuckerberg Initiative** (CZI) and its Biohubs have made virtual cells a central aim. They run an open *Virtual Cells Platform* with models, data sets and benchmarks, and in 2025 started the *Billion Cells Project* to generate single-cell data for training models. Models include TranscriptFormer, trained on single-cell data from twelve species (Pearce et al. 2025), and rBio, a language model trained with virtual cell models as a source of feedback (Istrate et al. 2025).
- The **Arc Institute** developed State, a model of the response of cells to perturbations trained on more than 100 million perturbed cells (Adduri et al. 2026), and runs the annual **Virtual Cell Challenge**, a blind test of perturbation prediction in the spirit of CASP (Roohani et al. 2025) (Section 9.2).
- **Alpha Cell**, a strategic programme of SciLifeLab funded by the Knut and Alice Wallenberg Foundation and led by Jan Ellenberg and Mathias Uhlén, aims to build predictive AI models of human cells. It starts from the data of the Human Protein Atlas, and adds spatial models from light and electron microscopy and temporal models of how cells change. In 2026 it was funded until 2033, with KTH, Stockholm University, Karolinska Institutet and Uppsala University as partners (scilifelab.se/alpha-cell).

- Google DeepMind has said publicly that a virtual cell is a long-term goal after AlphaFold, but has not described a specific project.

13.7.3 How good are the models?

Predicting the effect of a perturbation on gene expression is the most common test of a virtual cell. GEARS used a knowledge graph of gene–gene relations to predict the effect of combinations of perturbations (Roohani et al. 2023), and single-cell foundation models (Section 7.6) have been fine-tuned for the same task. Independent evaluations, however, found that deep-learning models did not outperform deliberately simple linear baselines (Ahlmann-Eltze et al. 2025), and that the embeddings of foundation models used without fine-tuning were often no better than simpler methods (Kedzierska et al. 2025). The organisers of the first Virtual Cell Challenge in 2025 reached a similar conclusion: most models did not consistently beat simple baselines across all metrics, and no single metric captured what makes a model good. These results do not show that the goal is wrong, but they show that the claims should be tested, as for protein structure prediction, by blind benchmarks against simple baselines (4).

>
> Background from the Wikipedia article Human Cell Atlas (CC BY-SA 4.0, retrieved 5 October 2026), and from the web pages of the CZI Virtual Cells Platform, the Arc Institute Virtual Cell Challenge and SciLifeLab Alpha Cell (retrieved 5 October 2026).

13.8 Whole-cell models and cryo-electron tomography

The AI virtual cell (Section 13.7) is learned from data. An older and complementary approach builds a model of a cell from its known parts: genes, reactions, molecules and their structures. Such models are explicit about mechanism, but need a complete parts list, which exists only for the simplest cells.

13.8.1 Mechanistic whole-cell models

The first **whole-cell model** simulated the complete life cycle of *Mycoplasma genitalium*, a bacterium with 525 genes. It combined 28 sub-models of different cellular processes, such as metabolism, transcription, translation and DNA replication, each described with the mathematics best suited to it, and predicted phenotypes, such as the growth of single-gene deletion strains, from the genotype (Karr et al. 2012).

The synthetic minimal cell JCVI-syn3A, with 493 genes, has been modelled in more detail. A kinetic model in which the geometry of the cell and the positions of its ribosomes were taken from cryo-electron tomograms reproduced the doubling time and the distribution of mRNA half-lives (Thornburg et al. 2022), and a later model simulated the complete cell cycle, including chromosome segregation and division, in space and time (Thornburg et al. 2026). Such models show which behaviours follow from the known parts, and where knowledge is missing.

13.8.2 Structural models of a cell

Going further, the physical structure of an entire cell can be modelled. Structural models of a whole *Mycoplasma* cell have been built by packing experimental and predicted protein structures, the genome and membranes into a cell volume (Maritan et al. 2022), and work towards simulating an entire minimal cell with molecular dynamics (Section 9.11), at a coarse-grained level, is under way (Stevens et al. 2023). All-atom simulations of a small part of a bacterial cytoplasm showed that crowding and weak interactions between proteins affect their stability and diffusion (Yu et al. 2016). Predicted structures and complexes (Chapter 9 and Chapter 11) provide many of the parts for such models.

13.8.3 Cryo-electron tomography and visual proteomics

Cryo-electron tomography (cryo-ET) images frozen cells, or thin slices of them cut with a focused ion beam, from many angles, and reconstructs a three-dimensional image of the cell interior at close to molecular resolution (Young and Villa 2023; Beck and Baumeister 2016). Unlike single-particle cryo-EM (Section 9.4), it shows complexes in their native context. The idea of **visual proteomics** is to identify and locate every large complex in such tomograms, so that the composition and organisation of a cell can be read from an image (Nickell et al. 2006). In the small bacterium *Mycoplasma pneumoniae*, cryo-ET combined with cross-linking mass spectrometry revealed how RNA polymerase and the ribosome are coupled (O'Reilly et al. 2020), and averaging many copies of the ribosome in cells reached 3.5 Å resolution (Tegunov et al. 2021).

Finding particles in noisy tomograms is an image-analysis problem of the kind described in Section 13.3. Deep-learning methods segment membranes and locate complexes, either trained for specific targets (Teresa-Trueba et al. 2023) or with embeddings that generalise to new ones (Rice et al. 2023), and dedicated tools analyse membranes and membrane proteins (Lamm et al. 2026). The CZ Imaging Institute's **CryoET Data Portal** provides standardised, annotated tomograms for training (Ermel et al. 2024), and a Kaggle competition on particle picking showed how open challenges can improve the methods (Peck et al. 2026). Cryo-ET thus connects the two directions of this chapter: it provides images of whole cells at molecular detail, and the geometry needed by mechanistic and structural models.

13.9 Key concepts

A checklist for revision.

- **Images as data:** pixels, channels, z-stacks and time series; intensity is not a molecule count; transmitted light, fluorescence, electron microscopy and histology; whole-slide images
- **Classical analysis:** preprocessing, thresholding and watershed segmentation, feature extraction; Fiji, CellProfiler, ilastik, QuPath, napari
- **Data and standards:** metadata (REMBI), OME-Zarr; BioImage Archive, Image Data Resource, BBBC; the Cell Tracking Challenge
- **Tasks:** image and cell classification; semantic vs. instance segmentation; detection and tracking; restoration and label-free prediction

- **Architectures:** CNNs (AlexNet, ResNet); U-Net and skip connections; StarDist (star-convex polygons) and Cellpose (flow fields); vision transformers
- **Self-supervision and foundation models:** DINO and DINOv2, masked autoencoders; Segment Anything and its microscopy versions; why self-supervision matters when labels are scarce
- **Pitfalls:** batch effects between plates, microscopes and hospitals; splitting by experiment; disagreement between annotators; hallucinated structures in predicted images; site signatures in pathology
- **Image-based profiling:** Cell Painting (six dyes, five channels, eight components); single-cell features, aggregation and normalisation to controls; batch correction; profile similarity and mechanism of action; JUMP and RxRx3
- **Protein localisation:** the HPA subcellular atlas; multi-localising proteins and cell-to-cell variation; the HPA Kaggle competitions, multi-label classification and macro-F1; weak supervision; OpenCell, endogenous tagging and cytoself; SubCell; combining image and sequence embeddings
- **Tissues:** CODEX, imaging mass cytometry and MIBI; imaging-based spatial transcriptomics; segmentation, cell-type assignment and neighbourhood analysis; multiple-instance learning on whole slides; pathology foundation models (UNI, CONCH, Virchow, Prov-GigaPath); predicting expression from histology
- **Atlases:** the Human Cell Atlas, HuBMAP, the Allen Institute for Cell Science; what is a cell type?
- **AI virtual cells:** definition; perturbation prediction (GEARS, State); the Virtual Cell Challenge; CZI (Virtual Cells Platform, Billion Cells Project, TranscriptFormer) and SciLifeLab's Alpha Cell; why simple baselines are often as good as deep models
- **Mechanistic models:** the *M. genitalium* whole-cell model; the JCVI-syn3A minimal cell in 4D; structural and molecular-dynamics models of whole cells; learned vs. mechanistic models
- **Cryo-electron tomography:** in situ structural biology; focused-ion-beam milling; subtomogram averaging; visual proteomics; deep learning for particle picking and membrane segmentation; the CryoET Data Portal

13.10 Recommended reading

These papers are recommended for reading in full:

- Chamier et al. (2019) — what a biologist should know about deep learning for microscopy, including its pitfalls.
- Stringer et al. (2020) — Cellpose; a generalist deep-learning method for cell segmentation.
- Ouyang et al. (2019) — image classification of protein localisation as a community challenge, with lessons for evaluation.
- Chandrasekaran et al. (2024) — Cell Painting and image-based profiling of matched chemical and genetic perturbations (JUMP).
- Bunne et al. (2024) — the AI virtual cell; what it is meant to be and how it could be built.
- Ahlmann-Eltze et al. (2025) — a critical test; deep-learning models of perturbation effects against simple baselines.
- Thornburg et al. (2026) — a mechanistic, spatial model of the complete cell cycle of a minimal cell.

Titles, abstracts, links and the full texts are in Section A.13; a longer list of further papers is in Section B.13.

13.11 Background reading (open access)

- **Microscopy (Wikipedia)** — Microscopy is the technical field of using microscopes to view subjects too small to be seen with the naked eye. There are three well-known branches of

microscopy: optical, electron, and scanning probe microscopy, along with the emerging field of X-ray microscopy.
https://en.wikipedia.org/wiki/Microscopy

- **Image segmentation (Wikipedia)** — In digital image processing and computer vision, image segmentation is the process of partitioning a digital image into multiple image segments, also known as image regions or image objects. The goal of segmentation is to simplify and/or change the representation of an image into something that is more meaningful and easier to analyze. Image segmentation is typically used to locate objects and boundaries in images.
https://en.wikipedia.org/wiki/Image_segmentation
- **Convolutional neural network (Wikipedia)** — A convolutional neural network (CNN) is a type of feedforward neural network that learns features via filter optimization. This type of deep learning network has been applied to process and make predictions from many different types of data including text, images and audio.
https://en.wikipedia.org/wiki/Convolutional_neural_network
- **U-Net (Wikipedia)** — U-Net is a convolutional neural network that was developed for image segmentation. The network is based on a fully convolutional neural network whose architecture was modified and extended to work with fewer training images and to yield more precise segmentation. Segmentation of a 512 × 512 image takes less than a second on a modern (2015) GPU using the U-Net architecture.
https://en.wikipedia.org/wiki/U-Net
- **Vision transformer (Wikipedia)** — A vision transformer (ViT) is a transformer designed for computer vision. A ViT decomposes an input image into a series of patches, serializes each patch into a vector, and maps it to a smaller dimension with a single matrix multiplication. These vector embeddings are then processed by a transformer encoder as if they were token embeddings.
https://en.wikipedia.org/wiki/Vision_transformer
- **High-content screening (Wikipedia)** — High-content screening (HCS), also known as high-content analysis (HCA) or cellomics, is a method that is used in biological research and drug discovery to identify substances such as small molecules, peptides, or RNAi that alter the phenotype of a cell in a desired manner.
https://en.wikipedia.org/wiki/High-content_screening
- **Human Protein Atlas (Wikipedia)** — The Human Protein Atlas (HPA) is a Swedish-based program started in 2003 with the aim to map all the human proteins in cells, tissues and organs using integration of various omics technologies, including antibody-based imaging, mass spectrometry-based proteomics, transcriptomics and systems biology.
https://en.wikipedia.org/wiki/Human_Protein_Atlas
- **Digital pathology (Wikipedia)** — Digital pathology is a sub-field of pathology that focuses on managing and analyzing information generated from digitized specimen slides. It utilizes computer-based technology and virtual microscopy to view, manage, share, and analyze digital slides on computer monitors.
https://en.wikipedia.org/wiki/Digital_pathology
- **Spatial transcriptomics (Wikipedia)** — Spatial transcriptomics, or spatially resolved transcriptomics, is a method that captures positional context of transcriptional activity within intact tissue. The historical precursor to spatial transcriptomics is in situ hybridization, where the modernized omics terminology refers to the measurement of all the mRNA in a cell rather than select RNA targets. It comprises an important part of spatial biology.
https://en.wikipedia.org/wiki/Spatial_transcriptomics
- **Human Cell Atlas (Wikipedia)** — The Human Cell Atlas is a global project to describe all cell types in the human body, to understand human health and for diagnosing, monitoring, and treating disease.
https://en.wikipedia.org/wiki/Human_Cell_Atlas
- **Cellular model (Wikipedia)** — A cellular model or virtual cell is a computational model of

aspects of a biological cell, for the purposes of in silico research.
https://en.wikipedia.org/wiki/Virtual_cell

- **Cryogenic electron tomography (Wikipedia)** — Cryogenic electron tomography (cryoET) is an imaging technique used to reconstruct high-resolution (~1–4 nm) three-dimensional volumes of samples, often biological macromolecules and cells.
https://en.wikipedia.org/wiki/Cryogenic_electron_tomography

13.12 Student recommendations

Recommended by students preparing for the exam: papers, reviews, online lectures, tutorials and short explanations. To suggest something, use the suggestion form (SU login).

No recommendations yet.

13.13 Review problems

The format of these problems follows Matteo Tadiello, *Modern Bioinformatics: From Foundations to Frontiers* (CC BY 4.0); the problems were written for this book, since that book has no chapter on image analysis. In the HTML version, click a box to show the extensions, solution outline and common errors.

13.13.1 Intensity is not abundance

A fluorescence screen reports that the mean nuclear intensity of a tagged protein is twice as high in treated as in untreated cells. What does this show about the amount of the protein in the nucleus, and what would you check before concluding that the treatment increases it?

Extensions, solution outline and common errors

Extensions:

- Which steps of acquisition and analysis affect the measured intensity?
- How do segmentation errors change a per-nucleus mean?
- What metadata are needed for the result to be reusable?

Solution outline:

1. Each pixel value depends on the label, microscope, exposure, detector and background, not only on the number of molecules; images are comparable only if acquired in the same way.
2. Check that treated and untreated wells were imaged with the same settings, on the same plates or with plate controls, and corrected for background and uneven illumination.
3. Segmentation determines which pixels are counted: if the treatment changes nuclear size or shape, the segmentation may include cytoplasm or miss parts of the nucleus, and a mean can change while the total does not (or the reverse).
4. A change in localisation (from cytoplasm to nucleus) is not the same as a change in total amount; measure both compartments.
5. Use replicate wells and plates as the units, not individual cells, and confirm with an independent method such as western blotting or mass spectrometry.

6. Report acquisition and analysis metadata following REMBI, and deposit the images, for example in the BioImage Archive.

Common errors:

- Treating intensity as a molecule count.
- Counting thousands of cells as independent replicates.
- Ignoring that the treatment can change cell shape and so the segmentation.

Connections: Section 13.2 (images as data, classical analysis, metadata); 4 (non-independent examples).

13.13.2 Choosing a segmentation method

A laboratory needs to segment densely packed, touching nuclei and irregularly shaped cells in a new kind of tissue image. Compare thresholding with watershed, StarDist and Cellpose, and describe how you would evaluate the result.

Extensions, solution outline and common errors

Extensions:

- What is the difference between semantic and instance segmentation?
- Why do U-Net skip connections help?
- How can a general model be adapted to new data with few annotations?

Solution outline:

1. Separating touching objects is an instance-segmentation problem; semantic segmentation (nucleus vs. background) is not enough.
2. Thresholding with a watershed transform is fast and transparent but sensitive to uneven staining and tends to over- or under-split.
3. StarDist predicts star-convex polygons, which suits roughly round nuclei but not irregular cell shapes.
4. Cellpose predicts flow fields towards cell centres and works for many shapes without retraining; Cellpose 2.0 can be adapted with a few corrected images (human in the loop).
5. Evaluate on images annotated independently, ideally by more than one person, from experiments not used for training, with object-level measures (for example matched objects at an overlap threshold) rather than pixel accuracy alone.
6. Check that downstream measurements, such as cell counts or marker intensities, are robust to the choice of method.

Common errors:

- Evaluating on tiles from the same images used for training.
- Reporting pixel accuracy, which is dominated by background.
- Assuming that a general model works on a new tissue without checking.

Connections: Section 13.3 (U-Net, StarDist, Cellpose); 4 (evaluation and test sets).

13.13.3 Self-supervised models and foundation models for images

Explain how self-supervised learning can produce useful features for microscopy images without labels, and how you would test whether a pre-trained image model is better than CellProfiler features for classifying protein localisation.

Extensions, solution outline and common errors

Extensions:

- Compare DINO and masked autoencoders.
- Why have self-supervised methods become important for vision transformers?
- What is a fair comparison?

Solution outline:

1. Vision transformers treat image patches as tokens and need large training sets; labels for microscopy are scarce, which makes self-supervision attractive.
2. In DINO, a student network learns to match a teacher network on different views of the same image; masked autoencoders hide most patches and reconstruct them, like masked language modelling.
3. Features are evaluated by probing: train a simple classifier, for example logistic regression, on frozen embeddings, and compare with the same classifier on CellProfiler features.
4. Split by protein, cell line or experiment rather than by image or cell, so that the same protein does not occur in both training and test sets.
5. Use measures suited to multi-label, imbalanced classes (for example macro-F1 or per-class precision–recall).
6. Check that the embeddings do not mainly encode plate, batch or microscope.

Common errors:

- Splitting by cell, so that images of the same protein are on both sides.
- Comparing a tuned deep model with an untuned baseline.
- Assuming that a model pre-trained on natural images, such as SAM, works on microscopy without fine-tuning or testing.

Connections: Section 13.3 (vision transformers and self-supervision); Section 13.5 (HPA and image-based localisation); Section 12.6 (evaluating foundation models).

13.13.4 Image-based profiling

Describe how a Cell Painting experiment is turned into profiles, and how such profiles can be used to suggest the mechanism of action of an uncharacterised compound.

Extensions, solution outline and common errors

Extensions:

- What do the six dyes label?
- Why normalise to negative controls on the same plate?
- How would you test whether a compound has any effect at all?

Solution outline:

1. Six dyes, imaged in five channels, label DNA, RNA and nucleoli, the endoplasmic reticulum, actin, Golgi and plasma membrane, and mitochondria.
2. Cells are segmented and hundreds to thousands of size, shape, intensity and texture features (or deep embeddings) are measured per cell.
3. Features are aggregated per well, normalised against negative controls on the same plate, reduced to informative, uncorrelated features, and corrected for batch effects between plates and sites.
4. Test whether a compound's profile differs from controls more than replicate controls differ from each other.
5. Compare its profile with profiles of compounds of known mechanism, or of genetic perturbations, for example by cosine similarity; similar profiles suggest a shared mechanism, a hypothesis to be tested.
6. Evaluate such matching with held-out plates and replicate consistency, as in the CPJUMP1 benchmark.

Common errors:

- Interpreting profile similarity as proof of a shared target.
- Ignoring plate and batch effects, so that compounds on the same plate look similar.
- Using cells rather than wells or plates as replicates.

Connections: Section 13.4 (Cell Painting, JUMP, RxRx3); Section 7.4 (normalisation, batch effects, clustering).

13.13.5 Site signatures in computational pathology

A model trained on whole-slide images from The Cancer Genome Atlas predicts patient survival with high accuracy. Explain how site signatures could inflate this result and how you would design a fair evaluation.

Extensions, solution outline and common errors

Extensions:

- How is a whole-slide image turned into a single prediction?
- Why does colour normalisation not solve the problem?
- What role can pathology foundation models play?

Solution outline:

1. Slides are split into tiles, each tile is embedded, and the embeddings are aggregated, often with attention, in multiple-instance learning.
2. Staining, scanning and preparation differ between hospitals, and the submitting site can be recognised from the image even after colour normalisation.
3. If survival or patient mix differs between sites, a model can predict outcome by recognising the site; with slides from the same sites in training and test sets, accuracy is inflated.
4. Split by site, keep all slides from a patient together, and test on an external cohort.
5. Check whether the site can be predicted from the embeddings and whether performance holds within sites.

6. Foundation models such as UNI or Virchow give general features, but their embeddings can also encode site, and their pre-training data may overlap with the test slides.

Common errors:

- Splitting by tile or slide rather than by patient and site.
- Assuming colour normalisation removes all site effects.
- Interpreting attention maps as the cause of the prediction.

Connections: Section 13.6 (computational pathology); 4 (data leakage and external validation); Section 12.4 (interpretability).

13.13.6 Spatial analysis of multiplexed images

A study of multiplexed tissue images (for example imaging mass cytometry) reports that T cells are found next to tumour cells more often than expected in patients who respond to therapy. Describe the analysis, and what is needed before the result is trusted.

Extensions, solution outline and common errors

Extensions:

- What are the steps from image to cell types?
- What is a suitable null model for neighbourhood enrichment?
- What is the independent unit?

Solution outline:

1. Segment the cells, quantify each marker per cell, and assign cell types by clustering or by a classifier such as CellSighter.
2. Segmentation errors cause spill-over of markers between neighbouring cells, which can create apparent mixed cell types and spurious neighbours.
3. Neighbourhood enrichment is tested against permutations of cell-type labels within each image, which keep the positions and density of cells.
4. Tissue architecture (for example tumour borders) and the area sampled can cause enrichment by themselves.
5. The patient is the unit: many cells or regions from one patient are not independent replicates, and the comparison between responders and non-responders must be made between patients, with an independent cohort.
6. Spatial association is not causation; a role of T-cell contact would need perturbation or longitudinal data.

Common errors:

- Treating each cell or image region as an independent sample.
- Using a null model that ignores tissue structure.
- Ignoring marker spill-over from segmentation errors.

Connections: Section 13.6 (multiplexed imaging and spatial omics); Section 7.6 (spatial transcriptomics and cell types); Section 12.8 (prediction and causation).

13.13.7 How good is a virtual cell?

A company claims that its AI virtual cell model predicts the transcriptional response of human cells to genetic perturbations that were never measured. What evidence would you require?

Extensions, solution outline and common errors

Extensions:

- What baselines should be used?
- How should the test perturbations be chosen?
- Why did the first Virtual Cell Challenge find no single good measure?

Solution outline:

1. Define what is predicted (expression changes, cell-type shifts, combinations) and in which cell types.
2. Hold out perturbations, and ideally cell types or experiments, that were not in training; combinations should not have their single perturbations in the test set if that is the claim.
3. Compare with simple baselines, such as predicting the mean response or a linear model, which in independent evaluations have matched deep models.
4. Use several measures (correlation of changes, error on differentially expressed genes, ranking of perturbations), since a model can look good on one and poor on another.
5. Prefer blind benchmarks, such as the Virtual Cell Challenge, in which predictions are made before the data are released.
6. Confirm selected predictions experimentally.

Common errors:

- Accepting performance on perturbations similar to the training data as generalisation.
- Omitting simple baselines.
- Reporting only the most favourable measure.

Connections: Section 13.7 (virtual cells and their evaluation); Section 12.6 (foundation models and baselines); Section 9.2 (blind benchmarks).

13.13.8 Mechanistic and learned models of cells

Compare a mechanistic whole-cell model, such as that of *Mycoplasma genitalium* or JCVI-syn3A, with a learned AI virtual cell. What can each do, and how can cryo-electron tomography contribute to both?

Extensions, solution outline and common errors

Extensions:

- Why have mechanistic models been built only for minimal cells?
- What is visual proteomics?
- What are the image-analysis problems of cryo-ET?

Solution outline:

1. Mechanistic models are built from known genes, reactions and structures, combine sub-models of processes such as metabolism and replication, and predict phenotypes, such as

the growth of deletion strains, from genotype; they need a nearly complete parts list and many parameters.
2. Learned models are trained on atlases, perturbation screens and images; they can cover human cells but are only as good as their training data and must be tested against simple baselines.
3. Mechanistic models show which behaviours follow from known parts and where knowledge is missing; learned models may predict without explaining.
4. Cryo-ET gives three-dimensional images of the cell interior near molecular resolution; visual proteomics aims to identify and locate every large complex.
5. Finding particles in noisy tomograms is a deep-learning problem; annotated data such as the CryoET Data Portal and open challenges help.
6. The geometry from cryo-ET (cell shape, ribosome positions) was used in the JCVI-syn3A model, and structural maps can provide training data and parts for both kinds of model.

Common errors:

- Assuming either kind of model is complete or correct because it reproduces some observations.
- Confusing cryo-ET with single-particle cryo-EM.

Connections: Section 13.8 (whole-cell models and cryo-ET); Section 13.7 (AI virtual cells); Section 9.4 (cryo-EM); Section 11.3 (systems biology and metabolic models).

A Recommended reading

For each chapter, about six papers are recommended for reading in full. Most of them come from the reading lists used for the exam in earlier years. They are listed here with their titles, abstracts and links. In the PDF version the open-access papers follow each list in full; the others are available with your SU login through the library link.

A.1 Sequence searching

Recommended reading for Chapter 1 (listed in Section 1.13).

  > The BLAST programs are widely used tools for searching protein and DNA databases for sequence similarities. For protein comparisons, a variety of definitional, algorithmic and statistical refinements described here permits the execution time of the BLAST programs to be decreased substantially while enhancing their sensitivity to weak similarities. A new criterion for triggering the extension of word hits, combined with a new heuristic for generating gapped alignments, yields a gapped BLAST program that runs at approximately three times the speed of the original. In addition, a method is introduced for automatically combining statistically significant alignments produced by BLAST into a position-specific score matrix, and searching the database using this matrix. The resulting Position-Specific Iterated BLAST (PSI-BLAST) program runs at approximately the same speed per iteration as gapped BLAST, but in many cases is much more sensitive to weak but biologically relevant sequence similarities. PSI-BLAST is used to uncover several new and interesting members of the BRCT superfamily.

Abstract

Profile hidden Markov models (profile HMMs) and probabilistic inference methods have made important contributions to the theory of sequence database homology search. However, practical use of profile HMM methods has been hindered by the computational expense of existing software implementations. Here I describe an acceleration heuristic for profile HMMs, the "multiple segment Viterbi" (MSV) algorithm. The MSV algorithm computes an optimal sum of multiple ungapped local alignment segments using a striped vector-parallel approach previously described for fast Smith/Waterman alignment. MSV scores follow the same statistical distribution as gapped optimal local alignment scores, allowing rapid evaluation of significance of an MSV score and thus facilitating its use as a heuristic filter. I also describe a 20-fold acceleration of the standard profile HMM Forward/Backward algorithms using a method I call "sparse rescaling". These methods are assembled in a pipeline in which high-scoring MSV hits are passed on for reanalysis with the full HMM Forward/Backward algorithm. This accelerated pipeline is implemented in the freely available HMMER3 software package. Performance benchmarks show that the use of the heuristic MSV filter sacrifices negligible sensitivity compared to unaccelerated profile HMM searches. HMMER3 is substantially more sensitive and 100- to 1000-fold faster than HMMER2. HMMER3 is now about as fast as BLAST for protein searches.

Introduction

Sequence database homology searching is one of the most important applications in computational molecular biology. Genome sequences are being acquired rapidly for an ever-widening array of species. To make maximal use of sequence data, we want to maximize the power of computational sequence comparison tools to detect remote homologies between these sequences, to learn clues to their functions and evolutionary histories. The most widely used tool for sequence comparison and database search is BLAST [1–3].

Since BLAST's introduction, some important advances have been made in the theory of sequence comparison, particularly by using probabilistic inference methods based on profile hidden Markov models (profile HMMs) [4]. Probabilistic modeling approaches provide a consistent framework for parameterizing complex position-specific models of sequence conservation and evolution [5]. Numerous improvements have been made in BLAST in light of these advances [6–9]. Fundamentally, though, the BLAST implementation computes optimal local alignment scores using *ad hoc* gap penalties. This implementation core may not be readily adaptable to a probabilistic insertion/deletion model and the more powerful "Forward/Backward" HMM algorithm that computes not just one best-scoring alignment, but a sum of probabilities over the entire local alignment ensemble. The Forward algorithm allows a more powerful and formal log-likelihood score statistic to be assigned to each target sequence, and Forward/Backward allows confidence values to be assigned to each aligned residue.

Nonetheless, regardless of any of the attractive advantages of HMMs, no implementation of fully probabilistic sequence comparison methods has yet approached the utility of BLAST. The most widely used implementations of profile HMM technology, including HMMER from my laboratory, have been slow and computationally expensive, on the order of 100- to 1000-fold slower than BLAST for a comparably sized search. In an era of enormous sequence databases, this speed disadvantage outweighs any advantage of HMM methods. Profile HMM methods have become important only in the niche of protein domain family analysis, where the speed differential is compensated by being able to use a single profile HMM to represent a family of hundreds of homologous individual sequences [10,11].

HMMER has been a target of many acceleration and optimization efforts [12–15] but these efforts have had limited impact. The only accelerations that have reported large gains have implemented HMMER's native dynamic programming algorithms on specialized hardware, including FPGAs (field-programmable gate arrays) [16–19], VLSI ASICs (special-purpose chips), GP-GPUs (general purpose graphics processor units) [20,21], and large multiprocessor clusters [22,23]. Fewer efforts have been made to develop fast heuristic profile HMM algorithms for standard commodity processors [24–26] in ways comparable to how BLAST heuristically approximates and accelerates Smith/Waterman optimal dynamic programming alignment [27]. The challenge is that to preserve the significant yet narrow gain in sensitivity that profile HMM methods show over BLAST [28–30], any useful profile HMM acceleration heuristic must be more sensitive than BLAST's already excellent heuristics.

Another reason for the limited impact of previous acceleration efforts is that they have almost exclusively focused on accelerating the optimal local alignment scoring algorithm (known as the

Author Summary

Searching sequence databases is one of the most important applications in computational molecular biology. The main workhorse in the field is the BLAST suite of programs. Since the introduction of BLAST in the 1990's, important theoretical advances in homology search methodology have been made using probabilistic inference methods and hidden Markov models (HMMs). However, previous software implementations of these newer probabilistic methods were slower than BLAST by about 100-fold. This hindered their utility, because computation speed is so critical with the rapidly increasing size of modern sequence databases. Here I describe the acceleration methods I implemented in a new, freely available profile HMM software package, HMMER3. HMMER3 makes profile HMM searches about as fast as BLAST, while retaining the power of using probabilistic inference technology.

Viterbi algorithm in the HMM literature) as opposed to the more desirable Forward algorithm. In part, this is because optimal local alignment algorithms are more well known, and in part it is because previous versions of HMMER itself implemented Viterbi rather than Forward scoring. Forward implementations are about 3- to 9-fold slower than Viterbi implementations, and the expected statistical distribution of Forward scores for profile HMMs was not understood well enough to assign accurate E-values (expectation values). I recently described a satisfactory solution to the latter problem [31], which leaves the problem of acceleration.

Here I describe the heuristic acceleration pipeline implemented by HMMER3, a reimplemented version of the HMMER software. In comparison to the previous version of HMMER, HMMER3 is about 100-fold faster because of the use of a new heuristic algorithm called the MSV filter, while also being significantly more powerful because it moves from optimal local Viterbi alignment to full Forward/Backward evaluation of alignment ensembles, exploiting more of the mathematical advantages of probabilistic modeling. Thus HMMER3 is now about as fast as BLAST, while extending the performance advantages of profile HMM methods.

Results

Overview

The main algorithm that accelerates HMMER3 is called MSV, for Multiple (local, ungapped) Segment Viterbi. It was inspired by a technique used in ParAlign [32]. As shown in Figure 1, the MSV model is an ungapped version of HMMER3's multihit local alignment model. MSV's probabilistic model of multihit ungapped local alignment is achieved simply by ignoring the match, delete, and insert state transitions of the original profile and implicitly treating match-match transitions as 1.0.

An MSV score is essentially analogous to BLAST's "sum score" of one or more ungapped HSPs (high scoring pairs). A difference is that MSV does not impose alignment consistency (two ungapped alignments are not required to be consistent with a single gapped alignment). In a filtering heuristic, this difference is not important. HMMER3 calculates the MSV score directly by dynamic programming, bypassing the word hit and hit extension heuristics of BLAST.

The fact that MSV essentially bypasses two of BLAST's main heuristics provides an intuitive argument why MSV scores are expected to be a more sensitive overall heuristic than BLAST's approach. However, I have not attempted to rigorously compare the performance of HMMER's MSV heuristic to other acceleration heuristics such as those in BLAST or FASTA.

The HMMER3 implementation takes advantage of several synergistic statistical and computational features of the MSV model. I summarize these features here before describing them in detail:

- MSV alignment scores can be calculated efficiently using so-called "striped" vector-parallel techniques originally developed for Smith/Waterman local sequence alignment [33], because the MSV model removes deletion and insertion states that interfere with vector parallelism.
- Because the MSV model gives predictable score distributions for nonhomologous sequences, with scores confined to a narrow range that is largely independent of query and target sequence characteristics, MSV values can be approximated with reduced precision (8 bits, in a score range of 0–255). This allows a 16-fold vector parallelism in current commodity processors with 128-bit vector registers.
- The MSV model remains a full probabilistic local alignment model, so MSV scores obey conjectures about the expected Gumbel distribution of probabilistic local alignment scores [31]. This allows the rapid calculation of P-values.
- Because we can calculate MSV P-values, we can use MSV scores as a tunable and selective sequence filter. If a target sequence has an MSV score with a P-value less than a chosen threshold, we pass the entire sequence to more accurate and computationally intensive scoring algorithms. By definition, the P-value threshold is the fraction of nonhomologous sequences expected to pass the filter.

The MSV filter is a heuristic acceleration, not guaranteed to find all high-scoring targets. Overall performance of the HMMER3 acceleration pipeline in terms of speed, specificity, and sensitivity depends on several issues and tradeoffs, including how fast the filters are, how accurately and quickly P-values can be estimated for filter scores, and whether a threshold on MSV P-values can be set to remove most nonhomologs while removing few if any true homologs that an unfiltered search would have detected. These are empirical questions, which I have addressed by benchmarking experiments.

The following sections, especially on vector parallelization and on assuring that scores can be kept in limited numeric ranges, are necessarily technical and terse. On a first reading, the reader may want to skip or skim ahead to the "HMMER3 acceleration pipeline" section to see how these technical aspects fit together into an overall scheme, and how that acceleration scheme performs.

MSV model: notation and parameterization

The MSV score for target sequence $\mathbf{x}$ is a standard HMM Viterbi score, a log likelihood ratio score of a single optimal (maximally likely) alignment: the ratio of the probability of the optimal alignment $\mathring{\pi}$ for $\mathbf{x}$ given the MSV model M^{MSV} and the probability of the sequence given a null hypothesis model R:

$$\mathrm{S}^{\mathrm{MSV}}(\mathbf{x}) = \log_2 \frac{\mathrm{Prob}(\mathbf{x},\mathring{\pi}|M^{\mathrm{MSV}})}{\mathrm{Prob}(\mathbf{x}|R)}$$

For a query of length M positions, the MSV profile has KM match emission parameters (where K is the alphabet size, 4 nucleotides or 20 amino acids), plus $M+8$ additional state transition parameters involving the flanking N, B, E, C, and J states that account for nonhomologous residues. Other state

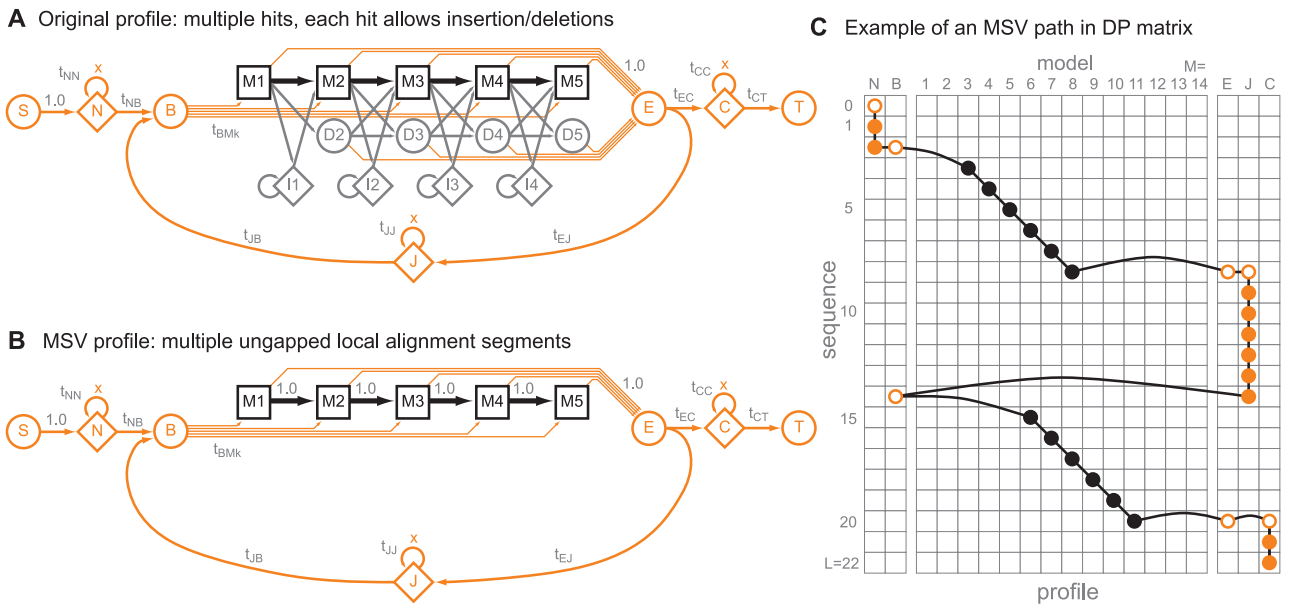

Figure 1. The MSV profile. A: Profile HMM architecture used by HMMER3 [4,5,31]. Regions homologously aligned to the query are represented by a linear core model consisting of M consensus positions (in this example, $M=5$), each consisting of a match, a delete, and an insert state (shown as boxes marked M, circles marked D, and diamonds marked I), connected by state transition probabilities (arrows). Match states carry position-specific emission probabilities for scoring residues at each consensus position. Insert states emit residues with emission probabilities identical to a background distribution. Additional flanking states (marked N, C, and J) emit zero or more residues from the background distribution, modeling nonhomologous regions preceding, following, or joining homologous regions aligned to the core model. Start (S), begin (B), end (E) and termination (T) states do not emit. B: The MSV profile is formed by implicitly treating all match-match transition probabilities as 1.0. This corresponds to the virtual removal of the delete and insert states. The rest of the profile parameterization stays the same. This model generates sequences containing one or more ungapped local alignment segments. Note that both models appear to be improperly normalized; for example, each match state in the MSV model has probability 1.0 local exit transition (orange arrows) in addition to the probability 1.0 match-match transition. This is because of a trick used to establish a uniform local fragment length distribution, in which these profiles are collapsed representations of a much larger (and properly normalized) "implicit probability model", as explained in [31]. C: An example of what an alignment of a larger MSV profile (of length $M=14$) to a target sequence (of length $L=22$) might look like, as a path through a dynamic programming (DP) matrix. Here, the model identifies two high-scoring ungapped alignment segments (black dots, indicating residues aligned to profile match states), and assigns all other residues to N, J, and C states in the model (orange dots; unfilled indicates a "mute" nonemitting state or state transition). Note that the ungapped diagonals are not enforced to be consistent with a single gapped alignment.
doi:10.1371/journal.pcbi.1002195.g001

transitions in the original profile are ignored, which means implicitly treating match-match transitions as 1.0.

The null model R is assumed to be an HMM with a single state R emitting residues a with background frequencies $f(a)$ (i.e. a standard i.i.d. null model: independent, identically distributed residues), with a geometric length distribution specified by a transition parameter t_{RR}.

The KM position-specific match scores $\sigma_k(a)$ are precomputed as log-odds ratios for a residue a emitted from match state M_k with emission probability $e_k(a)$, compared to the null model background frequencies f_a:

$$\sigma_k(a) = \log_2 \frac{e_k(a)}{f_a}.$$

These match scores (as well as the emission probabilities and background frequencies) are the same as in the original profile.

The only state transition parameters in the MSV model are those that control target sequence length modeling, the uniform local alignment fragment length distribution, and the number of hits to the core homology model per target sequence [31]. These too are identical to the parameterization of the original profile [31]. Specifically, they are set as follows for a target sequence of length L residues and a model of length M consensus positions:

Target sequence length modeling:

$$t_{NN} = t_{CC} = t_{JJ} = \frac{L}{L+3},$$
$$t_{NB} = t_{CT} = t_{JB} = \frac{3}{L+3},$$
$$t_{RR} = \frac{L}{L+1}.$$

Uniform local alignment fragment length distribution:

$$t_{BM_k} = \frac{2}{M(M+1)},$$
$$t_{M_kE} = 1.0.$$

Multiple hits per target:

$$t_{EC} = 0.5,$$
$$t_{EJ} = 0.5.$$

MSV score algorithm (serial version)

The MSV alignment score can be calculated by a dynamic programming recursion in a two-dimensional matrix $W(i,s)$ indexed by HMM state (M_k,*NBECJ*) and target sequence residue i:

Initialization:

$$W(0,\mathrm{E}) = W(0,\mathrm{C}) = W(0,\mathrm{J}) = -\infty;$$
$$W(0,\mathrm{M}_k) = -\infty, \forall k;$$
$$W(i,\mathrm{M}_0) = -\infty, \forall i;$$
$$W(0,\mathrm{N}) = 0;$$
$$W(0,\mathrm{B}) = t_{\mathrm{NB}}.$$

Recursion:

for $i = 1$ to L:

for $k = 1$ to M:

$$W(i,\mathrm{M}_k) = \sigma_k(x_i) + \max\left\{ W(i-1,\mathrm{M}_{k-1}),\ W(i-1,\mathrm{B}) + \log_2 t_{\mathrm{BM}_k} \right\};$$

$$W(i,\mathrm{E}) = \max_k W(i\mathrm{M}_k);$$

$$W(i,\mathrm{N}) = W(i-1,\mathrm{N}) + \log_2\ t_{\mathrm{NN}};$$

$$W(i,\mathrm{J}) = \max\{ W(i-1,\mathrm{J}) + \log_2\ t_{\mathrm{JJ}},\ W(i-1,\mathrm{E}) + \log_2\ t_{\mathrm{EJ}} \};$$

$$W(i,\mathrm{C}) = \max\{ W(i-1,\mathrm{C}) + \log_2\ t_{\mathrm{CC}},\ W(i,\mathrm{E}) + \log_2\ t_{\mathrm{EC}} \};$$

$$W(i,B) = \max\{ W(i-1,\mathrm{N}) + \log_2\ t_{\mathrm{NB}},\ W(i,J) + \log_2\ t_{\mathrm{JB}} \}.$$

Termination: $S^{\mathrm{MSV}}(\mathbf{x}) = W(L,\mathrm{C}) + \log_2 t_{\mathrm{CT}} - (L \log_2 t_{\mathrm{RR}} + \log_2(1 - t_{\mathrm{RR}}))$

The M_0 "state" in the initialization is solely needed for a boundary condition; there is no such state in the model.

Log-odds ratio scoring relative to the null model is built into the calculation, in the match scores $\sigma_k(a)$ and in counting the total (constant) null model state transition contribution of $L \log_2\ t_{\mathrm{RR}} + \log_2(1 - t_{\mathrm{RR}})$ as terms in the DP termination step.

Like other linear sequence alignment recursions, the algorithm requires $O(ML)$ time. It is implemented in a single lattice row of $O(M)$ space for purposes of obtaining just the optimal score. In the HMMER3 source code, this algorithm is implemented in generic_msv.c::p7_GMSV().

MSV score algorithm: SIMD vector parallelization

The MSV algorithm is highly amenable to vector parallelization using commodity SIMD (single instruction, multiple data) instructions, such as the Streaming SIMD Extensions (SSE) instructions on Intel-compatible systems and Altivec/VMX instructions on PowerPC systems. These vector instruction sets use 128-bit vectors to compute up to 16 simultaneous operations.

Several vector methods have been described for accelerating classical Smith/Waterman local sequence alignment [34,35], and methods for accelerating Smith/Waterman dynamic programming (DP) recursions are readily adapted to profile HMMs. A remarkably efficient vector-parallel approach called *striped* Smith/Waterman was described by Farrar [33].

Striping addresses a challenge in the data dependency pattern in Smith/Waterman-style dynamic programming recursions. The calculation of each cell (i,k) in the dynamic programming lattice requires having previously calculated cells $(i-1,k)$, $(i,k-1)$, and $(i-1,k-1)$. In a row-vectorized implementation, V individual cells (typically 4, 8, or 16) are stored in each individual vector, such that each row i of the vectorized DP matrix stores cells $k = 1..M$ in Q vectors numbered $q = 1..Q$, where $Q = (M + V - 1)/V$. In Farrar's approach, cells $k = 1..M$ are assigned nonconsecutively to vectors $q = 1..Q$ in a striped pattern (Figure 2). In striped vectors, when we calculate the set of several cells (i,k) contained in one vector (i,q) on a current row, all the previous diagonal cells $(i-1,k-1)$ that we need are neatly available in the correct order in a vector $(i-1,q-1)$ on the previous row, and the cells above are in vector $(i-1,q)$. Striping minimizes expensive operations such as shifting or rearranging cell values inside vectors. The disadvantage is that calculations on delete paths (dependent on cells $i,k-1$ to the left) may need to be fully serialized. Farrar described effective techniques for minimizing this problem. In the MSV algorithm, because only ungapped diagonals are calculated, this drawback is avoided altogether. The essential idea of how striped indexing works is schematized in Figure 2.

To maximize parallelism, I implemented MSV as a 16-fold parallel calculation with score values stored as 8-bit unsigned integers restricted to range 0..255. This takes advantage of the fact that local alignment scores under HMMER3's probabilistic model have a narrow and predictable dynamic range, enabling a numerical stability analysis that justifies using reduced precision. (The details of this analysis are given in the next section.) This rescaling is specified by three values (base, bias, and scale), where "base" is an initial offset from zero to make MSV scores nonnegative (default: 190), "scale" is the scaling factor (default 3, so MSV scores are in units of one-third bits), and "bias" is an offset on individual residue scores, used to make all individual residue scores unsigned byte costs relative to the maximum residue score. Using the scale and bias terms, position-specific residue scores $\sigma_k(x_i)$ are converted to precomputed scaled costs by $-1 * \mathrm{roundf}(\mathrm{scale} * \sigma_k(x_i)) + \mathrm{bias}$ (saturated at a maximum cost of 255) and stored in striped order in vectors $\hat{\sigma}_{x_i}(q)$ (Figure 2). Transition scores $\log_2\ t_{xx}$ are converted to precomputed scaled costs $\hat{t}_{xx}$ by $-1 * \mathrm{roundf}(\mathrm{scale} * \log_2\ t_{xx})$ (saturated at a maximum cost of 255).

To define MSV's SIMD recursion, I will use five pseudocode vector instructions for operations on $b-$bit integers ($b = 8$ in our implementation), either scalars x or vectors v containing V $b-$bit integer elements numbered $v[1]..v[z]..v[V]$. Each of these operations are either available or easily constructed in both SSE and Altivec/VMX:

Operation	Pseudocode	Definition
saturated addition	v = vec_adds(v1,v2)	$v[z] = \mathrm{MIN}(2^b - 1, v1[z] + v2[z])\ \forall z,$
saturated subtraction	v = vec_subs(v1,v2)	$v[z] = \mathrm{MAX}(0, v1[z] - v2[z])\ \forall\ z,$
max	v = vec_max(v1,v2)	$v[z] = \mathrm{MAX}(v1[z], v2[z])\ \forall\ z,$
assignment	v = vec_splat(x)	$v[z] = x\ \forall\ z,$
right shift	v = vec_rightshift(v)	$v[1] = 0;\ v[z] = v[z\text{-}1]\ \forall\ z > 1.$
horizontal max	x = vec_hmax(v)	$x = \max_z v[z]$

In this pseudocode, the vectorized MSV algorithm is the following:

Initialization:

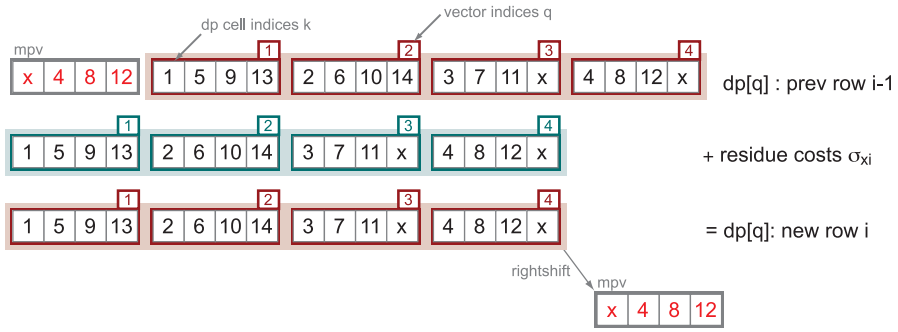

Figure 2. Illustration of striped indexing for SIMD vector calculations. The top row (magenta outline) shows one row of the dynamic programming lattice for a model of length $M=14$. Assuming an example of vectors containing $V=4$ cells each, the 14 cells $k=1..14$ are contained in $Q=4$ vectors numbered $q=1..4$. (Two unused cells, marked x, are set to a sentinel value.) In the dynamic programming recursion, when we calculate each new cell k in a new row i, we access the value in cell $k-1$ in the previous row $i-1$. With striped indexing, vector $q-1$ contains exactly the four $k-1$ cells needed to calculate the four cells k in a new vector q on a new row of the dynamic programming matrix (turquoise outline). For example, when we calculate cells $k=(2,6,10,14)$ in vector $q=2$, we access the previous row's vector $q-1=1$ which contains the cells we need in the order we need them, $k-1=(1,5,9,13)$ (dashed lines and box). If instead we indexed cells into vectors in the obvious way, in linear order ($k=1..4$ in vector $q=1$ and so on), there is no such correspondence of $q,q-1$ with four $k-1,k$'s, and each calculation of a new vector q would require expensive meddling with the order of cells in the previous row's vectors. With striped indexing, only one shift operation is needed per row, outside the innermost loop: the last vector on each finished row is rightshifted (mpv, in grey with red cell k indices) and used to initialize the next row calculation.
doi:10.1371/journal.pcbi.1002195.g002

$$\text{biasv} = \text{vec\_splat}(\text{bias})$$
$$\text{dp[q]} = \text{vec\_splat}(0)\ \forall q$$
$$\text{xB} = \text{base} - \hat{t}_{NB}$$
$$\text{xJ} = 0$$

Recursion:

for $i=1$ to L:

$$\text{xEv} = \text{vec\_splat}(0)$$
$$\text{xBv} = \text{vec\_splat}(\text{xB} - \hat{t}_{BM})$$
$$\text{mpv} = \text{vec\_rightshift}(\text{dp}[\text{Q}-1])$$

for $q=1$ to Q:

$$\text{tmpv} = \text{vec\_max}(\text{mpv}, \text{xBv})$$
$$\text{tmpv} = \text{vec\_adds}(\text{tmpv}, \text{biasv})$$
$$\text{tmpv} = \text{vec\_subs}(\text{tmpv}, \hat{\sigma}_{x_i}(q))$$
$$\text{xEv} = \text{vec\_max}(\text{xEv}, \text{tmpv})$$
$$\text{mpv} = \text{dp[q]}$$
$$\text{dp[q]} = \text{tmpv}$$

$$\text{xE} = \text{vec\_hmax}(\text{xEv})$$
$$\text{xJ} = \max\{\text{xJ}, \text{xE} - \hat{t}_{EJ}\}$$
$$\text{xB} = \max\{\text{base}, \text{xJ}\} - \hat{t}_{JB}$$

Termination: $S^{\text{MSV}}(\mathbf{x}) \simeq \dfrac{\text{xJ} - \hat{t}_{CT} - \text{base}}{\text{scale}} - 4.3 - (L \log_2 t_{\text{RR}} + \log_2 t_{\text{RT}})$

The constant term of -4.3 bits in the termination step arises from an approximation that deals with roundoff error in counting t_{NN} and t_{CC} transition costs. This is explained in the following section. The termination condition is assuming that $\hat{t}_{EC} = \hat{t}_{EJ}$, so that values for the C state are the same as for the J state (thus saving having to calculate C state values in the recursion).

This algorithm is implemented both for SSE and Altivec/VMX instructions in the HMMER3 source code in impl_{sse,vmx}/msvfilter.c::p7_MSVFilter().

Analysis of consequences of reduced numerical precision

This section is particularly technical, and may be skipped in a first reading. In reducing the dynamic range of score calculations to small unsigned integers, we must make sure that underflow or overflow either do not occur, or have no erroneous consequences. We must also be sure that the magnitude of any accumulated roundoff error is tolerable. Because the HMMER3 acceleration pipeline (described below) uses vector-parallel, striped, reduced precision implementations of both the MSV algorithm (described above) and the standard Viterbi (optimal alignment) algorithm for the original profile model with insertions/deletions, the following analysis considers both MSV and Viterbi scores.

For underflow, we use the fact that there is a lower bound on optimal local alignment scores as a function of model length M and target sequence length L. In the worst possible positive-scoring optimal local alignment, the core profile matches only one match state M_k against one residue x_i with a score $\sigma_k(x_i) \geq 0$, and the remaining $L-1$ residues of the target sequence are accounted for by flanking N and C states. The worst case therefore has a

log-odds likelihood score S of

$$S \geq (i-1)\log_2 t_{NN} + \log_2 t_{NB} + \log_2\ t_{BM_k} + \log_2\ t_{M_kE} + \log_2\ t_{EC} + (L-i)\log_2\ t_{CC} + \log_2\ t_{CT} - L\log_2\ t_{RR} - \log_2\ t_{RT}$$

which is:

$$S \geq 2\log_2 \frac{3}{L+3} + (L-1)\log_2 \frac{L}{L+3} + \log_2 \frac{2}{M(M+1)} + \log_2 \frac{1}{2} - L\log_2 \frac{L}{L+1} - \log_2 \frac{1}{L+1} \text{ bits.}$$

Known protein sequences can be over 30,000 residues long (human titin, for example, is 34,350aa). If we specify $L,M \leq 10^6$ as design limits, we can assume a lower score bound of $S \geq -60$ bits for optimal local alignments.

For managing overflow, we use the fact that we will only use a reduced-precision implementation as a filter on target sequences. Any sequence with a P-value $\leq$ a chosen threshold will be passed on to a slower routine for recomputation at full precision. Using *saturated* arithmetic instructions, any target sequences that overflow will be scored as the highest possible score. Now we only need to be able to guarantee that the upper score bound has a P-value $\leq$ the lowest P-value threshold we ever plan to use. From Milosajevic [31,36], we know a conservative bound $P(S > t) \leq 2^{-t}$ for a bit score threshold t. For a design limit allowing filter thresholds $\geq 10^{-5}$, an upper score bound of 17 bits suffices. (0.02 is the default P-value threshold for MSV, and 0.001 is the default for Viterbi scores, as discussed below).

This range of -60 to 17 bits applies to *complete* optimal local alignments; in individual cells of the dynamic programming calculation, we need a little more dynamic range. A high scoring alignment of 17 bits, for example, will have a score of more than 17 bits in the last cell that aligns a match state to a homologous residue, because this state is always followed by negative scores from EC, CC, and CT transitions in the optimal alignment. Taking this into account (including some order of evaluation issues - the fact that the contributions of some transitions, including the null model's contributions, are included in a termination step after the dynamic programming recursion is complete) it can be shown that a range of $-61 \ldots 21$ bits suffices to guarantee that no DP cell involved in an optimal local alignment of range $-60 \ldots 17$ bits will underflow or overflow.

These same bounds apply to both the original local alignment model (Viterbi alignments with insertions and deletions) and the MSV model, because no step in ascertaining these bounds required any consideration of the transition probabilities in the core model (match, insertion, and delete states).

Thus we need a dynamic range of 82 bits (-61 … 21 bits), and the maximum range of an 8-bit integer is 256 values, so scaling log-odds scores to units of 1/3 bits suffices. (Coincidentally, this is comparable to the scaling and roundoff of standard scoring matrices used by BLAST or FASTA; BLOSUM45, for example, is in units of 1/3 bits.) A "base" offset term is then used to adjust the represented value range to the range of bit scores. For unsigned 8-bit integers, a base of +190 means that values 0..255 represent the range of $\frac{-190}{3} \ldots \frac{65}{3}$ bits.

Rounding scores to the nearest 1/3 bit introduces a roundoff error of $-\frac{1}{6} \ldots \frac{1}{6}$ bit per scoring term. A sum of N independent, identically distributed random deviates uniformly distributed on an interval (a,b) has mean zero and variance $N\frac{(b-a)^2}{12}$. Because a local alignment score for a target sequence of length L is modeled as a sum of $\geq 2L$ emission and transition scoring terms, even if each term's roundoff error were independent and uniformly distributed, accumulated roundoff error would be large (normally distributed with mean zero and variance $\geq 2L\frac{(1/3)^2}{12}$; so for $L = 400$ the accumulated error would have a standard deviation of ± 2.7 bits). Worse, roundoff errors are neither independent nor uniformly distributed. A particularly bad case is contributed by transition probabilities t close to 1.0, such as most match-match transitions in the original gapped profile model, where $3\log_2\ t$ for all sufficiently large t rounds to a zero cost. Another bad case is contributed by HMM states that have self-loops, such as insert-insert transitions, where a roundoff error is multiplied by the number of times the state is visited. These two bad cases make the self-loops producing chains of N, C, J, or insert states particularly problematic, because these self-transition probabilities are often close to 1.0; an entire chain of them often gets scored as zero, accumulating a large roundoff error.

The MSV model and its implementation use several features to reduce roundoff error to tolerable limits. First, by eliminating match, delete, and insert transitions and setting all match-match transition probabilities to 1.0 (thus zero cost), the MSV model itself has already eliminated many of the transitions that accumulate non-independent roundoff error, leaving in the core model only the M match state emission probabilities (which are all approximately independent and uncorrelated as far as roundoff error analysis is concerned). Second, the emission probabilities in N, C, and J states are assumed to be equal to the background (null model) frequencies, so the emission scores in N, C, and J are treated as zero by construction, thus they contribute no roundoff error terms. Third, we can take advantage of the fact that the total contribution of the NN, CC, and JJ transitions approximates a constant for sufficiently large L, because a local alignment typically assigns nearly all residues of the target sequence to N, C, and J states and few to match states. Thus we expect a typical local alignment to involve on the order of L NN, CC, and JJ transitions, each scoring $\log_2 \frac{L}{L+3}$, and $L\log_2 \frac{L}{L+3} \simeq -4.3$ bits for large L. Therefore we can score NN, CC, and JJ transitions as zero cost during the recursion, then later add a constant -4.3 bits back onto the score to approximate their missing contribution. This approach may alter the optimal local alignment (during the recursion, paths using NN, CC, and JJ transitions look more favorable than they actually are) but in a score filter, we are not interested in the optimal alignment, only its score.

Thus the roundoff error in a reduced-precision MSV algorithm implementation consists of a bias arising from treating the NN, CC, JJ contributions totalling $(L-\ell)\log_2 \frac{L}{L+3} \geq L\log_2 \frac{L}{L+3} \geq -4.3$ bits as a constant -4.3 bits, and a sum of more or less independent and uniformly distributed error terms including five or more log transition probabilities (t_{NB},t_{BM_k},t_{EC},t_{JB},t_{CT}) and ℓ emission scores for match states involved in ungapped alignment diagonals of total length ℓ residues. For large L, and assuming $\ell \simeq 40$ or so for typical MSV alignments at the edge of statistical significance, a back of the envelope calculation suggests an expected error of mean zero and standard deviation of about $\sqrt{\ell\frac{(1/3)^2}{12}} \simeq 0.6$ bits, and a worst-case maximum error of about $\ell/6 \simeq \pm 6$ bits. Because higher-scoring alignments involve more match emission terms than low-scoring alignments, ℓ is correlated

to the optimal score, so the roughly Gaussian error distribution for a given ℓ will be convolved with a Gumbel score distribution, resulting in a slightly non-Gaussian error distribution with some skew towards the higher error side.

To confirm that this expected roundoff error agrees with empirical observation, I performed simulations in which I examined the differences in MSV scores of a reduced precision implementation (unsigned bytes in $\frac{1}{3}$ bit units) compared to a full-precision floating point implementation. I did this for many different profiles (9,318 models from Pfam release 22) aligned to 1,000 random sequences of varying lengths $L=25,100,400,1600,6400,25600$, and to 207,132 real sequences in SwissProt 49.0 (in UniProt 7.0). This experiment showed roundoff errors for each model were distributed with a standard deviation of 0.4–0.6 bits for real sequences in Swissprot and for random sequences of each length. The mean error was approximately zero for random sequences of lengths >100; a 0.4 bit mean underestimate for UniProt sequences; a 0.5 bit mean underestimate for $L=100$ random sequences; and a 2.2 bit mean underestimate for $L=25$ random sequences. On real UniProt sequences, I observed some extreme differences of up to ± 11 bits. These invariably corresponded to long and highly biased composition sequences, where presumably the alignment length ℓ was large, increasing the potential for accumulated roundoff error. Because these were rare, and MSV is to be used only as a filter, these extremes seem safe to ignore. Overall the range of roundoff error appears tolerable, particularly for large L.

MSV scores obey conjectures allowing fast P-value determination

Previously [31] I conjectured that expected scores for certain probabilistic local alignment models, including the HMMER3 local alignment model, follow easily predictable distributions. Specifically, I conjectured that optimal alignment Viterbi bit scores show Gumbel distributions of fixed slope $\lambda \simeq \log 2$, and the high scoring tail of Forward bit scores follow exponentials of the same slope $\lambda \simeq \log 2$. The MSV model is fully probabilistic and thus ought to obey these conjectures. Therefore MSV optimal alignment scores are predicted to follow a Gumbel distribution

$$P(S \geq t) = 1 - \exp\left[-e^{-\lambda(t-\mu)}\right]$$

with slope $\lambda \simeq \log 2$ and a location μ that is estimated by fitting to a small simulation of scores from 200 or so random sequences.

These statistical conjectures are best obeyed by models or scoring systems with high relative entropy per position (i.e. high mean expected score) [31]. Default HMMER3 models have low relative entropy per position (about 0.6 bits/position) because HMMER3 model parameterization uses a technique called entropy-weighting [29,37], an *ad hoc* method to re-weight the effective number of observed sequences relative to the prior (pseudocounts) to achieve a desired relative entropy target. The standard pairwise residue alignment scoring system (BLOSUM62) has a similar relative entropy of about 0.6 bits per aligned position. At lower relative entropy per position, longer alignments are required to achieve high scores and a finite-length "edge effect" becomes considerable. HMMER3 ameliorates edge effect by calculating an *ad hoc* corrected $\hat{\lambda} = \log_2 + \frac{1.44}{MH}$, where M is the length of the profile in match states and H is the relative entropy per match emission state in bits [31]. Although the same *ad hoc* correction suffices for both Viterbi and Forward distributions, it was obtained by empirical fitting with little theoretical guidance, so there is little reason to trust that the same correction would apply to MSV scores. Therefore I empirically tested the ability to estimate accurate P-values for MSV scores for a wide range of HMMER/Pfam models.

Figure 3A shows an example of an MSV score distribution for one typical profile HMM (the CNP1 model from Pfam version 24, representing a lipoprotein family, chosen because it has the median length, median number of representative sequences, and median average pairwise identity over all Pfam 24 seed alignments), for 10^8 scores of random i.i.d. sequences of varying lengths. For all but the shortest sequences (L = 25), the observed score distributions closely match the conjectured distribution including the *ad hoc* edge correction term (orange line).

Figure 3B shows results of simulations in which 11,912 different profile HMMs from Pfam version 24 [11] were scored by the MSV algorithm against 10^5 random sequences of length 400, the resulting distributions were fit to Gumbel distributions to determine maximum likelihood estimates of μ and λ, and a histogram of the λ estimates is plotted. For high relative entropy models (grey line), this distribution is tightly clustered at the expected $\lambda = \log 2$. For default entropy-weighted models (black line), the distribution is broader with a higher mean, in accordance with what is observed for Viterbi scores and attributed to finite-length edge effect.

Figure 3C shows a direct evaluation of the accuracy of MSV P-values across many Pfam models and various random sequence lengths. For each of 11,912 Pfam 24 models, MSV scores are calculated for 500,000 random sequences generated at each of several lengths $L=25,50,100,400,1600,6400$ and 25600, and the number of random sequences that pass the MSV filter at $P \leq 0.02$ is counted. If P-values are accurate, we would expect to see an approximately normal distribution centered at 2% of random sequences passing the filter. Within a tolerance of about 2-fold error, this is true for almost all models and for target sequence lengths ≥ 100 or so. A few models have less well-predicted distributions and produce modest outliers. The largest problems appear with short target sequences ($L=25,50$) where P-values can be up to about five-fold overestimated (i.e., fewer sequences pass than predicted), as seen in the CNP1 example in panel A. Default entropy-weighted models (black) are more affected than models with high relative entropy (gray).

This analysis shows that in general, reasonably accurate P-values for MSV scores can be obtained. It also shows that on short sequences of $L \leq 50$ or so, the MSV filter may be too aggressive (removing more sequences than predicted), and that a few models are outliers with either too few or too many sequences getting through the filter. These are minor issues that would be good to deal with in the future.

Vector parallelization of the Forward and Backward algorithms

The MSV implementation described above is about 500-fold faster than a standard serial implementation of the full Forward algorithm. This means that a search will still be rate-limited by the speed of the computationally intensive Forward/Backward calculations. Suppose we allow the top 2% (1/50) of sequences through the MSV filter to full HMM Forward log-likelihood scoring; then Forward must be no more than 50-fold slower than MSV, or Forward will be rate-limiting. It was therefore necessary to seek significant accelerations of at least an order of magnitude in the implementations of the Forward and Backward algorithms.

Numerical underflow is a problem for implementing the Forward and Backward algorithms. The probability of a partial alignment path generally underflows the smallest representable floating-point value. In a Viterbi implementation, underflow is avoided by working in the log probability domain, replacing

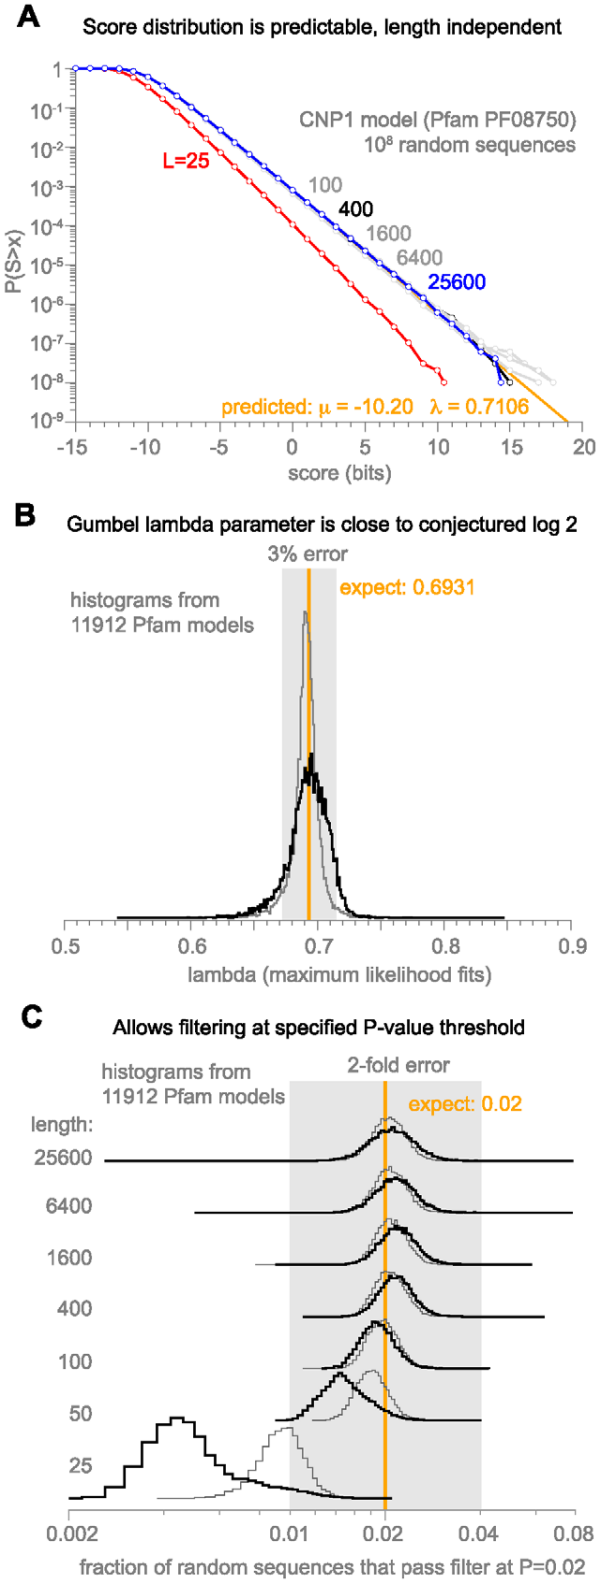

Figure 3. MSV scores follow a predictable distribution. A: example MSV score distributions for a typical Pfam model, CNP1, on 10^8 random i.i.d. sequences of varying lengths from 25 to 25,600, with the shortest, typical, and longest lengths highlighted as red, black, and blue lines, respectively. The predicted distribution, following the procedure of [31] including an edge correction on the slope λ, is shown in orange (though largely obscured by the data lines right on top of it). B: Histogram of maximum likelihood λ values obtained from score distributions of 11,912 Pfam models, showing that most are tolerably close to the conjectured $\lambda = \log_2$, albeit with more dispersion for default entropy-weighted models (black line) than high relative entropy models without entropy-weighting (gray line). C: The observed fraction of nonhomologous sequences that pass the filter at a P-value of 0.02 should be 0.02. Histograms of the actual filter fraction for 11,912 different Pfam 24 models are shown, for a range of random sequence lengths from 25 to 25,600, for both default models (black lines) and high relative entropy models with no entropy weighting (gray lines).
doi:10.1371/journal.pcbi.1002195.g003

multiplication and maximization of probabilities with addition and maximization of their logarithms [5,38]. However, the Forward and Backward dynamic programming recursions require addition of partial paths in the probability domain.

In both sequence analysis and speech recognition HMM applications, this problem is customarily solved by working in the log probability domain and implementing a "log-sum" operation, such that addition $c = a + b$ in the probability domain is replaced by $A = \log a$, $B = \log b$, and $\log c = \log(a+b) = \log(e^A + e^B)$ [5,39]. An efficient log-sum operation rearranges the log-sum to $A + \log(1 + e^{B-A})$ for $A \geq B$, and finds an approximate $\log(1 + e^{B-A})$ term to add to A in a precalculated lookup table indexed by the difference $(A - B)$ scaled and rounded to an appropriate precision. The lookup table has finite size, because the term is negligible for large $(A - B)$, but nonetheless it is large (16,000 entries in the HMMER3 "generic" non-vectorized implementation; see logsum.c). I do not know how to implement a large lookup table efficiently in SIMD vector instructions. Only small lookup tables appear feasible using vector permutation instructions (up to perhaps 256 entries in Altivec/VMX, fewer in SSE).

Another approach is rescaling [5,38]. In rescaling, the entries in each row i (for each target residue x_i) of the dynamic programming matrix are multiplied by some scale value s_i. The scale values s_i are chosen to keep the largest entries in each row within the allowable numeric range. If the smallest values in a row differ from the largest by greater than the numeric range, the smallest values still underflow, but for many HMMs one can show that no partial path prefix that underflows could have ever rebounded to have a non-negligible probability as a complete path. However, in general this is not the case for profile HMMs (nor for other HMMs with paths involving silent states), because of the possibility of long deletions. Even an optimal alignment can contain a long D-D-D path along a single row i. After many DD transition probabilities are multiplied together, the values in the states at the start versus the end of a long deletion path on the same row can differ by more than the allowable range. A standard normalized IEEE754 32-bit float type has a range of about $-2^{128}..2^{128}$, equivalent to 256 bits in the log-odds score domain. Given a typical deletion extension penalty of about -1 to -2 bits, a deletion of about 200 residues or so will typically underflow the rescaled delete states in the correct path. Deletions of this length are rare, but do occur.

I use the following steps to make an approach that I call "sparse rescaling" work for HMMER3's SIMD vector implementations of the Forward/Backward algorithms.

First, Forward/Backward values are calculated in an odds-ratio domain rather than the probability domain, so they are naturally pre-scaled to some extent. Each match emission probability $e_k(a)$ is replaced by its odds ratio $e_k(a)/f(a)$, the same ratio used for log-odds scores. By the same arguments used to analyze underflow of

the MSV implementation above, the odds ratio of the worst-case optimal local alignment path is a simple function of model and target lengths M and L, with a lower bound of about 2^{-60} (about 10^{-26}) if we assume $L,M \leq 10^6$ as design limits, well within the allowable range of an IEEE754 float representation.

Second, I exploit the fact that the HMMER3 profile HMM is a multihit local alignment model, not a glocal alignment model (glocal means global with respect to the model, local with respect to the target). When the profile HMM is a multihit local alignment model, a rescaling approach works. For any path with two aligned regions connected by a long deletion, there must exist an alternative path that counts the same two aligned regions as two local alignments, connected by a reinitiation path ($M_k \rightarrow E \rightarrow J \rightarrow B$). This reinitiation path, with only three transition probabilities on the same row, presents no underflow difficulties. The path with a long deletion may underflow, but then its complete path must be negligible relative to the alternative multihit local alignment path.

Determining the appropriate scale factor s_i requires examining each value in the row, which typically requires extra computation. I exploit the fact that the value in the cell for the E state has already calculated a maximum over all M_k states. It is sufficient to use the E cell value itself as the scale value s_i, setting the E cell value to 1 and rescaling all other values in the row.

Still, rescaling a row also requires extra computation. Here I exploit the fact that rescaling every row is unnecessary. Instead, when the E cell odds-ratio value exceeds a certain threshold, this triggers a rescaling event for that row. Other rows have $s_i = 1$.

I implemented Forward and Backward using sparse rescaling and striped SIMD vectors of four parallel 32-bit floats. Overall these implementations are about 16-fold faster than standard serial implementations using the log-sum lookup table operation. The overall 16-fold acceleration is likely a combination of about a 4-fold speedup from the SIMD vector parallelization with about 4-fold from replacing the log-sum operation with addition and multiplication. This makes the Forward/Backward algorithms only about 30-fold slower than the MSV filter.

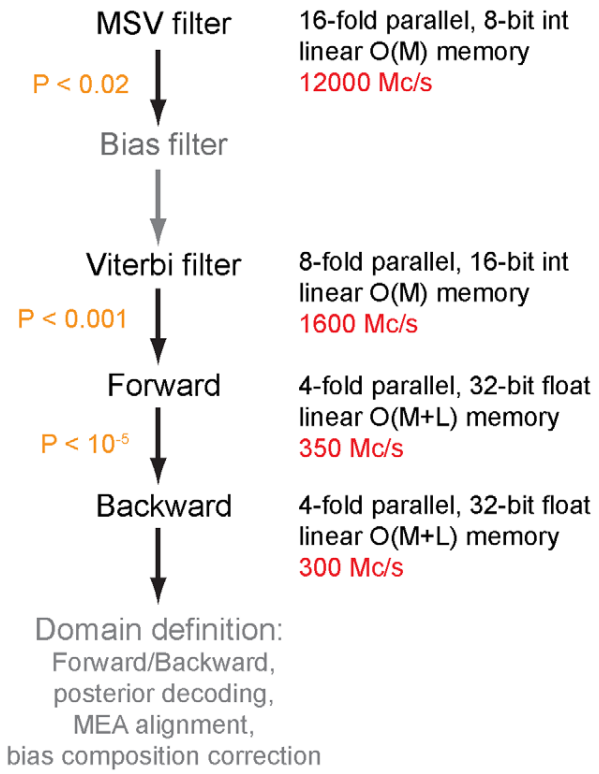

Figure 4. The HMMER3 acceleration pipeline. Representative calculation speeds are shown in red, in units of millions of dynamic programming cells per second (Mc/s). Default P-value thresholds for MSV, Viterbi, and Forward filtering steps are shown in orange. The bias filter and the domain definition steps are not described in detail in this manuscript, and are shown in gray.
doi:10.1371/journal.pcbi.1002195.g004

The HMMER3 acceleration pipeline

The MSV and Forward/Backward methods described above are implemented in the so-called "acceleration pipeline" at the core of the HMMER3 software implementation (http://hmmer.janelia.org). The acceleration pipeline is summarized in Figure 4. One call to the p7_Pipeline() function is executed for each model/sequence comparison.

The pipeline either accepts or rejects the entire comparison at each step, based on the P-value of the log-odds score. For example, by default the MSV filter passes if a comparison gets a P-value of less than 0.02 (i.e., the top-scoring 2% of random nonhomologous sequences are expected to pass the filter). I have not yet explored the more sophisticated approach of using alignment information from earlier and faster steps in the pipeline to constrain (band) subsequent dynamic programming calculations.

All P-value calculations assume that the query profile and target sequence have residue compositions close to the overall average for proteins. In some cases, a query profile has a biased composition, and this bias matches a bias found in many target database sequences. Membrane proteins, for example, are skewed towards a more hydrophobic composition, and tend to match other nonhomologous membrane proteins with scores higher than expected under a simple average-composition null hypothesis. HMMER3 has methodology for recalculating scores and P-values to compensate for biased composition, but this methodology (the so-called "null2" correction, not described here for reasons of space) is placed late in the pipeline because it is computationally intensive. At the MSV filter step, the uncorrected MSV P-value may be underestimated in biased composition matches, which means more than the expected fraction of nonhomologous sequences may passes the MSV filter, which in some cases can be sufficient to slow the pipeline. HMMER3 inserts a "bias filter" step to reduce this problem. The bias filter step is shown in gray in Figure 4 because it is not described in detail in this paper. Briefly, the bias filter calculates a fast, heuristic biased composition correction to the MSV filter score using a two-state hidden Markov model with one emission distribution set to the average protein residue composition and the other emission distribution set to the average composition of the query profile, fully connected by four arbitrary hand-tuned transition probabilities. The pipeline rescores the sequence with this correction applied, and retests the modified P-value against the MSV filter threshold of 0.02. The bias filter has no effect on the final reported score of a sequence, which is calculated by the full Forward algorithm; the bias filter only has the effect of making the MSV filter remove additional matches that appear to be due to biased composition.

To further reduce the computational load that arrives at the full Forward step, an additional filter, the Viterbi filter, was implemented and inserted in the pipeline. The Viterbi filter is a striped SIMD vector implementation of optimal gapped alignment to the profile (Figure 1A). It is implemented 8-fold vector parallel in 16-bit integers, because the numerical analysis of roundoff error accumulation is less favorable for Viterbi than for MSV and more precision is required. Following the same arguments as described

for MSV, Viterbi filter scores do not underflow (within design limits of $L,M \leq 10^6$) but may overflow the 16-bit representation, which is in units of 1/500 bits with an integer offset of 12,000, such that representable scores range from −89.5 to 41.5 bits. Any score that overflows the 41.5 bit upper limit is sure to pass any reasonable filter P-value anyway ($P(x>41.5)<10^{-12}$; the default Viterbi filter threshold is $P<0.001$).

The Forward and Backward algorithms for the pipeline are implemented in specialized efficient-memory forms called p7_ForwardParser() and p7_BackwardParser(). Each parser stores only a single row i of the dynamic programming matrix for each sequence residue x_i, plus the complete columns for the "special" states E, N, J, B, and C. This yields $O(M+L)$ linear-memory implementations, with sufficient stored information to allow Forward/Backward posterior decoding of the probable positions of B and E states on the target sequence, defining the probabilities of local alignment endpoints. A target sequence that passes the Viterbi filter is scored with the full Forward parsing algorithm. If the Forward score passes a P-value threshold (default $P<10^{-5}$), the Backward parser is calculated. Forward/Backward probabilities are used to estimate local alignment "regions" of substantial posterior probability mass in the target sequence. Each region is then subjected to a conceptually separate analysis pipeline, the "domain definition" pipeline, which identifies individual homologous regions and alignments, using a series of steps including full-matrix Forward/Backward, posterior decoding, maximum expected accuracy alignment, and a region-specific biased composition score correction. The domain definition procedure is not described in detail in this paper.

The acceleration pipeline is memory efficient. The MSV and Viterbi filters are only concerned with scores, not alignments, so they are implemented in linear-memory $O(M)$ forms that store only a single dynamic programming row. The Forward and Backward algorithms are used in a $O(M+L)$ "parser" form just described. The domain definition pipeline, however, is not memory efficient. It currently calculates full $O(ML')$ Forward/Backward and posterior decoding matrices for each identified subsequence (region) of length $L' \leq L$ in the target sequence. Until these steps in the domain postprocessor are replaced with more memory-efficient algorithms, HMMER3 can occasionally exhaust available memory on some large model/sequence comparisons.

Speed benchmarking

Figure 5 shows benchmark measurements of the speed of HMMER3, compared to the speed of BLAST [3], FASTA [40], SSEARCH (the FASTA implementation of Smith/Waterman), HMMER2, and the UCSC SAM profile HMM software [37]. Search speeds are shown in units of millions of dynamic programming cells calculated per second (Mc/s), measured on a single processor core (see Methods). The number of dynamic programming cells is the product of the query length M and the target database length L in residues. A straightforward implementation of dynamic programming sequence alignment scales in time as $O(ML)$, so reporting a speed in units of Mc/s is expected to be relatively independent of query and target length. In practice, the fastest search programs tend to show some additional dependence on query sequence length, with more efficient performance on longer queries. Figure 5 looks at a range of different queries of different lengths.

To measure the "typical" performance of each program, without complicating variation arising from producing the voluminous alignment output for some queries that hit large protein superfamilies, panel A (left) shows benchmarks done on random (shuffled) target sequences. The panel shows results for 76 query profiles (or representative single sequences), chosen to sample the full range of query lengths in the Pfam protein domain database from 7 to 2,217 residues. These results show that HMMER3 performance is comparable to other fast database search programs; somewhat slower (by about 2- to 3-fold) than NCBI BLAST, and somewhat faster (by about 3-fold) than WU-BLAST, for example. The speed of SSEARCH, the Smith/Waterman local alignment implementation in the FASTA package, is worth noting in this figure; SSEARCH has recently been accelerated by implementing Farrar's striped SIMD vector

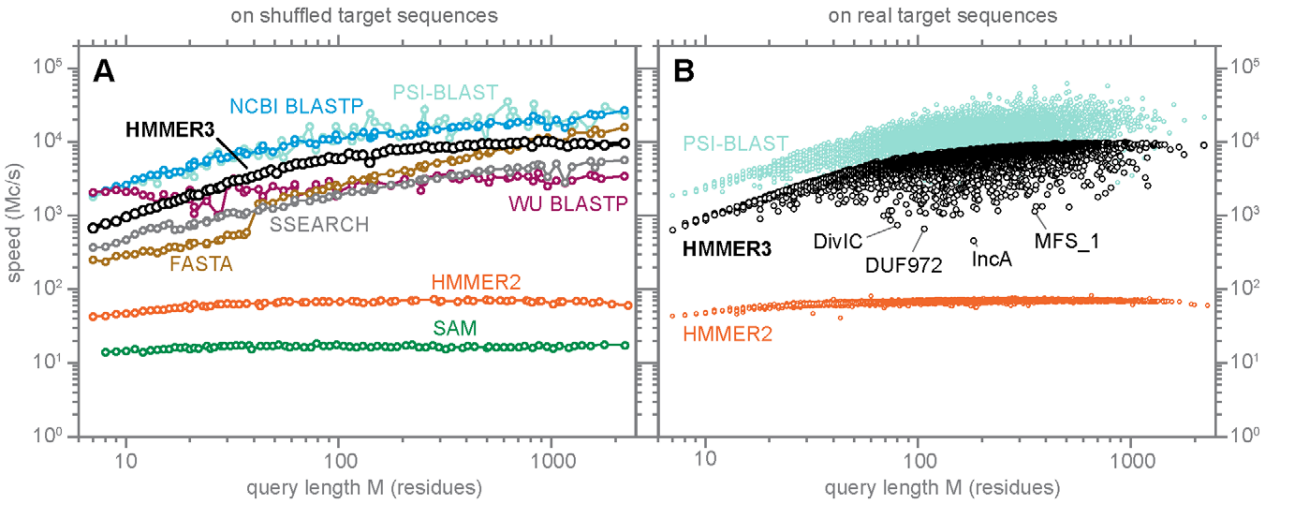

Figure 5. Speed benchmarks. Each point represents a speed measurement for one search with one query against 10^6 target sequences (10^4 for the slow HMMER2 and SAM programs, 10^5 for FASTA and SSEARCH), on a single CPU core (see Methods for more details). Both axes are logarithmic, for speed in millions of dynamic programming cells per second (Mc/s) on the y-axis and query length in residues on the x-axis. Panel A shows "typical best performance" speed measurements for several different programs including HMMER3, for 76 queries of varying consensus lengths, chosen from Pfam 24, for searches of randomized (shuffled) target sequences. Panel B shows a wider range of more realistic speed measurements for all 11,912 profiles in Pfam 24, on searches of real target protein sequences from UniProt TrEMBL.
doi:10.1371/journal.pcbi.1002195.g005

methods, allowing it to achieve speed comparable to the heuristic FASTA and WU-BLAST programs. HMMER3 is faster than HMMER2 by up to 140×, even though HMMER3 calculates full Forward scores whereas HMMER2 calculated faster Viterbi optimal alignment scores. Compared to SAM, which does calculate full Forward scores, HMMER3 is about 600× faster.

To measure a wider and more realistic range of real-world performance, panel B (right) shows benchmarks for 11,912 different queries (every Pfam 24 profile) on real sequences from UniProt TrEMBL. Programs that simply do a dynamic programming alignment to each target sequence, such as HMMER2 (orange points) or SSEARCH (not shown), show performance essentially independent of the properties of the query and target sequences. Programs that use heuristics and filters, however, are sensitive to how well a given search obeys the assumptions of the heuristic and/or filter thresholds. Both HMMER3 and PSI-BLAST speed vary not only by query length, but also vary substantially around their average for a given query length. PSI-BLAST speed in panel B varies both up (by up to about 3-fold) and down (by up to about 10-fold) from its "typical" performance in panel A, presumably reflecting variation in how many word hits and hit extensions need to be processed for a given search. HMMER3 speed tends to vary only downwards from its typical performance, by up to about 20-fold. In panel B, I highlight examples of four poorest-performing HMMER3 searches, on the DivIC, DUF972, IncA, and MFS_1 models. Even with the bias filter step included in the acceleration pipeline, the dominant cause of poorer HMMER3 search performance remains biased composition sequences (such as transmembrane proteins) in which more comparisons pass the fast filters of the acceleration pipeline than expected by P-value calculations that assume average target sequence compositions, causing more comparisons to reach the compute-intensive Forward/Backward calculations.

Sensitivity/specificity benchmarking

A filtering approach will generally compromise search sensitivity by some degree, because a filter will erroneously remove true homologs at some rate. We want this rate to be negligible. To measure how much search sensitivity is attenuated by the use of the MSV filter and the HMMER3 acceleration pipeline, I performed benchmarks to compare sensitivity/specificity of default HMMER3 hmmsearch (with the acceleration filter pipeline) to hmmsearch --max, an option that turns off all the filters and runs the full Forward scoring algorithm on every target sequence. I also benchmarked HMMER2 and several other homology search programs for comparison. These results are shown in Figure 6.

These benchmarks are automatically and semi-randomly generated by a program (create-profmark). The program starts from a source of trusted alignments of homologous protein domains (here, Pfam 24 seed alignments), a source of typical full-length protein sequences (here, UniProt SwissProt 2011_03), and a choice of method for synthesizing nonhomologous sequence segments (such as shuffling a randomly chosen segment of a UniProt sequence). A query alignment and a set of true test domains (trusted to be homologous to the query) is created by applying single-linkage-clustering by percent identity to a Pfam alignment, and using that clustering to select sequences such that no true test domain has more than 25% pairwise identity to any sequence in the query alignment, and no more than 50% pairwise identity to any other test domain. True test sequences are created by concatenating one or two test domains together with nonhomologous sequence segments, with a total sequence length sampled from the distribution of UniProt sequences. False (nonhomologous) test sequences are created by concatenating nonhomologous sequence segments, with both segment length and total sequence length sampled from the length distributions of the true test sequences. The procedure, its rationale, and some of its caveats are described in more detail in Methods.

To benchmark a profile method (HMMER, SAM, or PSI-BLAST), a profile is built from each query alignment and searched against the target database of test sequences and decoys. The results of all searches (for all different queries) are merged and sorted by E-value, and this ranked list is used to calculate a plot of fraction of true positives detected at increasing thresholds of false positives per query from 0.001 to 10.

To benchmark a single-sequence query method (BLAST, SSEARCH, FASTA) more fairly against profile methods, a family-pairwise-search (FPS) method is used [41] (as opposed to selecting just one query sequence from the alignment). Each individual sequence in the query alignment is searched against the target database; the best E-value found to any query sequence is treated as the E-value of the target sequence, and results for all queries are merged, sorted, and treated as above.

Figure 6 shows results for two different benchmarks. Panel A shows results where true test sequences have a single embedded domain, and nonhomologous sequences are synthesized as i.i.d. (independent identically distributed) random sequence from the average UniProt residue frequency distribution; there are 2,141 query alignments, 11,547 true test sequences, and 200,000 decoys. Because nonhomologous sequences are unrealistically simple (no biased composition, no repetitive sequence), this benchmark does not exercise the various corrections for biased composition that some programs have (such as HMMER and BLAST), and is more of a baseline test of the best-case sensitivity of a search program. Panel B shows results of my default profmark benchmark, where there are two embedded domains per true test sequence (in order to test the ability of a program to correctly detect and align multiple domains per sequence, although such results are not shown here), and where nonhomologous sequence segments are created by shuffling randomly chosen segments of UniProt sequences. Because nonhomologous segments in this benchmark can show more realistic monoresidue composition biases (though not higher-order bias such as tandem repeats), this version of the benchmark is more realistic and exercises more *ad hoc* parts of programs that try to correct for biased composition. Panel A shows results that are largely independent of biased composition issues, but less realistic. Panel B shows results that are more dependent on the ability of a program to handle biased composition, and probably more realistic.

The main result in both panels is that sensitivity and specificity are essentially identical for HMMER3 either with the acceleration pipeline (dark black lines) and without it (--max; red lines). There is a slight loss in sensitivity caused by the acceleration pipeline, but this loss is more than compensated by the gain in sensitivity of HMMER3 over HMMER2 (either in its default "glocal" alignment search mode or its local alignment search mode; orange circles and squares respectively). At high specificity (low false positive rates) on more realistic biased decoys, default HMMER3 can appear to be better than unfiltered HMMER3 (hmmsearch --max) because the bias filter removes some problematic biased false positive decoys that the supposedly more powerful biased composition corrections in HMMER3 Forward scores fail to correct.

Benchmarks for other programs (such as BLAST, SAM, FASTA, and SSEARCH) are shown only for the sake of rough comparison. The intent is not to thoroughly benchmark HMMER against these programs, but to provide an additional sense of scale, putting the difference between HMMER3 with and without its acceleration pipeline in context – that is, showing that the

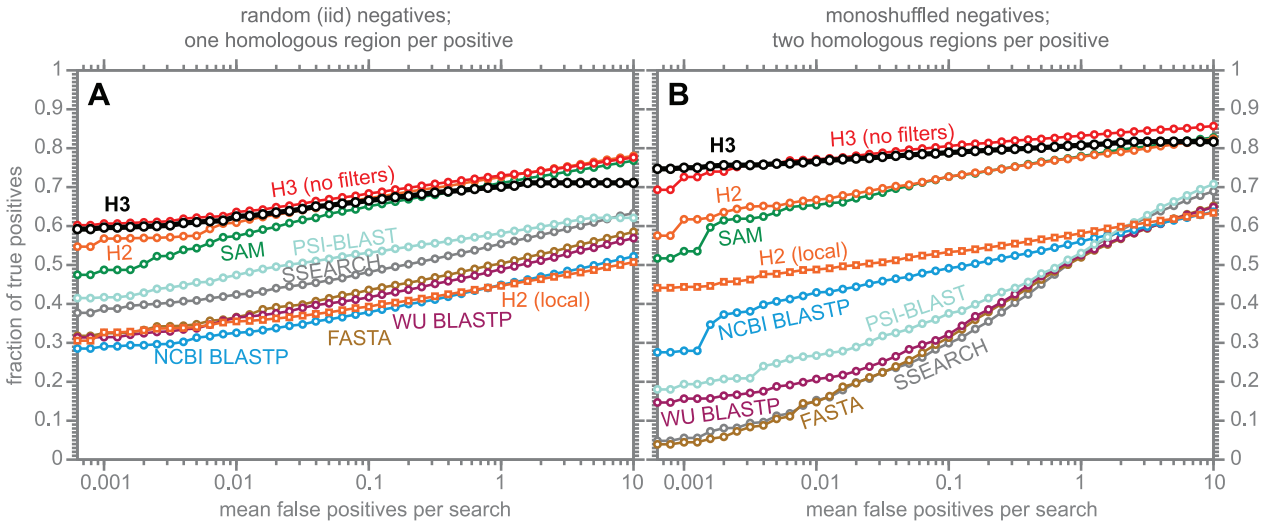

Figure 6. Benchmark of search sensitivity and specificity. For different programs, searches are performed either by constructing a single profile from the query alignment (HMMER3, HMMER2, SAM, PSI-BLAST), or by using "family pairwise search" [41] in which each individual sequence is used as a query and the best E-value per target sequence is recorded (BLASTP, SSEARCH, FASTA). In each benchmark, true positive subsequences have been selected to be no more than 25% identical to any sequence in the query alignment (see Methods). Panel A shows results where nonhomologous sequence has been synthesized by a simple random model, and each true positive sequence contains a single embedded homologous subsequence (a total of 2,141 query multiple alignments, 11,547 true positive sequences, and 200,000 decoys). Panel B shows results where nonhomologous sequence is synthesized by shuffling randomly chosen subsequences from UniProt, and each true positive contains two embedded homologous subsequences (a total of 2,141 query alignments, 24,040 true positive sequences, and 200,000 decoys). The Y-axis is the fraction of true positives detected with an E-value better than the number of false positives per query specified on the X-axis.
doi:10.1371/journal.pcbi.1002195.g006

difference between HMMER3 with and without its acceleration pipeline is minor, compared to differences among programs. These programs were only run in their default configuration. I did not explore available options that might improve their performance on this benchmark. Although I believe the results to be fair and representative, I have to interpret these results with caution. I benchmark HMMER routinely on these benchmarks during development. It is impossible to avoid some degree of training on the benchmark, even though the benchmarks are somewhat randomized. Nonetheless, some informative trends in these results agree with previous independent published benchmarking from other groups, so the comparisons are probably useful as a rough guide. For example, Madera and Gough published a benchmark [28] in which they concluded that SAM significantly outperformed HMMER2, which at the time disagreed with my experience. Johnson [29] traced this to the fact that Madera and Gough had switched HMMER2 from its default glocal alignment mode to its nondefault local search mode, which we had not spent much time testing or tuning, and we had not previously realized how sensitive local alignment is to the model's information content per position. This led us to realize how important SAM's entropy-weighting technique is for local alignment, whereas it is much less important in glocal alignment [29]. This story is reflected in the benchmarks in Figure 6, where HMMER2 *local* alignment performs poorly relative to SAM, HMMER2 *glocal* alignment is comparable to SAM, and HMMER3 local alignment (with the entropy-weighting technique) is perhaps a bit better than SAM. Most of the difference between HMMER3 and SAM is in the high-specificity regime of the more realistic benchmark that includes biased-composition segments (Panel B), and thus is likely to result from differences in the *ad hoc* bias composition corrections that differ between SAM and HMMER, rather than any fundamental difference in their profile HMM parameterizations or their Forward scoring algorithms, which I believe are quite similar.

Another story reflected in these benchmarks is about the widespread belief that full Smith/Waterman alignment is superior to BLAST's fast heuristic approximation of Smith/Waterman. This is true in the easier benchmark (Panel A) but not when decoy sequences include biased composition segments (Panel B). Indeed, in Panel A all three fast sequence search programs (WU-BLAST, NCBI-BLAST, and FASTA) perform comparably (and worse than SSEARCH), whereas in Panel B, NCBI BLAST outperforms WU-BLAST, FASTA, and SSEARCH. This again seems likely to be showing the importance of biased composition score corrections. Biased composition correction has received close attention in NCBI BLAST software development [7,8,42], but is not part of the textbook description of "optimal" Smith/Waterman local alignment.

My main conclusion (that the acceleration pipeline has a negligible impact on the sensitivity/specificity of HMMER3 compared to unaccelerated Forward scoring) is supported by a more direct experiment. I searched all 11,912 Pfam 24 profile HMMs against the 516,081 sequences in UniProt SwissProt 2011_03 using five different option settings to hmmsearch, starting with --max and then successively turning on one filter step at a time in the acceleration pipeline (MSV, bias, Viterbi, and Forward), up to the default configuration with all four filter steps on. With --max, a total of 799,893 hits were found with an E-value of 0.0001 or less. Turning on the MSV filter loses 718 hits (0.09%). Overall, the default pipeline with all filter steps loses 2,701 hits (0.3%). Differences in significant hits are not necessarily all due to true homologs. It is possible for the unfiltered search to find a false positive that one or more of the filters would remove. However, the majority of these differences appear to be true homologs that are removed by the filters. Other than the 718 hits removed by the MSV filter, the great majority of the other losses are due to the bias filter inappropriately removing sequences that have strong biased compositions, but also contain a true homology region. The

most obvious problems with HMMER3 sensitivity/specificity seem to lie in its bias filter and bias composition score corrections, rather than in the use of the MSV filter as its primary acceleration.

Discussion

In describing the MSV heuristic and other acceleration methods implemented in HMMER3, I have not addressed the question of whether the MSV heuristic is better or worse than other heuristics, such as those in BLAST or FASTA. In sensitivity/specificity benchmarks (Figure 6), BLAST and FASTA perform about the same as unaccelerated Smith/Waterman, and HMMER3 performs about the same with and without its acceleration pipeline. This show that the overall sensitivity and specificity of these programs are not limited by their respective heuristics, but rather by their fundamental (unaccelerated) sequence comparison methods. Thus a better heuristic would be unlikely to improve overall sensitivity/specificity. A better heuristic would be a faster one with the same sensitivity/specificity. In a question about speed, we cannot satisfactorily show that one algorithm is necessarily faster than another. We can only rigorously compare particular implementations. Trying to mix and match different heuristic approaches and make definitive comparisons of their fully optimized speeds requires a time-consuming engineering and optimization effort dedicated to each implementation. So it remains an open question whether, for example, BLAST-style heuristics could be tuned to have enough sensitivity/specificity to match HMMER3 performance while still being faster. I developed MSV because it was easy for me, not because I tried different heuristics and found MSV to be better. I was working on striped SIMD vectorization of the Viterbi algorithm, and an MSV implementation is easily derived from striped SIMD Viterbi just by deleting the code that handles deletions and insertions. The heuristic approaches in BLAST and FASTA have the advantage of focusing subsequent slower computations on particular diagonals, whereas in HMMER's current approach, we wastefully recalculate full sequence alignments at each step of the acceleration pipeline. I expect that it will be fruitful to develop heuristics focused around high-likelihood diagonals, as BLAST and FASTA do, while using HMMER's SIMD vectorization methods.

Although this paper is about the acceleration methods used in HMMER3, HMMER3 also appears to be more sensitive than HMMER2. The main reason for this is the adoption of "entropy-weighting", a method introduced by the UC Santa Cruz group in the SAM profile HMM package [29,37], where the information content per position is reduced to a specified target number of bits. A second reason is the switch from Viterbi optimal alignment scores to Forward scores summed over the alignment ensemble [29].

On the other hand, I believe that the switch from default glocal alignment in HMMER2 to local alignment in HMMER3 has probably compromised some search sensitivity ("glocal" means global in the query, local in the target sequence: requiring a full-length domain alignment). Restoring glocal alignment to HMMER3 should improve search performance for profiles that are expected to match over their entire length, such as Pfam protein domain models. However, the fast E-value statistics for Forward and Viterbi scores (including MSV filter scores) are only valid for local alignment, and the numeric underflow analysis of the sparse rescaling technique in the Forward/Backward implementation assumes local alignment. Both problems will need to be addressed before glocal alignment is implemented usefully in HMMER3.

Here I have only described single-core performance. I have not discussed parallelization across multiple cores. HMMER3 search programs include rudimentary implementations of POSIX threads and MPI parallelization (message-passing in a cluster of computing nodes). These implementations currently scale poorly, to only modest numbers of processor cores (2–4 for multithreading, for example). Improved parallelization is a priority for future development.

HMMER3's handling of biased composition sequences is problematic. I chose to introduce an *ad hoc* "bias filter" into the acceleration pipeline, to deal with a small number of profiles that let too many sequences through the MSV filter and bog down in the slow Forward/Backward stages of the pipeline. The bias filter occasionally filters true positive hits. A disturbing failure mode can occur when a target sequence consists of a homologous subsequence surrounded by a large amount of nonhomologous biased composition sequence; in this case, the bias filter may aggressively remove the entire sequence. Although other database search programs have analogous issues with over-aggressive composition masking, one future focus for HMMER3 development will be on improving its formal probability model of *non*homologous sequence.

This paper describes an initial baseline for HMMER3 speed performance on a single processor core. The prospects for substantial future improvements are good. There are many obvious opportunities for incremental optimizations. Bjarne Knudsen (CLCbio, Aarhus, Denmark) has already contributed an important optimization of the MSV filter that increases overall HMMER3 speed by about two-fold. The Knudsen optimization will appear in the next HMMER code release, and we will likely describe it in a future manuscript. Another optimization opportunity is to preprocess the target database sequence file into an efficient binary format, as BLAST does with its BLAST databases. HMMER3 still reads standard flatfile sequence databases, such as FASTA and UniProt text formats. Another optimization opportunity is to convert the filters in the pipeline from their current mode of filtering entire target sequences (which was easy to implement) to instead store and retrieve more information about the location of alignment probability mass, so subsequent steps (including Forward/Backward) can be done as banded dynamic programming calculations within high-probability envelopes, as opposed to reprocessing the entire query/target comparison at each pipeline step. Because of these and other straightforward optimization opportunities, I expect HMMER3 speed will surpass NCBI BLAST speed in the relatively near future.

This speed makes it feasible to apply profile HMM technology to standard sequence database searches with single sequence queries, including iterative database searches. A position-independent scoring system for single sequences is just a special case of a profiled position-specific scoring system. A "profile" HMM can be built from a single sequence, using position-independent probabilities obtained from standard scoring matrices such as BLOSUM62, plus a couple of parameters for gap-open and gap-extend probabilities. The HMMER3 software package includes a program *phmmer* for protein database searches akin to *blastp*, and a program *jackhmmer* for iterative protein database searches akin to *psiblast*. These programs, their parameterization, and the effect of extending profile HMM technology, the Forward algorithm, and probabilistic inference methods to routine sequence database searches will be described elsewhere.

Materials and Methods

Software implementation and availability

HMMER3 is implemented in POSIX ANSI/ISO C99. Vector implementations are provided for Intel-compatible (SSE) and

PowerPC (Altivec/VMX) processors. A "dummy" non-vectorized implementation is provided for other processors, sufficient to enable compilation but about 100× slower than normal HMMER3 vectorized performance. HMMER3 is portable to any POSIX-compliant operating system, including Linux and Mac OS/X, and also to Windows if an optional POSIX compatibility package has been installed (such as Cygwin). It builds from source using a standard GNU configure script and UNIX make. It includes a suite of automated tests written in Perl, C, and Bourne shell. User documentation is provided as PDF and man pages. Source code is freely available under a GNU GPLv3 license. Precompiled binary distributions are available for several platforms including Intel/Linux, Intel/MacOSX, and Intel/Windows. A web interface to HMMER3-based database searches is available, including batch searches and RESTful web services, hosted on computational resources supported by the Howard Hughes Medical Institute. All these resources are at http://hmmer.janelia.org.

Software and database versions used

Software versions used: SAM 3.5 (Jul 2005) [37], NCBI BLAST+ 2.2.24+ (Aug 2010) [3], FASTA 36.3.3 (Feb 2011) [40], WU-BLAST 2.0MP-WashU (May 2006), HMMER 2.3.2 (Oct 2003), and HMMER 3.0 (Mar 2010).

Example sequence alignments and profile HMMs were sampled from Seed alignments and profiles in Pfam 24 [11]. Example target sequences were sampled from UniProt version 2011_03 [43]. One experiment that characterized roundoff error used older versions, Pfam 22 and UniProt 7.0.

Speed benchmarking

All program timings were measured in total (wall clock) time on a single execution thread (single core) of a dedicated and unloaded cluster node, where a node has eight 2.66 GHz Intel Gainestown X5550 cores and 24 GB RAM. The same search was run twice sequentially and timed in the second run, to allow filesystem caching of target databases.

For speed benchmarks of programs that take a single sequence as a query (instead of an alignment), the median length sequence was extracted from the query alignment.

Construction of the sensitivity/specificity benchmark

Sensitivity/specificity benchmarks were created with the create-profmark program, included in the HMMER3 source code. This program allows construction of the wide range of different and randomized benchmarks used during HMMER development. My concern is that because benchmarking is repeated at every step of code development, it is nearly impossible for a developer to avoid overtraining on any in-house benchmark. Synthesizing a variety of partially randomized benchmarks helps mitigate this effect somewhat, compared to relying on a single static benchmark.

The profmark benchmarks use a set of trusted multiple alignments (such as Pfam Seed alignments) as a source of both *query multiple alignments* and distantly related *true test sequences* trusted to be homologous. The individual sequences in each input alignment are clustered by pairwise percent identity, and different clusters are selected to be queries versus test sequences such that no true test domain has more than 25% identity to any sequence in the query alignment, and no true test domain has more than 50% identity to another true test domain. To create realistic-length true test sequences, and to challenge the ability of a program to detect homologous local alignments in a larger target sequence, true test sequences are synthesized by embedding one or two test domains in a larger nonhomologous sequence.

Using a sequence database like Pfam instead of a 3D structure database like SCOP or CATH as a source of trusted true homology relationships has the advantage that a more challenging variety of sequences is tested. Structure databases are biased toward well-ordered globular domains. A weakness of a sequence-based benchmark is that "true homologs" are inferred by current computational sequence comparison methods, rather than being defined by an independent criterion like 3D structure comparison. In particular, my profmark benchmarks are constructed from Pfam alignments as a trusted definition of true homologs, and Pfam is itself constructed with HMMER. There may be some danger that this circularity creates a bias against other search programs. Specifically the danger is that if there are remote homologs that are undetected by profile HMM methods, but that could be detected by another method, any such sequences have been selected against in Pfam. Intuitively, I think this danger is negligible. If a search program was sufficiently powerful that it could detect homologs excluded from Pfam, it ought to be even better at detecting the closer homologs that were included and artificially separated (by profmark's clustering procedure) into challengingly dissimilar query alignment and true test domains. Empirically too, any danger has seemed negligible, because profmark benchmarks tend to be broadly concordant with other published benchmarks [28,44]. Nonetheless, I have more confidence in using profmark benchmarks for internal comparisons (HMMER vs. HMMER, for different option settings) than for comparisons to other search programs.

False (decoy) sequences (including the nonhomologous flanking sequence around embedded test domains in true test sequences) are created synthetically. If we are trying to find methods that detect previously undetectable homologies, no source of real biological sequences will ever be reliably known to be nonhomologous to the benchmark, and we certainly do not want to penalize a powerful method that identifies new true relationships that are currently annotated as nonhomologous "false positives" [29]. One disadvantage of synthetic nonhomologous sequence is that it is difficult to create realistic sequences with the same challenging properties of real biological sequences, such as biased composition and repetitive sequence.

In detail, the profmark creation procedure is the following, starting from a source of multiple alignments (usually Pfam seeds) and a source of typical single target sequences (usually UniProt/SwissProt):

- Convert all degenerate residue characters to X. (Although HMMER reads all standard degeneracy codes for protein and nucleic acid sequences, some search programs do not.)
- Remove sequence fragments. By default, any sequence of length less than 70% of the mean unaligned sequence length in the alignment is defined as a fragment.
- Cluster the sequences by single-linkage clustering at a default threshold of $\geq 25\%$ percent identity (defined as the number of identical residues divided by the shorter sequence length, in the given pairwise alignment). Between any two clusters, there is no pair of sequences closer than 25% identity. If there is only one cluster, exclude this alignment from the benchmark and skip to the next alignment. Define the largest cluster as the *query*. Save it to a file, in its original multiple alignment.
- Cluster the remaining sequences by single-linkage clustering at a default threshold of $\geq 50\%$ identity. If there are less than two clusters, exclude this alignment from the benchmark and skip to the next alignment. From each cluster, select one sequence at random. These are the *true test domains*.

- Create synthetic true test sequences by embedding one or two true test domains in a larger nonhomologous sequence. The total length of the test sequence is sampled from the length distribution of the input sequence database, conditional on being at least as long as the true test domain(s). True test domains are inserted at randomly sampled locations in the sequence. The remaining two or three nonhomologous sequence segments are synthesized as described below. Thus true test sequences are composed either of three segments (one homologous, two not) or five segments (two homologous, three not).
- The program implements a choice of several different methods for generating nonhomologous sequence segments. The default is "monoshuffling": to select a sequence segment at random from the input sequence database and shuffle its residues, preserving 0th-order residue composition and bias. Figure 6 also shows the use of i.i.d. (independent identically distributed) synthetic sequence with each residue simply sampled from the average residue frequency distribution of proteins. Other options include reversed sequences and shuffling while preserving di-residue composition. Though more realistic, and useful when looking carefully and manually for failure modes, di-residue shuffling and reversed sequences are problematic as a source of nonhomologous segments in automated benchmarking. Exact di-residue shuffling preserves significant sequence identity to the original sequence over surprising segment lengths, and reversed sequences are surprisingly significantly more likely to show a significant match to the original sequence (because of a counterintuitive statistical effect of the frequency of approximate palindromes in any sequence).
- Decoys (negative sequences) are created by randomly selecting a true test sequence (solely to obtain its three or five segment lengths – not its sequence) then concatenating nonhomologous segments of the same lengths. The length distribution of negative sequences, and the length distribution of potentially biased nonhomologous subsequences embedded in them, is therefore matched to the distributions for the true test sequences.

For the experiments in Figure 6, the create-profmark procedure was applied to 11,912 Pfam 24 seed alignments [11] and the UniProt/SwissProt sequence database (version 2011_03, 516,081 sequences) [43] either with options –iid –mono (Figure 6A) or default (Figure 6B). The benchmark in panel A is composed of 2,141 query alignments, 24,040 true test sequences containing single homologous domains, and 200,000 decoys. The benchmark in panel B is composed of 2,141 query alignments, 11,547 true test sequences containing two homologous domains, and 200,000 decoys.

Acknowledgments

Jeremy Buhler and Christopher Swope (Washington University, St. Louis) contributed important optimizations for the Viterbi and Forward implementations in HMMER2. Erik Lindahl (Stanford) contributed the first SIMD vector implementation of HMMER2, for PowerPC processors with VMX/Altivec instructions. Alex Coventry (Cornell), Steve Johnson (Washington Univ., St. Louis), and Elon Portugaly (Hebrew University) did exploratory work that led to the HMMER3 project. Bjarne Knudsen (CLCbio, Denmark) has contributed several optimizations and suggestions based on a careful analysis of the HMMER3 source code. Elena Rivas (Janelia Farm) contributed numerous clarifications and improvements to the source code in the course of reimplementing the core of HMMER3 for continuous emission variables for modeling mouse vocalizations. Although space permits only these brief personal acknowledgments, a great many others have contributed to the development of HMMER3, and I also thank this wide community of developers and users. Goran Ceric provided masterful support of Janelia Farm's high performance computing resources. Heidi Henning, HHMI deputy general counsel, provided invaluable legal assistance on open source issues. HMMER is a trademarked open source project supported by the Howard Hughes Medical Institute. I dedicate this paper to the memory of my colleague and friend Michael Farrar, principal software engineer on the HMMER3 project, who died unexpectedly in December 2010.

As structure prediction methods are generating millions of publicly available protein structures, searching these databases is becoming a bottleneck. Foldseek aligns the structure of a query protein against a database by describing tertiary amino acid interactions within proteins as sequences over a structural alphabet. Foldseek decreases computation times by four to five orders of magnitude with 86%, 88% and 133% of the sensitivities of Dali, TM-align and CE, respectively.

The recent developments in in silico protein structure prediction at near-experimental quality[1,2] are advancing structural biology and bioinformatics. The European Bioinformatics Institute already holds over 214 million structures predicted by AlphaFold2 (ref. 3), and the ESM Atlas contains over 617 million metagenomic structures predicted by ESMFold[4]. The scale of these databases poses challenges to state-of-the-art analysis methods.

The most widely used approach to protein annotation and analysis is based on sequence similarity search[5–8]. The goal is to find homologous sequences from which properties of the query sequence can be inferred, such as molecular and cellular functions and structure. Despite the success of sequence-based homology inference, many proteins cannot be annotated because detecting distant evolutionary relationships from sequences alone remains challenging[9].

Detecting similarity between protein structures by three-dimensional (3D) superposition offers higher sensitivity for identifying homologous proteins[10]. The availability of high-quality structures for any protein of interest allows us to use structure comparison to improve homology inference and structural, functional and evolutionary analyses. However, despite decades of effort to improve speed and sensitivity of structural aligners, current tools are much too slow to cope with today's scale of structure databases.

Searching with a single query structure through a database with 100 million protein structures would take the popular TM-align[11] tool a month on one CPU core, and an all-versus-all comparison would take 10 millennia on a 1,000-core cluster. Sequence searching is four to five orders of magnitude faster: an all-versus-all comparison of 100 million sequences would take MMseqs2 (ref. 6) only around a week on the same cluster.

Structural alignment tools (reviewed in ref. 12) are slower for two reasons. First, whereas sequence search tools employ fast and sensitive prefilter algorithms to gain orders of magnitude in speed, no similar prefilters exist for structure alignment. Second, structural similarity scores are non-local: changing the alignment in one part affects the similarity in all other parts. Most structural aligners, such as the popular TM-align, Dali and CE[11,13,14], solve the alignment optimization problem by iterative or stochastic optimization.

To increase speed, a crucial idea is to describe the amino acid backbone of proteins as sequences over a structural alphabet and compare structures using sequence alignments[15]. Structural alphabets thus reduce structure comparisons to much faster sequence alignments. Many ways to discretize the local amino acid backbone have been proposed[16]. Most, such as CLE, 3D-BLAST and Protein Blocks, discretize the conformations of short stretches of usually 3–5 C_α atoms[17–19].

For Foldseek, we developed a type of structural alphabet that does not describe the backbone but, rather, tertiary interactions. The 20 states of the 3D interaction (3Di) alphabet describe for each residue *i* the geometric conformation with its spatially closest residue *j*. 3Di has three key advantages over traditional backbone structural alphabets. (1) Weaker dependency between consecutive letters and (2) more evenly distributed state frequencies, both enhancing information density and reducing false positives (FPs) (Supplementary Table 1). (3) The highest information density is encoded in conserved protein

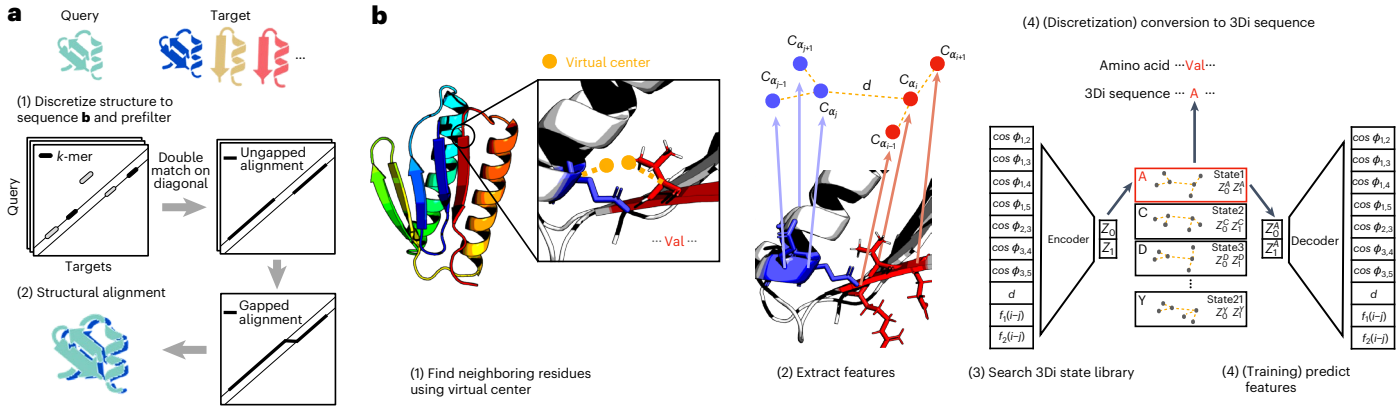

Fig. 1 | Foldseek workflow. a, Foldseek searches a set of query structures through a set of target structures. (1) Query and target structures are discretized into 3Di sequences (see **b**). To detect candidate structures, we apply the fast and sensitive *k*-mer and ungapped alignment prefilter of MMseqs2 to the 3Di sequences, (2) followed by vectorized Smith–Waterman local alignment combining 3Di and amino acid substitution scores. Alternatively, a global alignment is computed with a 1.7-times accelerated TM-align version (Supplementary Fig. 12). **b**, Learning the 3Di alphabet. (1) 3Di states describe tertiary interaction between a residue *i* and its nearest neighbor *j*. Nearest neighbors have the closest virtual center distance (yellow). Virtual center positions (Supplementary Fig. 1) were optimized for maximum search sensitivity. (2) To describe the interaction geometry of residues *i* and *j*, we extract seven angles, the Euclidean C_α distance and two sequence distance features from the six C_α coordinates of the two backbone fragments (blue and red). (3) These 10 features are used to define 20 3Di states by training a VQ-VAE[28] modified to learn states that are maximally evolutionary conserved. For structure searches, the encoder predicts the best-matching 3Di state for each residue.

cores and the lowest in non-conserved coil/loop regions, whereas the opposite is true for backbone structural alphabets.

Foldseek (https://foldseek.com/) (Fig. 1a) (1) discretizes the query structures into sequences over the 3Di alphabet and then uses a pre-trained 3Di substitution matrix (Supplementary Table 2) to search through the 3Di sequences of the target structures using the double-diagonal *k*-mer-based prefilter and gapless alignment prefilter modules from MMseqs2, our open-source sequence search software[6]. (2) High-scoring hits are aligned locally using 3Di (default) or globally with TM-align (Foldseek-TM). The local alignment stage combines 3Di and amino acid substitution scores. The construction of the 3Di alphabet is summarized in Fig. 1b and Supplementary Figs. 1–3.

To reduce high-scoring FPs and provide reliable *E* values, we subtracted the reversed query alignment score from the original score and applied a compositional bias correction within a local 40-residue sequence window (see the 'Pairwise local structural alignments' subsection). *E* values are calculated using an extreme-value score distribution, with parameters predicted by a neural network based on 3Di sequence composition and query length (see the '*E* values' subsection). Ranking of hits is determined by alignment bit score multiplied by the geometric mean of alignment TM-score and local distance difference test (LDDT). Foldseek also reports the probability for each match to be homologous, based on a fit of true and false matches on SCOPe.

We measured the sensitivity and speed of Foldseek, six protein structure alignment tools, an alignment-free structure search tool (Geometricus[20]) and a sequence search tool (MMseqs2 (ref. 6)) on the SCOPe dataset of manually classified single-domain structures[21]. Clustering SCOPe 2.01 at 40% sequence identity yielded 11,211 non-redundant protein sequences (SCOPe40). We performed an all-versus-all search and compared the tools' performance for finding members of the same SCOPe family, superfamily and fold (true-positive (TP) matches) by measuring for each query the fraction of TPs out of all possible correct matches until the first FP, a match to a different fold (see the 'SCOPe benchmark' subsection).

We first measured the sensitivity to detect relationships at family and superfamily level by the area under the curve (AUC) of the cumulative receiver operating characteristic (ROC) curve up to the first FP (Fig. 2a and Supplementary Fig. 4). Foldseek's sensitivity is below Dali and TM-align, higher than the structural aligner CE and much above the structural alphabet-based search tools 3D-BLAST and CLE-SW (Fig. 2a). In a precision-recall analysis, Foldseek-TM and Foldseek have the highest and third-highest area under the precision-recall curve on each of the three levels (Fig. 2b and Supplementary Fig. 4). Notably, Foldseek-TM improves over TM-align because its prefilter suppresses high-scoring FPs. Both sort hits by the average query and target length normalized TM-scores for best performance in the SCOPe benchmark.

Foldseek's performance is similar across all six secondary structure classes in SCOPe (Supplementary Fig. 5). On this small SCOPe40 benchmark set, Foldseek is more than 4,000 times faster than TM-align and Dali and over 21,000 times faster than CE (Fig. 2c). On the much larger AlphaFoldDB (version 1), where Foldseek approaches its full speed, it is around 184,600 and 23,000 times faster than Dali and TM-align, respectively (see below).

We devised a reference-free benchmark to assess search sensitivity and alignment quality of structural aligners (Fig. 2d) on a realistic set of full-length, multi-domain proteins. We clustered the AlphaFoldDB (version 1) to 34,270 structures using BLAST and SPICi[22]. We randomly selected 100 query structures from this set and aligned them against the remaining structures. TP matches are those with an LDDT score[23] of at least 0.6 and FPs below 0.25, ignoring matches in between. We set the LDDT thresholds according to the median inter-fold and intra-fold superfamily and family LDDT scores of SCOPe40 alignments (Supplementary Fig. 6). For other thresholds, see Supplementary Fig. 7. A domain-based sensitivity assessment would require a reference-based prediction of domains. To avoid it, we evaluated the sensitivity per residue. Figure 2d shows the distribution of the fraction of query residues that were part of alignments with at least *x* TP targets with better scores than the first FP match. Again, Foldseek has similar sensitivity as Dali, CE and TM-align and much higher sensitivity than CLE-SW and MMseqs2.

We analyzed the quality of alignments produced by the top five matches per query. We computed the alignment sensitivity as the number of TP residues divided by the query length and the precision as the number of TP residues divided by the alignment length. TP residues are those with residue-specific LDDT score above 0.6; FP residues are below 0.25; and residues with other scores are ignored. Figure 2e shows the average sensitivity versus precision of the 100 × 5 structure alignments.

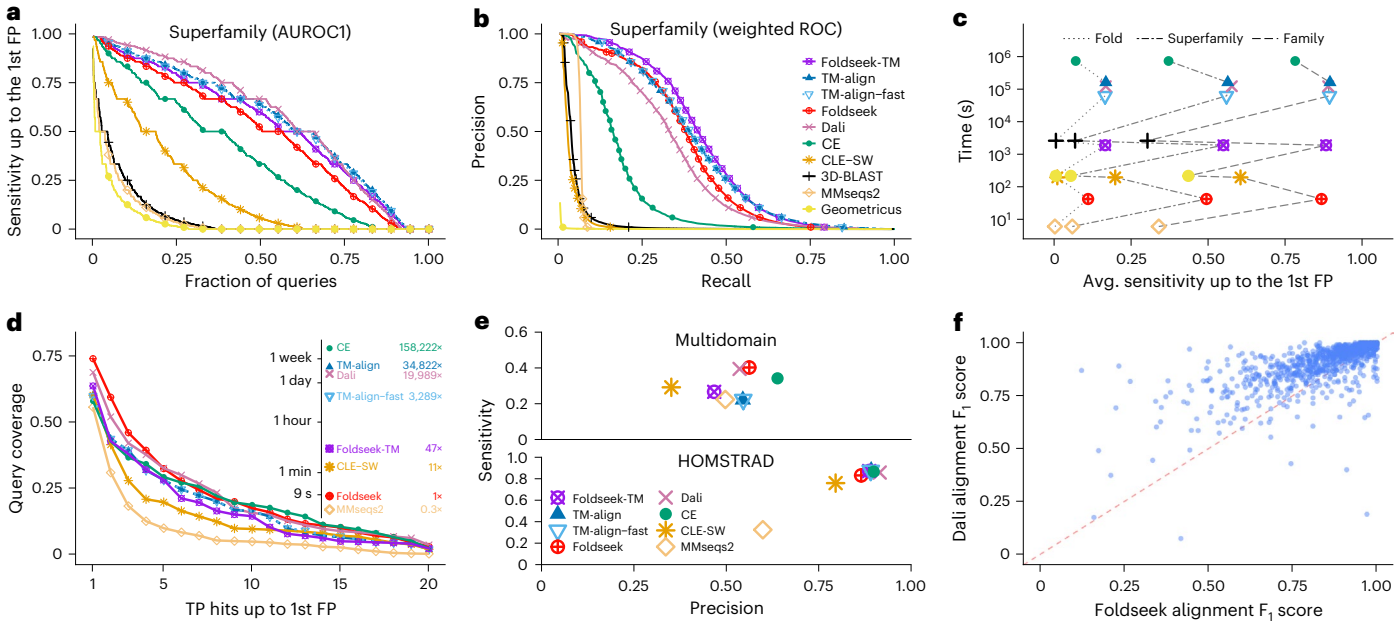

Fig. 2 | Foldseek reaches similar sensitivities as structural aligners at thousands of times their speed. a, Cumulative distributions of sensitivity for homology detection on the SCOPe40 database of single-domain structures. TPs are matches within the same superfamily; FPs are matches between different folds. Sensitivity is the area under the ROC (AUROC) curve up to the first FP (see Supplementary Fig. 4 for family and fold). **b**, Precision-recall curve of SCOPe40 superfamilies (see Supplementary Fig. 4 for family and fold). **c**, Average sensitivity up to the first FP for family, superfamily and fold versus total runtime on an AMD EPYC 7702P 64-core CPU for the all-versus-all searches of 11,211 structures of SCOPe40. **d**, Search sensitivity on multi-domain, full-length AlphaFold2 protein models. One hundred queries, randomly selected from AlphaFoldDB (version 1), were searched against this database. Per-residue query coverage (*y* axis) is the fraction of residues covered by at least *x* (*x* axis) TP matches ranked before the first FP match. **e**, Alignment quality for alignments of AlphaFoldDB (version 1) protein models (top panel), averaged over the top five matches of each of the 100 queries. Sensitivity = TP residues in alignment / query length; precision = TP residues / alignment length. Reference-based alignment quality benchmark on HOMSTRAD alignments. **f**, Alignment quality comparison between Foldseek and Dali for each HOMSTRAD family. The F_1 score is the harmonic mean between sensitivity and precision.

Foldseek alignments are more accurate and sensitive than MMseqs2, CLE-SW and TM-align, similarly accurate as Dali and 13% less precise but 15% more sensitive than CE. In the reference-based HOMSTRAD alignment quality benchmark[24], Foldseek performs slightly below CE, Dali and TM-align (Fig. 2e). Figure 2f shows the comparison between Foldseek and Dali in alignment quality for all HOMSTRAD families (see Supplementary Fig. 8 for example alignments).

To find potentially problematic high-scoring Foldseek FPs, we searched the set of unfragmented models in AlphaFoldDB (version 1) with average predicted LDDT[1]≥80 against itself. We inspected the 1,675 (of 133,813) high-scoring FPs (score per aligned column ≥ 1.0, TM-score < 0.5), revealing queries with multiple structured segments but with incorrect relative orientations (Supplementary Table 3 and Supplementary Fig. 9). The folded segments were correctly aligned by Foldseek. This illustrates that 3D aligners such as TM-align may overlook homologous structures that are not globally superposable, whereas Foldseek (as well as the two-dimensional (2D) aligner Dali) is independent of relative domain orientations and excels at detecting homologous multi-domain structures[12].

We developed a webserver (https://search.foldseek.com) for multi-database searches, including AlphaFoldDB (version 4: Proteomes and Swiss-Prot), AlphaFoldDB (version 4) and CATH[25] clustered at 50% sequence identity, ESM Atlas-HQ and Protein Data Bank (PDB)[26].

We compared Foldseek webserver, TM-align and Dali using SARS-CoV-2 RdRp (PDB: 6M71, chain A (ref. 27); 942 residues) in AlphaFoldDB (version 1). Search times were 10 d for Dali, 33 h for TM-align and 6 s for Foldseek, making it 180,000 and 23,000 times faster. All top 10 hits were known RdRp homologs (Supplementary Table 4).

The availability of high-quality structures for nearly every folded protein is transformative for biology and bioinformatics. Sequence-based analyses will soon be largely superseded by structure-based analyses. The main limitation in our view—the four orders of magnitude slower speed of structure comparisons—is removed by Foldseek.

Methods

Overview

Foldseek enables fast and sensitive comparison of large structure sets. It encodes structures as sequences over the 20-state 3Di alphabet and, thereby, reduces structural alignments to 3Di sequence alignments. The 3Di alphabet developed for Foldseek describes tertiary residue–residue interactions instead of backbone conformations and proved critical for reaching high sensitivities. Foldseek's prefilter finds two *similar*, spaced 3Di *k*-mer matches in the same diagonal of the dynamic programming matrix. By not restricting itself to exact matches, the prefilter achieves high sensitivity while reducing the number of sequences for which full alignments are computed by several orders of magnitude. Further speed-ups are achieved by multi-threading and using single instruction, multiple data (SIMD) vector units. Owing to the SIMDe library (https://github.com/simd-everywhere/simde), Foldseek runs on a wide range of CPU architectures (x86_64, arm64 and ppc64le) and operating systems (Linux and macOS). The core modules of Foldseek, which build on the MMseqs2 framework[6], are described in the following paragraphs.

Create database

The `createdb` module converts a set of PDB (ref. 29), macromolecular crystallographic information file (mmCIF) formatted files or Foldcomp compressed structure (FCZ (ref. 30)) files into an internal Foldseek database format using the Gemmi package (https://gemmi.readthedocs.io/en/latest/) or the Foldcomp library. The format is compatible with the MMseqs2 database format, which is optimized for parallel access. We store each chain as a separate entry in the database. The module follows the MMseqs2 `createdb` module logic. However, in addition to the amino acid sequence, it computes the 3Di sequence from the 3D atom coordinates of the backbone atom and C_β coordinates (see the 'Descriptors for 3Di structural alphabet' and 'Optimize nearest-neighbor selection' subsections). Backbone atom and C_β coordinates are needed only for the nearest-neighbor selection. For C_α-only structures, Foldseek reconstructs backbone atom coordinates using PULCHRA[31]. Missing C_β coordinates (for example, in glycines) are defined such that the four groups attached to the C_α are arranged at the vertices of a regular tetrahedron. The 3Di and amino acid sequences and the C_α coordinates are stored in the Foldseek database. To save disk space, we optionally compress the C_α coordinates losslessly, beginning with three uncompressed 4-byte floating-point C_α coordinates and storing all subsequent coordinates as 2-byte signed integer differences[32]. If any difference is too large to be represented with a 2-byte signed integer, we fall back to 4-byte floats for all C_α coordinates.

Prefilter

The `prefilter` module detects double matches of similar, spaced words (*k*-mers) that occur on the same diagonal. The *k*-mer size is dynamically set to $k = 6$ or $k = 7$ depending on the size of the target database. Similar *k*-mers are those with a 3Di substitution matrix score above a certain threshold, whereas MMseqs2 uses an amino acid substitution matrix to compute the similarity (see the '3Di substitution score matrix' subsection). The gapless double-match criterion suppresses hits to non-homologous structures effectively, as they are less likely to have consecutive *k*-mer matches on the same diagonal by chance. To avoid FP matches due to regions with biased 3Di sequence composition, a compositional bias correction is applied in a way analogous to MMseqs2 (ref. 33). For each hit, we perform an ungapped alignment over the diagonals with double, consecutive, similar *k*-mer matches and sort those by the maximum ungapped diagonal score. Alignments with a score of at least 15 bits are passed on to the next stage. We implemented an optional taxonomy filter within the prefiltering step to help users search through taxonomic subsets of the target database. After the gapless double-diagonal matching stage and before the ungapped alignment stage, we reject all potential target hits that do not lie within a taxonomic clade specified by the user.

Pairwise local structural alignments

After the prefilter has removed the vast majority of non-homologous sequences, the `structurealign` module computes pairwise alignments for the remaining sequences using an SIMD-accelerated Smith–Waterman algorithm[34,35]. We extended this implementation to support amino acid and 3Di scoring, compositional bias correction and 256-bit-wide vectorization. The score linearly combines amino acid and 3Di substitution scores with weights 1.4 and 2.1, respectively. We optimized these two weights and the ratio of gap extend to gap open penalty on ~1% of alignments (all-versus-all on 10% of randomly selected SCOPe40 domains). A compositional bias correction is applied to the amino acid and 3Di scores. To further suppress high-scoring FP matches, for each match we align the reversed query sequence against the target and subtract the reverse bit score from the forward bit score.

Structural bit score

We rank hits by a 'structural bit' score—that is, the product of the bit score produce by the Smith–Waterman algorithm and the geometric mean of average alignment LDDT and the alignment TM-score.

Fast alignment LDDT computation

To improve the LDDT score computation speed, we store the 3D coordinates of the query in a grid using spatial hashing. Each grid cell spans 15 Å, which is the default radius considered for the LDDT computation. For each aligned query residue *i*, we compute the distances to all C_α atoms within a 15 Å radius by searching all neighboring grid cells of the query residue's grid cell. For each residue *j*, we compute the distance between the C_α atoms of *i* and *j* and the distance of the corresponding aligned target residues. Query and target distances for the aligned pairs are subtracted, and the differences *d* are transformed into LDDT scores $s = 0.25 \times ((d < 0.5) + (d < 1.0) + (d < 2.0) + (d < 4.0))$. For each *i*, we obtain the means of the scores for all Cα atoms *j* within the 15 Å radius of *i*. The LDDT score is the mean of these means over all query residues *i*.

E values

To estimate *E* values for each match, we trained a neural network to predict the mean μ and scale parameter λ of the extreme value distribution for each query. The module `computemulambda` takes a query and database structures as input and aligns the query against a randomly shuffled version of the database sequences. For each query sequence, the module produces *N* random alignments and fits to their scores an extreme value (Gumbel) distribution. The maximum likelihood fitting is done using the Gumbel fitting function taken from HMMER3 (`hmmcalibrate`)[36]. To train the neural network, it is critical to use query and target proteins that include problematic regions, such as structurally biased, disordered or badly modeled regions that occur ubiquitously in full-length proteins or modeled structures. We, therefore, trained the network on 100,000 structures sampled from the AlphaFoldDB (version 1). We trained a neural network to predict μ and λ from the amino acid composition of the query and its length (so a scrambled version of the query sequence would produce the same μ and λ). The network has 22 input nodes, two fully connected layers with 32 nodes each (ReLU activation) and two linear output nodes. The optimizer Adam with learning rate 0.001 was used for training. When testing the resulting *E* values on searches with scrambled sequences, the log of the mean number of FPs per query turned out to have an accurately linear dependence on the log of the reported *E* values, albeit with a slope of 0.32 instead of 1. We, therefore, correct the *E* values from the neural network by taking them to the power of 0.32. We compared how well the mean number of FPs at a given *E* value agreed with the *E* values reported by Foldseek, MMseqs2 and 3D-Blast (Supplementary Fig. 10; see Supplementary Fig. 11 for AlphaFoldDB). We considered a hit as FP if it was in a different fold and had a TM-score lower than 0.3. Furthermore, we ignored all cross-fold hits within the four-bladed to eight-bladed β-propeller superfamilies (SCOPe b.66-b.70) and within

the Rossman-like folds (c.2–c.5, c.27, c.28, c.30 and c.31) because of the extensive cross-fold homologies within these groups[37].

Probability of TP match

Foldseek computes for each match a simple estimate for the probability that the match is a TP match given its structural bit score. Here, hits within the same superfamily are TP; hits to another fold are FP; and hits to the same family or to another superfamily are ignored. We estimate the structural bit score distributions of TP and FP hits ($p(score|TP)$ and $p(score|FP)$), which allow us to calculate the probability of a TP $p(TP|score) = \frac{p(\text{score}|TP)p(TP)}{p(\text{score}|TP)p(TP)+p(\text{score}|FP)p(FP)}$. Both score distributions were fitted on SCOPe40 with a mixture model consisting of two gamma distributions (resulting in five parameters for each function). For the fitting, the function `gammamixEM` from the R package `mixtools`[38] was used. We excluded cross-fold hits between certain folds as in the *E* value estimation. For example, Foldseek finds around the same number of FPs and TPs with a score of 51 in SCOPe40. The probability for a hit with score 51 is, therefore, 50%.

Pairwise global structural alignments using TM-align

We also offer the option to use TM-align for pairwise structure alignment instead of the 3Di-based alignment. We implemented TM-align based on the C_α atom coordinates and made adjustments to improve the (1) speed and (2) memory usage. (1) TM-align performs multiple floating-point-based Needleman–Wunsch (NW) alignment steps while applying different scoring functions (for example, score secondary structure, Euclidean distance of superposed structures or fragments). TM-align's NW code did not take advantage of SIMD instructions; therefore, we replaced it by parasail's[39] SIMD-based NW implementation and extended it to support the different scoring functions. We also replaced the TM-score computation using fast_protein_cluster's SIMD-based implementation[40]. Our NW implementation does not compute exactly the same alignment because we apply affine gap costs, whereas TM-align does not (Supplementary Fig. 12). (2) TM-align requires 17 bytes × query length × target length of memory, and we reduce the constant overhead from 17 bytes to 4 bytes. If Foldseek is used in TM-align mode (parameter `--alignment-type 1`), TM-align is used for the alignment stage after the prefilter step, where we replace the reported *E* value column with TM-scores normalized by the query length. The results are ordered in descending order by average TM-score by default.

Descriptors for 3Di structural alphabet

The 3Di alphabet describes the tertiary contacts between residues and their nearest neighbors in 3D space. For each residue *i*, the conformation of the local backbone around *i*, together with the local backbone around its nearest neighbor *j*, is approximated by 20 discrete states (Supplementary Fig. 3). We chose the alphabet size $A = 20$ as a tradeoff between encoding as much information as possible (large *A*; Supplementary Fig. 13) and limiting the number of similar 3Di *k*-mers that we need to generate in the *k*-mer-based prefilter, which scales with A^k. The discrete single-letter states are formed from neighborhood descriptors containing 10 features encoding the conformation of backbones around residues *i* and *j* represented by the C_α atoms ($C_{\alpha,i-1}$, $C_{\alpha,i}$, $C_{\alpha,i+1}$) and ($C_{\alpha,j-1}$, $C_{\alpha,j}$, $C_{\alpha,j+1}$). The descriptors use the five unit vectors along the following directions:

$$\mathbf{u_1}: C_{\alpha,i-1} \to C_{\alpha,i} \quad \mathbf{u_4}: C_{\alpha,j} \to C_{\alpha,j+1}$$
$$\mathbf{u_2}: C_{\alpha,i} \to C_{\alpha,i+1} \quad \mathbf{u_5}: C_{\alpha,i} \to C_{\alpha,j}$$
$$\mathbf{u_3}: C_{\alpha,j-1} \to C_{\alpha,j}.$$

We define the angle between u_k and u_l as ϕ_{kl}, so $\cos\phi_{kl} = \mathbf{u_k^T u_l}$. The seven features $\cos\phi_{12}, \cos\phi_{34}, \cos\phi_{15}, \cos\phi_{35}, \cos\phi_{14}, \cos\phi_{23}, \cos\phi_{13}$ and the distance $|C_{\alpha,i} - C_{\alpha,j}|$ describe the conformation between the backbone fragments. In addition, we encode the sequence distance with the two features $\text{sign}(i-j)\ \min(|i-j|, 4)$ and $\text{sign}(i-j)\ \log(|i-j|+1)$.

Learning the 3Di states using a vector quantized variational autoencoder

The 10-dimensional descriptors were discretized into an alphabet of 20 states using a vector quantized variational autoencoder (VQ-VAE)[28]. In contrast to standard clustering approaches such as *k*-means, VQ-VAE is a nonlinear approach that can optimize decision surfaces for each of its states. In contrast to the standard VQ-VAE, we trained the VQ-VAE not as a simple generative model but, rather, to learn states that are maximally conserved in evolution. To that end, we trained it with pairs of descriptors $\mathbf{x}_n, \mathbf{y}_n \in \mathbb{R}^{10}$ from structurally aligned residues, to predict the distribution of y_n from x_n.

The VQ-VAE consists of an encoder and decoder network with the discrete latent 3Di state as a bottleneck in between. The encoder network embeds the 10-dimensional descriptor x_n into a 2D continuous latent space, where the embedding is then discretized by the nearest centroid, each centroid representing a 3Di state. Given the centroid, the decoder predicts the probability distribution of the descriptor y_n of the aligned residue. After training, only encoder and centroids are used to discretize descriptors. Encoder and decoder networks are both fully connected with two hidden layers of dimension 10, a batch normalization after each hidden layer and ReLU as activation functions. The encoder, centroids and decoder have 242, 40 and 352 parameters, respectively. The output layer of the decoder consists of 20 units predicting μ and σ^2 of the descriptors *x* of the aligned residue, such that the decoder predicts $\mathcal{N}(\mathbf{x}|\boldsymbol{\mu}, \boldsymbol{l\sigma^2})$ (with diagonal covariance).

We trained the VQ-VAE on the loss function defined in Equation (3) in ref. 28 (with commitment loss = 0.25) using the deep learning framework PyTorch (version 1.9.0), the Adam optimizer, with a batch size of 512, and a learning rate of 10^{-3} over four epochs. Using Kerasify (https://github.com/moof2k/kerasify), we integrated the encoder network into Foldseek. The domains from SCOPe40 were split 80%/20% by fold into training and validation sets. For the training, we aligned the structures with TM-align, removed all alignments with a TM-score below 0.6 and removed all aligned residue pairs with a distance between their C_α atoms of more than 5 Å. We trained the VQ-VAE with 100 different initial parameters and chose the model that was performing best in the benchmark on the validation dataset (the highest sum of ratios between 3Di AUC and TM-align AUC for family, superfamily and fold level).

3Di substitution score matrix

We trained a BLOSUM-like substitution matrix for 3Di sequences from pairs of structurally aligned residues used for the 'VQ-VAE training'. First, we determined the 3Di states of all residues. Next, the substitution frequencies among 3Di states were calculated by counting how often two 3Di states were structurally aligned. (Note that the substitution frequencies from state A to state B and the opposite direction are equal.) Finally, the score $S(x,y) = 2\log_2\frac{p(x,y)}{p(x)p(y)}$ for substituting state x through state y is the log-ratio between the substitution frequency $p(x, y)$ and the probability that the two states occur independently, scaled by the factor 2.

3Di alphabet cross-validation

We trained the 3Di alphabet (the VQ-VAE weights) and the substitution matrix by four-fold cross-validation on SCOPe40. We split the SCOPe40 dataset into four parts, such that all domains of each fold ended up in the same part of the four parts. 3Di alphabets were trained on three parts and tested on the remaining part, selecting each of the four parts in turn as a test set. The 80:20 split between training and validation sets to select the best alphabet out of the 100 VQ-VAE runs happens within the 3/4 of the cross-validation training data. Supplementary Fig. 14 shows the mean sensitivity (black) and the standard deviation (gray

area) in comparison to the final 3Di alphabet, for which we trained the 3Di alphabet on the entire SCOPe40 (red). No overfitting was observed, despite training 492 parameters (282 neural network and 210 substitution matrix entries). In Fig. 2, we, therefore, show the benchmark results for the final 3Di alphabet, trained on the entire SCOPe40.

Nearest-neighbor selection

To select nearest-neighbor residues that maximize the performance of the resulting 3Di alphabet in finding and aligning homologous structures, we introduced the virtual center V of a residue. The virtual center position is defined by the angle θ (V-C_α-C_β), the dihedral angle τ (V-C_α-C_β-N) and the length l ($|V - C_\alpha|$) (Supplementary Fig. 1). For each residue i, we selected the residue j with the smallest distance between their virtual centers. The virtual center was optimized on the training and validation structure sets used for the VQ-VAE training by creating alphabets for positions with $\theta \in [0, 2\pi]$, $\tau \in [-\pi, \pi]$ in 45° steps and $l \in \{1.53\text{ Å } k\text{: } k \in \{1, 1.5, 2, 2.5, 3\}\}$ (1.53 Å is the distance between C_α and C_β). The virtual center defined by $\theta = 270°$, $\tau = 0°$ and $l = 2$ performed best in the SCOPe benchmark.

This virtual center preferably selects long-range, tertiary interactions and only falls back to selecting interactions to $i + 1$ or $i - 1$ when no other residues are nearby. In that case, the interaction captures only the backbone conformation.

SCOPe benchmark

We downloaded the SCOPe40 structures (available at https://wwwuser.gwdg.de/~compbiol/foldseek/scop40pdb.tar.gz).

The SCOPe benchmark set consists of single domains with an average length of 174 residues. In our benchmark, we compare the domains all-versus-all. Per domain, we measured the fraction of detected TPs up to the first FP. For family-level, superfamily-level and fold-level recognition, TPs were defined as same family, same superfamily and not same family and same fold and not same superfamily, respectively. Hits from different folds are FPs.

Evaluation SCOPe benchmark

After sorting the alignment result of each query (described in the 'Tools and options for benchmark comparison' subsection), we calculated the sensitivity as the fraction of TPs in the sorted list up to the first FP, all excluding self-hits. For comparison, we took the mean sensitivity over all queries for family-level, superfamily-level and fold-level classifications. We evaluated only SCOPe members with at least one other family, superfamily and fold member. We measure the sensitivity up to the 1st FP (ROC1) instead, for example, up to the 5th FP, because ROC1 better reflects the requirements for low false discovery rates in automatic searches.

Additionally, we plotted precision-recall curves for each tool (Fig. 2b and Supplementary Fig. 4). After sorting the alignment results by the structural similarity scores (as described in the 'Tools and options for benchmark comparison' subsection) and excluding self-matches, we generated a weighted precision-recall curve for family-level, superfamily-level and fold-level classifications (precision = TP / (TP + FP) and recall = TP / (TP + FN)). All counts (TP, FP and FN) were weighted by the reciprocal of their family, superfamily or fold size. In this way, folds, superfamilies and families contribute linearly with their size instead of quadratically[36].

Runtime evaluations on SCOPe and AlphaFoldDB

We measured the speed of structural aligners on a server with an AMD EPYC 7702P 64-core CPU and 1,024 GB RAM memory. On SCOPe40, we measured or estimated the runtime for an all-versus-all comparison. To avoid excessive runtimes for TM-align, Dali and CE, we estimated the runtime by randomly selecting 10% of the 11,211 SCOPe domains as queries. We measured runtimes on AlphaFoldDB for searches with the same 100 randomly selected queries used for the sensitivity and alignment quality benchmarks (Fig. 2d,e). Tools with multi-threading support (MMseqs2 and Foldseek) were executed with 64 threads; tools without were parallelized by breaking the query set into 64 equally sized chunks and executing them in parallel.

Reference-free multi-domain benchmarks

We devised two reference-free benchmarks that do not rely on any reference structural alignments. We clustered the AlphaFoldDB (version 1)[3] using SPICi[22]. For this, we first aligned all protein sequences all against all using an E value threshold $<10^{-3}$ using BLAST (2.5.0+)[5]. SPICi produced 34,270 clusters from the search result. For each cluster, we picked the longest protein as representative. We randomly selected 100 representatives as queries and searched the set of remaining structures. The top five alignments of all queries are listed at https://wwwuser.gwdg.de/~compbiol/foldseek/multi_domain_top5_alignments/.

For the evaluation, we needed to adjust the LDDT score function taken from AlphaFold2 (ref. 1). LDDT calculates for each residue i in the query the fraction of residues in the 15 Å neighborhood that have a distance within 0.5, 1, 2 or 4 Å of the distance between the corresponding residues in the target[23]. The denominator of the fraction is the number of 15 Å neighbors of i that are aligned to some residue in the target. This does not properly penalize non-compact models in which each residue has few neighbors within 15 Å. We, therefore, use as denominator the *total* number of neighboring residues within 15 Å of i.

For the alignment quality benchmark (Fig. 2e), we classified each aligned residue pair as TP or FP depending on its residue-wise LDDT score—that is, the fraction of distances to its 15 Å neighbors that are within 0.5, 1, 2 and 4 Å of the distance to the corresponding residues in the query, averaged over the four distance thresholds. TP residues are those with a residue-wise LDDT score of at least 0.6 and FPs below 0.25, ignoring matches in between. For the search sensitivity benchmark (Fig. 2d), TP residue–residue matches are those with an LDDT score of the query-target alignment of at least 0.6 and FPs below 0.25, ignoring matches in between. (The LDDT score of the query-target alignment is the average of the residue-wise LDDT score over all aligned residue pairs.) The choice of thresholds is illustrated in Supplementary Fig. 6. The benchmark for other thresholds is shown in Supplementary Fig. 7.

All-versus-all search of AlphaFoldDB with Foldseek

We downloaded the AlphaFoldDB (version 1)[3] containing 365,198 protein models and searched it all-versus-all using Foldseek `-s 9.5 --max-seqs 2000`. For our second-best hit analysis, we consider only models with (1) an average C_α's predicted LDDT (pLDDT) greater than or equal to 80 and (2) models of non-fragmented domains. We also computed the structural similarity for each pair using TM-align (default options).

Tools and options for benchmark comparison

Owing to dataset overlap, we excluded methods from the benchmark that are likely to be overfitted on SCOPe. This applies to methods that trained many thousands of parameters (for example, deep neural networks) with strong data leakage among training, validation and test sets. For example, several tools allowed up to 40% sequence identity between sets. The following command lines were used in the SCOPe as well as the multi-domain benchmark:

Foldseek

We used Foldseek commit `aeb5e` during this analysis. Foldseek was run with the following parameters: `--threads 64 -s 9.5 -e 10 --max-seqs 2000`.

Foldseek-TM

For the Foldseek-TM benchmark, we first run a regular 3Di/AA-based Foldseek search using the following parameters: `--threads 64 -s 9.5 -e 10 --max-seqs 4000 --alignment-mode 1`. All hits

passing are then aligned by Foldseeks's `tmalign --tmalign-fast 1 --tmscore-threshold 0.0 -a`. We used Foldseek commit `aeb5e` during this analysis. We expose Foldseek-TM in our command-line interface as a search mode that combines regular Foldseek 3Di/AA-based workflow with our TM-align implementation within the `tmalign` module.

MMseqs2

We used the default MMseqs2 (release `13-45111`) search algorithm to obtain the sequence-based alignment result. MMseqs2 sorts the results by *E* value and score. We searched with: `--threads 64 -s 7.5 -e 10000 --max-seqs 2000.`

CLE-Smith–Waterman

We used PDB Tool version 4.80 (https://github.com/realbigws/PDB_Tool) to convert the benchmark structure set to CLE sequences. After the conversion, we used SSW[35] (commit `ad452e`) to align CLE sequences all-versus-all. We sorted the results by alignment score. The following parameters were used to run SSW: (1) protein alignment mode (`-p`); (2) gap open penalty of 100 (`-o 100`); (3) gap extend penalty of 10 (`-e 10`); (4) CLE's optimized substitution matrix (`-a cle.shen.mat`); and (5) returning alignment (`-c`). The gap open and extend values were inferred from DeepAlign[41]. The results are sorted by score in descending order.

```
ssw_test -p -o 100 -e 10 -a cle.shen.mat -c
```

3D-BLAST

We used 3D-BLAST (beta102) with BLAST+ (2.2.26) and SSW[34] (version ad452e). We first converted the PDB structures to a 3D-BLAST database using `3d-blast -sq_write` and `3d-blast -sq_append`. We searched the structural sequences against the database using `blastp` with the following parameters: (1) 3D-BLAST's optimized substitution matrix (`-M 3DBLAST`); (2) number of hits and alignments shown of 12,000 (`-v 12000 -b 12000`); (3) *E* value threshold of 1,000 (`-e 1000`); (4) disabling query sequence filter (`-F F`); (5) gap open of 8 (`-G 8`); and (6) gap extend of 2 (`-E 2`). 3D-BLAST's results are sorted by *E* value in ascending order:

```
blastall -p blastp -M 3DBLAST -v 12000 -b 12000 -e
1000 -F F -G 8 -E 2
```

For Smith–Waterman, we used (1) gap open of 8; (2) gap extend of 2; (3) returning alignments (`-c`); (4) 3D-BLAST's optimized substitution matrix (`-a 3DBLAST`); and (5) protein alignment mode (`-p`): `ssw_test -o 8 -e 2 -c -a 3DBLAST -p`. We noticed that the 3D-BLAST matrix with Smith–Waterman resulted in a similar performance to CLE: 0.717, 0.230 and 0.011 for family classification, superfamily classification and fold classification, respectively. We excluded 3D-BLAST's measurement from the multi-domain benchmark because it produced occasionally high scores (>10^7) for single residue alignments.

TM-align

We downloaded and compiled the `TMalign.cpp` source code (version 2019/08/22) from the Zhang group website. We ran the benchmark using default parameters and `-fast` for the fast version. TM-align reports two TM-scores: (1) normalized by the length of 1st chain (query) or (2) normalized by the length of the 2nd chain (target). We used the average of TM-scores normalized by the 1st chain (query) and 2nd chain (target) in all our analyses. We evaluated TM-align's performance by sorting the results based on both the query TM-score and the minimum, maximum and average TM-score for both the query and target. Our results showed that the average TM-score performed the best in our single-domain benchmark.

Default: `TMalign query.pdb target.pdb`
Fast: `TMalign query.pdb target.pdb -fast`

Dali

We installed the standalone DaliLite.v5. For the SCOPe40 benchmark set, input files were formatted in DAT files with Dali's `import.pl`. The conversion to DAT format produced 11,137 valid structures out of the 11,211 initial structures for the SCOPe benchmark and 34,252 structures out of 34,270 SPICi clusters. After formatting the input files, we calculated the protein alignment with Dali's structural alignment algorithm. The results were sorted by Dali's *z*-score in descending order:

```
import.pl -pdbfile query.pdb -pdbid PDBid -dat DAT
dali.pl -cd1 queryDATid -db targetDB.list -TITLE
systematic -dat1 DAT -dat2 DAT -outfmt "summary"
-clean
```

CE

We used BioJava's[42] (version 5.4.0) implementation of the combinatorial extension (CE) alignment algorithm. We modified one of the modules of BioJava under shape configuration to calculate the CE value. Our modified `CEalign.jar` file requires a list of query files, path to the target PDB files and an output path as input parameters. This Java module runs an all-versus-all CE calculation with unlimited gap size (`maxGapSize -1`) to improve alignment results[14]. The results were sorted by *z*-score in descending order. For the multi-domain benchmark, we excluded one query that was running over 16 d. The Jar file of our implementation of CE calculation is provided (see 'Code availability').

```
java -jar CEalign.jar querylist.txt
TargetPDBDirectory OutputDirectory
```

Geometricus

We included Geometricus[20] in the SCOPe benchmark as a representative of alignment-free tools, which are fast but can find only globally similar structures. Geometricus discretizes fixed-length backbone fragments (shape-mers) using their 3D moment invariants and represents structures as a fixed-length count vector over the shape-mers. To calculate the shape-mer-based structural similarity of the benchmark set, we used Caretta-shape's Python implementation (1e3adb0) of multiple structure alignment (https://github.com/TurtleTools/caretta/caretta/multiple_alignment.py), which computes the Bray–Curtis similarity between the Geometricus shape-mer vectors. Our modified version extracts structural information from the input files and generates all-versus-all pairwise structural similarity score as an output. We ran Geometricus on a single core because it would require substantial engineering efforts to implement parallelization on multiple cores. With an efficient multi-core implementation, Geometricus might be as fast as MMseqs2 on 64 cores. The Python code of our implementation of Geometricus is provided:

```
python runGeometricus_caretta.py -i querylist.txt
-o OutputDirectory
```

HOMSTRAD alignment benchmark

The HOMSTRAD database contains expert-curated homologous structural alignments for 1,032 protein families[24]. We downloaded the latest HOMSTRAD version (https://mizuguchilab.org/homstrad/data/homstrad_with_PDB_2022_Aug_1.tar.gz) and picked the pairwise alignments between the first and last members of each family, which resulted in structures of a median length of 182 residues. We used the same parameters as in the SCOPe and multi-domain benchmark. We forced Foldseek, MMseqs2 and CLE-Smith–Waterman to return an alignment by switching off the prefilter and *E* value threshold. With the HOMSTRAD alignments as reference, we measured for each pairwise alignment the sensitivity (fraction of residue pairs of the HOMSTRAD alignment that were correctly aligned) and the precision (fraction of correctly aligned residue pairs in the predicted alignment). Dali, CE

and CLE-Smith–Waterman failed to produce an alignment for 35, 1 and 1 out of 1,032 pairs, respectively, which were rated with a sensitivity of 0. The mean sensitivity and precision are shown in Fig. 2e, and all individual alignments are listed in `homstrad_alignments.txt` at https://wwwuser.gwdg.de/~compbiol/foldseek/.

Limitations of benchmarks

The SCOPe benchmark to measure search sensitivity uses only single-domain proteins as queries and targets (Fig. 2a–c). It, therefore, cannot assess the ability of tools to find local similarities—for example, finding homologous domains shared between two multi-domain proteins. The alignment benchmark based on HOMSTRAD (Fig. 2e) has the same limitation, as the vast majority of proteins in HOMSTRAD have a single domain (median length = 182 residues). A drawback of our reference-free multi-domain benchmark is the need to choose thresholds for TPs and FPs (Supplementary Fig. 6).

Pre-built and ready-to-download databases

Foldseek includes the `databases` module to aid users with the download and setup of structural databases. Currently, we include the four variants of the AlphaFoldDB (version 4): UniProt (214 million structures), UniProt50, a clustered database to 50% sequence identity and 90% bi-directional coverage using MMseqs2 (parameters `-c 0.9 --min-seq-id 0.5 --cluster-reassign`; 54 million structures), Proteome (564,000 structures) and Swiss-Prot (542,000 structures). Additionally, we regularly build and offer a 100% sequence identity clustered PDB. The update pipeline is available in the `util/update_webserver_pdb` folder in the main Foldseek repository. These databases are hosted on Cloudflare R2 for fast downloading. We additionally link to and provide an automatic setup procedure for the ESM Atlas High-Quality Clu30[4] database.

Webserver

The Foldseek webserver is based on the MMseqs2 webserver[43]. To allow for searches in seconds, we implemented MMseqs2's pre-computed database indexing capabilities in Foldseek. Using these, the search databases can be fully cached in system memory by the operating system and instantly accessed by each Foldseek process, thus avoiding expensive accesses to slow disk drives. A similar mechanism was used to store and read the associated taxonomic information. The AlpaFoldDB/UniProt50 (version 4), AlphaFoldDB/Proteome (version 4), AlphaFoldDB/Swiss-Prot (version 4), CATH50, ESM Atlas High-Quality Clu30 and PDB100 require 191 GB, 3.8 GB, 3.4 GB, 1.4 GB, 110 GB and 2.0 GB RAM, respectively. The databases are kept in memory using `vmtouch` (https://github.com/hoytech/vmtouch). Databases are only required to remain resident in RAM if Foldseek is used as a webserver. During batch searches, Foldseek adapts its memory use to the available RAM of the machine. We implemented a structural visualization using the NGL viewer[44] to aid the investigation of pairwise hits. Because we only store C_α traces of the database proteins, we use PULCHRA[30] to complete the backbone of these sequences, and also of the query if necessary, to enable a ribbon visualization[45] of the proteins. For a high-quality superposition, we use TM-align[11] to superpose the structures based on the Foldseek alignment. Both PULCHRA and TM-align are executed within the users' browser using WebAssembly. They are available as `pulchra-wasm` and `tmalign-wasm` on the npm package repository as free open-source software.

Structure prediction in the webserver

We use the ESM Atlas API to predict structures of user-supplied sequences that are, at most, 400 residues long. This enables sequence-to-structure searches in the webserver.

Reporting summary

Further information on research design is available in the Nature Portfolio Reporting Summary linked to this article.

Data availability

Benchmark data are available at https://wwwuser.gwdg.de/~compbiol/foldseek.

Code availability

Foldseek is GPLv3-licensed free open-source software. The source code and binaries for Foldseek can be downloaded at https://github.com/steineggerlab/foldseek. The webserver code is available at https://github.com/soedinglab/mmseqs2-app. The analysis scripts are available at https://github.com/steineggerlab/foldseek-analysis.

  full text below · DOI · open access (CC BY 4.0)

  UniProt: the Universal Protein Knowledgebase in 2025. Bateman et al. (2024). *Nucleic Acids Research.* doi:10.1093/nar/gkae1010

  > The aim of the UniProt Knowledgebase (UniProtKB; https://www.uniprot.org/) is to provide users with a comprehensive, high-quality and freely accessible set of protein sequences annotated with functional information. In this publication, we describe ongoing changes to our production pipeline to limit the sequences available in UniProtKB to high-quality, non-redundant reference proteomes. We continue to manually curate the scientific literature to add the latest functional data and use machine learning techniques. We also encourage community curation to ensure key publications are not missed. We provide an update on the automatic annotation methods used by UniProtKB to predict information for unreviewed entries describing unstudied proteins. Finally, updates to the UniProt website are described, including a new tab linking protein to genomic information. In recognition of its value to the scientific community, the UniProt database has been awarded Global Core Biodata Resource status.

  InterPro: the protein sequence classification resource in 2025. Blum et al. (2024). *Nucleic Acids Research.* doi:10.1093/nar/gkae1082

  > InterPro (https://www.ebi.ac.uk/interpro) is a freely accessible resource for the classification of protein sequences into families. It integrates predictive models, known as signatures, from multiple member databases to classify sequences into families and predict the presence of domains and significant sites. The InterPro database provides annotations for over 200 million sequences, ensuring extensive coverage of UniProtKB, the standard repository of protein sequences, and includes mappings to several other major resources, such as Gene Ontology (GO), Protein Data Bank in Europe (PDBe) and the AlphaFold Protein Structure Database. In this publication, we report on the status of InterPro (version 101.0), detailing new developments in the database, associated web interface and software. Notable updates include the increased integration of structures predicted by AlphaFold and the enhanced description of protein families using artificial intelligence. Over the past two years, more than 5000 new InterPro entries have been created. The InterPro website now offers access to 85 000 protein families and domains from its member databases and serves as a long-term archive for retired databases. InterPro data, software and tools are freely available.

  full text below · DOI · open access (CC BY 4.0)

  Protein Data Bank: the single global archive for 3D macromolecular structure data. Burley et al. (2018). *Nucleic Acids Research.* doi:10.1093/nar/gky949

  > The Protein Data Bank (PDB) is the single global archive of experimentally determined three-dimensional (3D) structure data of biological macromolecules. Since 2003, the PDB has been managed by the Worldwide Protein Data Bank (wwPDB; wwpdb.org), an international consortium that collaboratively oversees deposition, validation, biocuration, and open access dissemination of 3D macromolecular structure data. The PDB Core Archive houses 3D atomic coordinates of more than 144 000 structural models of proteins, DNA/RNA, and their complexes with metals and small molecules and related experimental data and metadata. Structure and experimental data/metadata are also stored in the PDB Core Archive using the readily extensible wwPDB PDBx/mmCIF master data format, which will continue to evolve as data/metadata from new experimental techniques and structure determination methods are incorporated by the wwPDB.

> Impacts of the recently developed universal wwPDB OneDep deposition/validation/biocuration system and various methods-specific wwPDB Validation Task Forces on improving the quality of structures and data housed in the PDB Core Archive are described together with current challenges and future plans.

  AlphaFold Protein Structure Database 2025: a redesigned interface and updated structural coverage. Bertoni et al. (2025). *Nucleic Acids Research.* doi:10.1093/nar/gkaf1226

  > The AlphaFold Protein Structure Database (AFDB; https://alphafold.ebi.ac.uk), developed by EMBL-EBI and Google DeepMind, provides open access to hundreds of millions of high-accuracy protein structure predictions, transforming research in structural biology and the wider life sciences. Since its launch, AFDB has become a widely used bioinformatics resource, integrated into major databases, visualization platforms, and analysis pipelines. Here, we report the update of the database to align with the UniProt 2025_03 release, along with a comprehensive redesign of the entry page to enhance usability, accessibility, and structural interpretation. The new design integrates annotations directly with an interactive 3D viewer and introduces dedicated domains and summary tabs. Structural coverage has also been updated to include isoforms plus underlying multiple sequence alignments. Data are available through the website, FTP, Google Cloud, and updated APIs. Together, these advances reinforce AFDB as a sustainable resource for exploring protein sequence-structure relationships.

- Szklarczyk et al. (2024) — STRING; how functional association networks are built and scored.
  full text below · DOI · open access (CC BY 4.0)

  The STRING database in 2025: protein networks with directionality of regulation. Szklarczyk et al. (2024). *Nucleic Acids Research.* doi:10.1093/nar/gkae1113

  > Proteins cooperate, regulate and bind each other to achieve their functions. Understanding the complex network of their interactions is essential for a systems-level description of cellular processes. The STRING database compiles, scores and integrates protein-protein association information drawn from experimental assays, computational predictions and prior knowledge. Its goal is to create comprehensive and objective global networks that encompass both physical and functional interactions. Additionally, STRING provides supplementary tools such as network clustering and pathway enrichment analysis. The latest version, STRING 12.5, introduces a new 'regulatory network', for which it gathers evidence on the type and directionality of interactions using curated pathway databases and a fine-tuned language model parsing the literature. This update enables users to visualize and access three distinct network types-functional, physical and regulatory-separately, each applicable to distinct research needs. In addition, the pathway enrichment detection functionality has been updated, with better false discovery rate corrections, redundancy filtering and improved visual displays. The resource now also offers improved annotations of clustered networks and provides users with downloadable network embeddings, which facilitate the use of STRING networks in machine learning and allow cross-species transfer of protein information. The STRING database is available online at https://string-db.org/.

- The Gene Ontology Consortium et al. (2023) — the Gene Ontology knowledgebase; terms, annotations and evidence.
  full text below · DOI · open access (CC BY 4.0)

  The Gene Ontology knowledgebase in 2023. The Gene Ontology Consortium et al. (2023). *GENETICS.* doi:10.1093/genetics/iyad031

  > The Gene Ontology (GO) knowledgebase (http://geneontology.org) is a comprehensive resource concerning the functions of genes and gene products (proteins and noncoding RNAs). GO annotations cover genes from organisms across the tree of life as well as viruses, though most gene function knowledge currently derives from experiments carried out in a relatively small number of model organisms. Here, we provide an updated overview of the GO knowledgebase, as well as the efforts of the broad, international consortium of scientists that develops, maintains, and updates the GO knowledgebase. The GO knowledgebase consists of three components: (1) the GO-a computational knowledge structure describing the functional characteristics of genes; (2) GO annotations-evidence-supported statements asserting that a specific gene product has a particular functional characteristic; and (3) GO Causal Activity Models (GO-CAMs)-mechanistic models of molecular ”pathways” (GO biological processes) created by linking

multiple GO annotations using defined relations. Each of these components is continually expanded, revised, and updated in response to newly published discoveries and receives extensive QA checks, reviews, and user feedback. For each of these components, we provide a description of the current contents, recent developments to keep the knowledgebase up to date with new discoveries, and guidance on how users can best make use of the data that we provide. We conclude with future directions for the project.

Abstract

The aim of the UniProt Knowledgebase (UniProtKB; https://www.uniprot.org/) is to provide users with a comprehensive, high-quality and freely accessible set of protein sequences annotated with functional information. In this publication, we describe ongoing changes to our production pipeline to limit the sequences available in UniProtKB to high-quality, non-redundant reference proteomes. We continue to manually curate the scientific literature to add the latest functional data and use machine learning techniques. We also encourage community curation to ensure key publications are not missed. We provide an update on the automatic annotation methods used by UniProtKB to predict information for unreviewed entries describing unstudied proteins. Finally, updates to the UniProt website are described, including a new tab linking protein to genomic information. In recognition of its value to the scientific community, the UniProt database has been awarded Global Core Biodata Resource status.

Graphical abstract

Introduction

The UniProt suite of databases (https://www.uniprot.org/) serves as a leading global data resource for protein sequence and functional information (1). The long-standing critical role of the data resource in underpinning molecular biology was recognized when UniProt became one of the first databases awarded Global Core Biodata Resource status (https://globalbiodata.org) in December 2022. The cen-

tral UniProt Knowledgebase (UniProtKB) is a curated resource. It is comprised of both a reviewed set of protein entries (UniProtKB/Swiss-Prot), where each record contains a summary of the experimentally verified, or computationally predicted, functional information, added and evaluated by an expert biocurator, and the unreviewed set (UniProtKB/TrEMBL). In the latter, entries are computationally annotated by automated systems. The UniRef databases cluster sequence sets at various levels of sequence identity and the UniProt Archive (UniParc) delivers a complete set of known unique sequences, including historical obsolete sequences. If a UniParc entry sequence is not included in UniProtKB, the reason for the exclusion of that sequence is provided (e.g. pseudo-gene). In addition, each UniParc record contains a reference to its source database(s) with accession and version numbers, tagged with its status in that database, indicating if the sequence still exists or has been deleted in the source database.
